Elevated fetal hemoglobin (HbF) is associated with improved outcomes in patients (pts) with transfusion-dependent β-thalassemia (TDT) and sickle cell disease (SCD). Exagamglogene autotemcel (exa-cel) is a cell therapy designed to reactivate HbF via non-viral, *ex vivo* CRISPR/Cas9 gene-editing at the erythroid enhancer region of *BCL11A* in autologous CD34+ hematopoietic stem and progenitor cells (HSPCs). We report efficacy and safety data from the first 75 pts dosed with exa-cel in the ongoing CLIMB THAL-111 and CLIMB SCD-121 pivotal trials. Following pharmacokinetic-adjusted busulfan myeloablation and exa-cel infusion, pts (12-35y) are monitored for engraftment, total Hb, HbF, *BCL11A* edited alleles, transfusions, VOCs (SCD only), and adverse events (AEs). Data presented as mean (min-max) unless noted. 44 pts with TDT (age 21.3 [12-35] y) and 31 pts with SCD (22.5 [12-34] y) had been infused with exa-cel at data cut (follow-up 12.3 [1.2-37.2] mo and 9.6 [2.0-32.3] mo, respectively). 26/44 pts with TDT (59.1%) had β^0/β^0 or a β^0/β^0like genotype (β^0/IVSI110, IVS-I-110/IVS-I-110). In 2y period before screening, pts with TDT received 36.0 (15.0-71.0) units RBC/y and pts with SCD had 3.9 (2.0-9.5) severe VOCs/y. After exa-cel infusion, all pts engrafted neutrophils and platelets (median 29 and 43 days in pts with TDT and 27 and 32 days in pts with SCD, respectively). 42/44 pts with TDT stopped RBC transfusions (duration 0.8-36.2 mo); 2 pts had not yet stopped transfusions but had 75% and 89% reductions in transfusion volume. By Month 3, increases in HbF and mean total Hb (>9 g/dL) were achieved, with mean total Hb increasing to >11 g/dL thereafter and maintained. All pts with SCD (n=31) no longer had severe VOCs (duration 2.0-32.3 mo). Mean proportion of HbF was >20% by Month 3, increasing to ~40% at Month 4 and stable thereafter, with mean total Hb >11 g/dL after Month 3. Pts with TDT and SCD with ≥1 y follow-up had stable proportions of edited *BCL11A* alleles in bone marrow $CD34^+$ HSPCs and peripheral blood mononuclear cells. 2 pts with TDT had serious AEs (SAEs) considered related to exa-cel. First pt was previously reported. Second pt had delayed neutrophil engraftment and thrombocytopenia, which were considered related to both exa-cel and busulfan. All SAEs resolved. No pts with SCD had SAEs considered related to exa-cel. There were no deaths, discontinuations, or malignancies. In summary, exa-cel infusion led to elimination of transfusions in almost all pts with TDT and elimination of VOCs in all pts with SCD, with associated clinically meaningful increases in HbF and total Hb that were maintained. Proportions of CRISPR/Cas9-edited *BCL11A* alleles remained stable after >1 y, indicating long-term HSCs were successfully edited. Safety profile was generally consistent with busulfan myeloablation and autologous transplant. These results indicate exa-cel has the potential to be the first CRISPR/Cas9-based therapy to provide a one-time functional cure for TDT and severe SCD.

2 Split Intein-Mediated Protein *trans*-Splicing to Express Large Dystrophins

Hichem Tasfaout[1,2], Christine L. Halbert[1,2], James M. Allen[1,2], Tim S. McMillen[3], Galina V. Flint[3], Stephen D. Hauschka[2,4], Michael Regnier[2,3], Jeffrey S. Chamberlain[1,2]

[1]Department of Neurology, University of Washington School of Medicine, Seattle, WA,[2]Senator Paul D. Wellstone Muscular Dystrophy Specialized Research Center, University of Washington School of Medicine, Seattle, WA,[3]Department of Bioengineering, College of Engineering and School of Medicine, University of Washington, Seattle, WA,[4]Department of Biochemistry, University of Washington School of Medicine, Seattle, WA

Gene replacement therapies mediated by Adeno-Associated Viral (AAV) vectors represent a promising approach for treating genetic diseases. Despite tremendous progress in capsid design and identification of novel serotypes with higher tropism and transduction activity an important constraint on using AAVs is their modest packaging capacity (~4.7 kb). This size restriction can significantly limit their application for many genetic disorders involving large genes, such as Duchenne muscular dystrophy (DMD), which is caused by mutations in the 2.2 MB dystrophin gene that has an 11.2 kb coding region. Affected patients develop body-wide muscle wasting and die from cardio-respiratory failure in their late teens to early 30s. Our group has pioneered the development of miniaturized forms of dystrophin (including micro-dystrophins) that can fit within and be transported by a single AAV vector. Although these smaller dystrophins are surprisingly functional, many clones tested thus far are unstable or showed incomplete rescue of the dystrophic phenotype when tested in DMD animal models and in patients. These observations suggest that the expression of larger dystrophins with additional functional domains is necessary to fully protect from, or reverse, muscle pathophysiology. Here, we present SIMPLI-GT (Split Intein-Mediated Protein Ligation for Gene Therapy), a novel method that allows the expression of large and stable proteins with high specificity and efficiency. This approach exploits the intrinsic ability of split inteins to ligate seamlessly multiple polypeptide fragments into a functional protein *via* a protein *trans*-splicing mechanism. We identified several split intein pairs that can efficiently join two or three fragments and generate, respectively, a large midi-dystrophin or the entire full-length dystrophin. In a proof-of-concept study, we show that

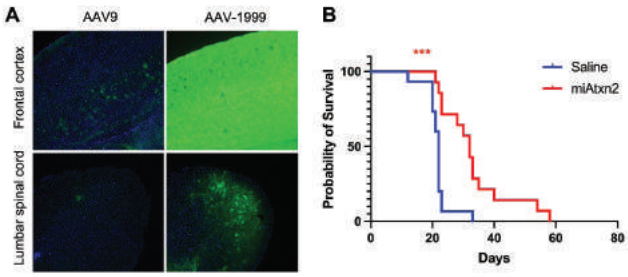
the delivery of two or three AAV vectors results in a strong expression of large and functional dystrophins with a significant improvement of muscle histology and force development. Moreover, using the potent myotropic AAVMYO capsid, we demonstrate that a low dose of 2e13 vg/kg (10-fold lower compared to what is used in clinical studies) is sufficient to express large dystrophins in striated muscles bodywide with an almost complete physiological rescue. Our data show a clear superiority of large dystrophins over miniaturized forms when tested in young or very old dystrophic mice. This novel strategy addresses emerging challenges of AAV-based gene replacement. If successful with DMD, it can be adapted to many other genetic disorders caused by loss-of-function mutations in large genes with a coding sequence beyond AAV packaging capacity.

3 Novel AAV-Capsid-Mediated Delivery of an RNAi Targeting *Atxn2* Extends Survival and Improves Strength and Neuroinflammation in a Mouse Model of Sporadic ALS

Defne A. Amado[1,2], Alejandro Mas Monteys[2], Katherine Whiteman[2], Alicia R. Smith[2], Guillem Chillon Bosch[2], Aleksandar Izda[2], Beverly L. Davidson[2]

[1]Neurology, University of Pennsylvania, Philadelphia, PA,[2]Children's Hospital of Philadelphia, Philadelphia, PA

Amyotrophic lateral sclerosis (ALS) is a fatal disease characterized by death of motor neurons. A key pathologic feature is the cytoplasmic mislocalization of a nuclear transcription and splice regulator, Tar-DNA binding protein of 43kDa (TDP-43). TDP-43 aggregates in cytoplasmic stress granules (SGs) and leads to toxicity through both cytoplasmic gain- and nuclear loss-of-function. Inhibiting formation of SGs is therefore a promising strategy, and downregulating the SG-associated protein Ataxin-2 (Atxn2) using antisense oligonucleotides (ASOs) prolongs survival by 35% in a mouse model of sporadic ALS (Becker et al. Nature 2017), a strategy that is now in human clinical trials. However, this strategy requires frequent CNS readministration of the Atxn2-targeting ASO and may not effectively reach the brain after intrathecal injections, limiting efficacy and safety. An alternative approach is to provide lasting knockdown throughout the brain and spinal cord after one treatment using AAV-mediated RNAi delivery. If successful, this strategy could be used to treat the vast majority of ALS. We designed miRNAs targeting Atxn2 and tested their efficacy in N2A cells, packaging the most effective candidate into a novel AAV9 capsid variant, AAV1999, engineered in our lab for superior CNS targeting in both mice (**Figure, A**) and nonhuman primates. A dosing study demonstrated 55% knockdown of Atxn2 in the frontal cortex and 25% knockdown throughout the brainstem and cervical and lumbar spinal cord after a one-time intracerebroventricular injection, with GFP-tagging demonstrating selective localization within the spinal cord to anterior horn cells. We then conducted an efficacy study in the same ALS mouse model used in the prior ASO study, in which wildtype human TDP-43 is overexpressed in neurons starting at P7 and mice exhibit a rapid decline in strength, succumbing around P22. After treatment, mean survival was increased by 54% and median survival by 45% ($p<0.002$; **Figure, B**). Mice showed marked improvement across several strength-related measures, including rotarod (2X duration, $p<0.02$); gait (30% improvement, $p<0.001$); kyphosis (66% improvement, $p<0.001$); tremor (34% improvement, $p<0.005$); and foot angling (48% improvement, $p<0.01$), with a trend towards improvement in abdominal droop and limping. Interestingly, mice showed an increase in vertical activity above that seen in wildtype mice, perhaps suggesting an unmasking of an FTD phenotype in the setting of improved strength. Histologically, treated mice showed normalization of the astrogliosis seen in mutant mice to wildtype levels ($p<0.05$). AAV-mediated RNAi targeting Atxn2 is therefore a promising strategy for treatment of the 97% of ALS characterized by TDP-43 pathology.



Clinical Trials Spotlight Symposium

4 Efficacy and Safety at Week 52 and up to Four Years in Adults with Glycogen Storage Disease Type IA (GSDIa): Results from a Phase 1/2 Clinical Trial and Long-Term Follow-Up Study of DTX401, an AAV8-Mediated, Liver-Directed Gene Therapy

Rebecca Riba-Wolman[1], David F. Rodriguez-Buritica[2], Ayesha Ahmad[3], Maria-Luz Couce Pico[4], Terry G. Derks[5], John Mitchell[6], David A. Weinstein[1], Deepali Mitragotri[7], Andrew Alexander Grimm[8], Eric Crombez[7]

[1]University of Connecticut, Farmington, CT,[2]University of Texas at Houston, Houston, TX,[3]University of Michigan, Ann Arbor, MI,[4]Hospital Clínico Universitario de Santiago de Compostela, Santiago de Compostela, Spain,[5]University of Groningen, Groningen, Netherlands,[6]Montreal Children's Hospital, Montreal, QC, Canada,[7]Ultragenyx Pharmaceutical Inc., Cambridge, MA,[8]Ultragenyx Pharmaceutical Inc., Novato, CA

***Background*:** Glycogen storage disease type Ia (GSDIa) results from a deficiency of glucose 6-phosphatase (G6Pase) which is essential for glycogenolysis and gluconeogenesis. DTX401 is an investigational adeno-associated virus serotype 8 (AAV8) vector expressing the human *G6PC* gene. ***Methods*:** An open-label, phase 1/2, dose escalation gene therapy trial (NCT03517085) evaluated the safety and efficacy of a single DTX401 intravenous infusion in 12 adults with GSDIa for 52 weeks. Three patients in Cohort 1 received DTX401 2.0×10^{12} genome copies (GC)/kg, and three patients each in Cohorts 2, 3, and 4 received 6.0×10^{12} GC/kg. Patients in Cohorts 1 through 3 received reactive steroids, and patients in Cohort 4 received a prophylactic steroid regimen to prevent transaminase elevation. All participants entered a long-term follow-up study (NCT03970278) to monitor safety and efficacy for up to 260 weeks after DTX401 administration. The

data cutoff for this analysis was 06-Dec-2022. ***Efficacy Results*:** Mean (SD [range]) total daily cornstarch intake reduction from baseline to Week 52 was 70.0% (23.1 [28-100%]), p<0.0001 among 11 patients with a cornstarch assessment within the ±14 day analysis window for the Week 52 visit. From baseline to last available timepoint in the follow-up study (~4 years for three patients in Cohort 1), mean (SD [range]) total daily cornstarch intake reduction was 65.6% (24.3 [9-100%]), p<0.0001 for all 12 patients. ***Safety Results:*** All patients experienced a treatment-emergent adverse event (TEAE) and a related TEAE; however, no infusion-related or treatment-related serious adverse events (SAEs) were reported. There were three patients with five related TEAEs of hypertriglyceridemia and one patient with two related TEAEs of proteinuria. All SAEs were classified as serious due to hospitalizations and were determined to be unrelated to study drug by both the investigator and study sponsor; all resolved. ***Conclusions*:** DTX401 showed a positive efficacy and safety profile in all treated patients at Week 52 that was sustained for up to four years in patients enrolled in Cohort 1. Patients in all cohorts showed a significant reduction in cornstarch needs from baseline to both Week 52 and to the last available timepoint. All participants remain in the follow-up study and updated efficacy and safety results will be reported.

5 Early Skeletal Outcome after Hematopoietic Stem Cell Gene Therapy for Mucopolysaccharidosis Type I Hurler

Mucopolysaccharidosis type I Hurler (MPSIH) is a rare lysosomal storage disorder caused by defects in *IDUA* gene and characterized by a range of clinical manifestations including severe skeletal dysplasia. While allogeneic hematopoietic stem cell transplantation (allo-HSCT) represents standard of care for MPSIH, skeletal abnormalities progress over time after allo-HSCT, requiring major orthopedic surgery and severely affecting patient's quality of life.We report the early skeletal outcome in 8 MPSIH patients treated with autologous HSPC genetically modified to overexpress human IDUA and followed-up for a median of 3 years after gene therapy (GT). This is a phase I/II HSPC-GT trial (NCT03488394) which enrolled 8 patients (6 M, 2 F; mean age at treatment: 1.9±0.5 years) who lacked a non-heterozygous-HLA-matched cord blood donor and displayed IQ/DQ>70. Primary efficacy endpoint was blood IDUA activity up to supraphysiologic levels at 1-year post-GT. Secondary efficacy endpoints included growth velocity at 1- and 3-year post-treatment. Motor function and spine MRI score at 1- and 3-year post-treatment were defined as exploratory endpoints. Skeletal dysplasia was evaluated in terms of clinical (growth, measures of dorso-lumbar kyphosis and genu valgum by goniometer), functional (motor function by Peabody scale, joint range of motion [ROM]) and radiological (acetabular index [AI] and migration percentage [MP] at hip X-Rays and MRIs, spine MRI score) parameters at baseline and at multiple timepoints, up to 3-year after treatment. All patients are alive at 3-year follow-up and show sustained engraftment of gene-corrected cells with supraphysiologic blood IDUA activity. Urinary GAG excretion reduced to normal or near-normal values by 1-year post GT and remains stable at 3-year follow-up. All patients have progressed along expected growth percentiles of healthy children and exhibit longitudinal growth within the normal range adjusted for age and gender at last follow-up. They also show progressive increase in sitting height and adequate height velocity. Clinical measures of sitting and standing kyphosis showed a trend toward reduction in evaluable patients. Genu valgum is clinically stable with degrees within the physiological range (≤ 10°) in all evaluable patients from year 2 after GT up to the latest follow-up. Motor function showed progressive acquisition of motor skills, while ROM measurement demonstrated improved stiffness at the level of shoulder, elbow, hip and knee joints. Mean AI and MP measured at hip X-Rays and MRIs showed progressive decrease after GT, indicating a reduction in hip dysplasia. Typical spine alterations measured at MRI through a specific score (*Pontesilli et al.*) showed an overall stabilization after GT up to 3-year follow-up (mean score: 3.5 at baseline, 3.3 at 3-year follow-up). HSPC-GT has shown extensive metabolic correction with a favorable safety profile. Early skeletal outcome after HSPC-GT indicates stabilization of skeletal dysplasia at multiple sites up to 3 years post-treatment. A longer follow-up is needed to draw definitive conclusions on the impact of HSPC-GT on MPSIH skeletal manifestations, as compared with standard of care.

Pontesilli S, et al. *J Pediatr*. 2022 Jan;240:297-301.e5.

6 Midbrain Gene Therapy for AADC Deficiency

Krystof Bankiewicz[1,2,3], Toni Pearson[4], Malgorzata Kohutnicka[5], Waldy San Sebastian[2], Dora Steel[6], Robert Spaull[6], Audrey Soo[6], Simon Heales[6], Roser Pons[7], Angeles Garcia-Cazorla[8], Salvador Ibanez-Mico[9], Jolanta Sykut-Cegielska[10], Krystyna Szymanska[10], Thomas Opladen[11], Kathrin Jeltsch[11], Mari Oppeboen[12], Herve Testard[13], Anne Roscher[14], Sandy Siegert[14], Michèl Willemsen[15], Saadet Andrews[16], Bruria Ben-Zeev[17], Manju Kurian[6], Miroslaw Zabek[5]

[1]The Ohio State University, Columbus, OH,[2]University of California San Francisco, San Francisco, CA,[3]Interventional Neuro Center, Warsaw, Poland,[4]Nationwide Children's Hospital, Columbus, OH,[5]Interventional Neuro Center, Brodno Hospital, Warsaw, Poland,[6]University College London, London, United Kingdom,[7]University of Athens, Athens, Greece,[8]San Joan de Deu Hospital, Barcelona, Spain,[9]Arrixaca Universitary Hospital, Murcia, Spain,[10]Institute of Mother and Child, Warsaw, Poland,[11]Heidelberg University Hospital, Heidelberg, Germany,[12]Oslo University Hospital, Oslo, Norway,[13]Centre Hospital Alpes, Contamine Sur Arve, France,[14]Medical University Hospital Vienna, Vienna, Austria,[15]Radboud University Medical Center, Nijmegen, Netherlands,[16]University of Toronto, Toronto, ON, Canada,[17]Sheba Medical Center, Tel Aviv, Israel

OBJECTIVEAromatic L-amino acid decarboxylase (AADC) deficiency is a neurodevelopmental disorder characterized by congenital deficiency of dopamine and serotonin. It presents in infancy with hypotonia, hypokinesia, oculogyric crises (OGC), dystonia, autonomic dysfunction, and global developmental delay. Here we describe interim findings from a Phase 1/2 dose escalation trial to evaluate the tolerability of MR-guided delivery of adeno-associated virus serotype 2 (AAV2)-hAADC to the bilateral midbrain in children and young adults with AADC deficiency.
METHODSTwenty-eight individuals (15F, 13M; median age 8.0 years, range 4-27 years) received AAV2-AADC (dose 4.2×10^{11}-1.5×10^{12} vector genomes(vg)) delivered in a single infusion of up to 300 microliters per hemisphere, targeting the substantia nigra pars compacta and ventral tegmental area. Changes in symptoms and motor function were assessed by caregiver log, neurologic examination and systematic review of home videos for attainment of motor milestones. Changes in dopamine metabolism were assessed by analysis of CSF homovanillic acid (HVA).
RESULTSResults were analyzed for 17 subjects who were followed for at least 12 months (range: 12-45 months). OGC improved in all subjects and resolved completely in 14/17 (82%) after gene delivery. All subjects had severe motor function impairment at baseline, with inability to sit without support. Motor function improvement was observed across the age spectrum. By 12 months post-surgery, head control was attained by 16/17 (94%) of subjects, and independent sitting by 80% (4/5) under age 7 years and 42% (5/12) age 7 years or older at time of surgery. Two subjects (baseline ages 4.8, 4.9 years) walked independently by 36 months. All subjects experienced improvements in mood, sleep, and feeding tolerance. CSF HVA increased from <20% of the lower limit of normal at baseline, to 24-100% at 6-12 months post-gene transfer (median increase 87 nmol/L, range 30-190), consistent with increased brain dopamine synthesis. All subjects tolerated the surgical procedure well. Post-treatment dyskinesia was experienced by all subjects, peaking between 6 and 12 weeks after surgery and improving over 6-12 months.
CONCLUSIONSMidbrain AAV2-AADC gene delivery has now been performed in a total of 35 individuals. The procedure is safe and produces consistent and sustained improvements for up to 5 years in oculogyric crises, mood, sleep, and motor function in patients with AADC deficiency.

7 Gene Therapy for Adenosine Deaminase Deficiency: Long-Term Outcome and Post-Marketing Experience

Autosomal recessive adenosine-deaminase (ADA) deficiency leads to severe combined immunodeficiency, treatable by enzyme replacement therapy (ERT), allogeneic hematopoietic stem cell transplantation (HSCT) or autologous CD34+ cell gene therapy (GT) following busulfan reduced-intensity conditioning. GT with bone marrow-derived CD34+ cells transduced with γ-retroviral vector (RV) (Strimvelis) was approved in 2016 in the EU. We describe the post-marketing experience of 19 subjects (STRIM cohort) up to 5 years of follow-up and provide extended follow-up data on the 22 subjects treated in the clinical development/named patient program (CDP+NPP cohort, #NCT00598481). We also report on 2 patients who received mobilized peripheral blood (mPB-HE). At data cut-off, all 43 patients were alive, with a median follow-up of 5.5 years (interquartile range (IQR) 3.4-13.0) and intervention-free survival (no need for long-term ERT or rescue HSCT) of 88% (95% CI: 78.7%-98.4%). Most adverse events/reactions were related to disease background, busulfan conditioning or immune-reconstitution. Long-term persistence of

gene-corrected cells, ADA detoxification in RBC, and immune-reconstitution, with 16/17 patients discontinuing IVIg supplementation and responding to most vaccinations, were observed in the CDP+NPP cohort. IFS, transduced cell engraftment, ADA detoxification, immunological reconstitution and the safety profile of the STRIM cohort were in line with the clinical development results. The overall insertion profile of γ-RV was polyclonal in the analyzed samples of the CDP+NPP and STRIM populations. However, a lymphoid T cell leukemia with retroviral insertion near LMO2 emerged 4.7 years post-GT in a patient from the CDP+NPP group, who is currently in clinical remission after 20 months following haploidentical HSCT. In the post-marketing population, we did not find evidence of clonal proliferation, nor new treatment-related events. In summary the safety and efficacy data in the post-marketing population are similar to the clinical development experience and efficacy is persisting long-term. Due to the risk of insertional oncogenesis, long-term safety monitoring remains important (#NCT03478670).

8 GPC3-CAR T Cells Co-Expressing IL15 Mediate Potent Antitumor Activity in Liver Cancer Patients Associated with Toxicity That Can Be Mitigated Using iC9 Safety Switch

David Steffin[1], Nisha Ghatwai[1], Chunchao Zhang[1], Purva Rathi[1], Amy N. Courtney[1], Ramy Sweidan[1], Huimin Zhang[1], Sachin Thakkar[1], Deborah Lyon[1], Hai Thuy Nguyen[1], Prakash Masand[1], Kalyani Patel[1], Carlos A. Ramos[1], Premal Lulla[1], Tannaz Armaghany[1], Bambi Grilley[1], Leonid S. Metelitsa[2], Helen E. Heslop[1], Malcolm K. Brenner[1], Pavel Sumazin[1], Andras Heczey[1]

[1]Baylor College of Medicine, Houston, TX,[2]Baylor College of Medicine, Sugar Land, TX

Glypican 3 (GPC3) is specifically expressed in several solid cancers. We optimized a GPC3-CAR with the 41BB costimulatory endodomain and showed that interleukin 15 (IL15) co-expression with this CAR enhances antitumor properties of transduced T cells. We hypothesized that IL15 co-expression (15.CAR) would increase CAR T cell expansion and antitumor activity in children and adults with GPC3+ relapsed or refractory liver cancers. Here, we analyze four phase I studies, two evaluating GPC3-CAR T cells (GAP: NCT02932956; GLYCAR: NCT02905188) and two evaluating the same CAR with IL15 co-expression (AGAR: NCT04377932; CATCH: NCT05103631). Trial objectives included characterizing safety and defining expansion, persistence, and antitumor activity of CAR or 15.CAR T cells. Six-six patients were infused with CAR or 15.CAR T cells at the $3x10^7/m^2$ dose. Toxicity was monitored using the Common Terminology Criteria of Adverse Events v5. *In vivo* persistence was quantified using qPCR and flow cytometry. CAR or 15.CAR T cell antitumor activity was determined by 3D imaging and serum alpha-fetoprotein levels. Compared to the CAR T treated patients, adverse events (AEs) were higher in the 15.CAR group (183 vs. 80, p=0.03), including cytokine release syndrome (one grade 2 event in CAR versus one grade 2 / two grade 4 events in 15.CAR). AEs were more frequent in responders vs. non-responders (15.89 versus 31; p=0.026) and specifically grade 2 AEs were observed more often (2.7 versus 10, p=0.025; **Figure 1A,B**). Expansion of 15.CAR T cells could be rapidly controlled using rimiducid, the inducible caspase 9 (iC9) safety switch alleviating side effects in all three patients that required its use (**Figure 1C,D**).15.CAR T cells had higher peak expansion than CAR T cells in the peripheral blood (6.77×10^7 vs 3.71×10^3 copy number/mcg DNA; p=0.016), and both groups demonstrated similar levels of tumor trafficking based on transgene qPCR from tumor biopsies (**Figure 2A**) which was likely due to the early use of iC9 in the 15.CAR group to alleviate AEs resulting lower number of 15.CAR T cells captured post-iC9 use. Increased expansion in responders versus non-responders was observed in the 15.CAR group (mean 36,17 versus 54,44; p=0.002; **Figure 2B**). In patients treated with CAR T cells, two had progressive disease (PD) and four had stable disease (SD). In patients treated with 15.CAR T cells, three had PD and three had partial responses including resolution of lung metastases. These results correspond to response rates of 0% for CAR T versus 50% for 15.CAR T treated patients (**Figure 2C-E**). Based on results from these phase I studies, co-expression of IL15 leads to increased but manageable toxicity with use of the iC9 safety switch, superior expansion of GPC3-CAR T cells resulting in more potent antitumor activity.

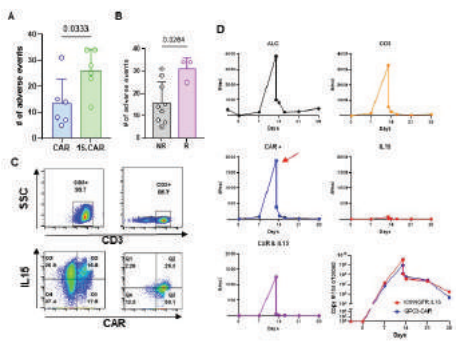

Figure 1. IL15 co-expression increases the frequency of side effects, which can be mitigated with the use of the inducible Caspase 9 (iC9) safety switch: A) Comparison of the number of adverse events (AEs) between patients receiving CAR T cells vs 15.CAR T cells. **B)** Number of AEs between non-responders (NR) vs responders (R) in both CAR T and 15.CAR T groups. **C)** Frequency of CAR+ and IL15+ T cell populations in the peripheral blood of patient "15.CAR 1" before and after rimiducid, the chemical inducer of iC9 dimerization. **D)** Expansion of circulating lymphocyte subsets by FACS and qPCR at indicated time points. Red arrow indicates mitigation of expansion in patient "15.CAR 1" by rimiducid administration. ALC, absolute lymphocyte count.

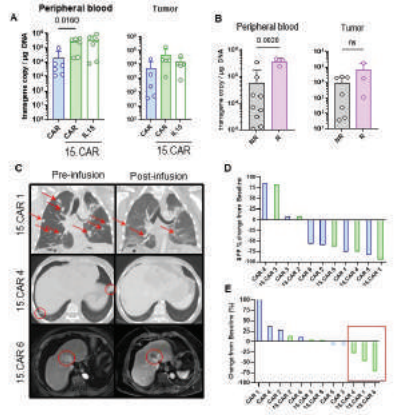

Figure 2. Co-expression of IL15 improves the expansion and antitumor activity of GPC3-CAR T cells in patients. A) Comparison of peak GPC3-CAR T cell expansion in CAR versus 15.CAR T cell-treated patients in peripheral blood and tumor biopsies post-infusion by transgene qPCR. **B)** Peak GPC3-CAR T cell expansion in responders vs non-responders by transgene qPCR. **C)** CT imaging from three responders pre-infusion and 4 weeks post-infusion. **D)** Percent change of serum AFP from baseline (pre-infusion) to post-infusion in all patients with AFP-secreting tumors (n=10). **E)** Percent change of the sum of primary and target lesions pre- and post-infusion for all patients (n=12). Patient "15.CAR 6" treatment response is consistent with complete necrosis on post-infusion biopsy sampling.

9 Danon Disease Phase 1 RP-A501 Results: The First Single-Dose Intravenous (IV) Gene Therapy with Recombinant Adeno-Associated Virus (AAV9:LAMP2B) for a Monogenic Cardiomyopathy

Barry Greenberg[1], Joseph Rossano[2], Matthew Taylor[3], Eric D. Adler[1], Kimberly Y. Lin[2], Emily Eshraghian[1], Jennifer Attias[1], Kimberly N. Hong[1], Marcus Anthony Urey[1], Monica Shah[4], David Ricks[4], Paul Yarabe[4], Jonathan Schwartz[4]

[1]University of California, San Diego Medical Center, La Jolla, CA,[2]Children's Hospital of Philadelphia, Philadelphia, PA,[3]University of Colorado Anschutz Medical Campus, Aurora, CO,[4]Rocket Pharmaceuticals, Inc., Cranbury, NJ

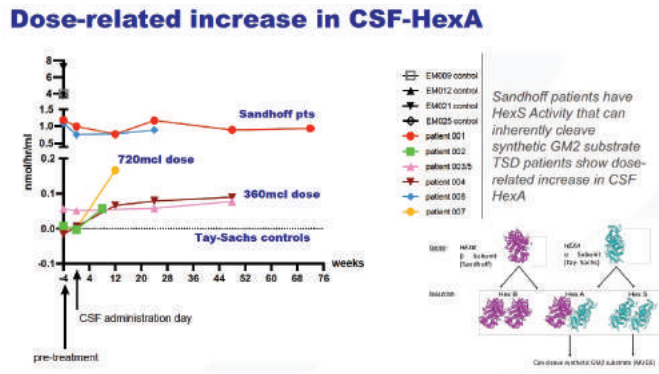
Background: Danon disease (DD) is a rare X-linked monogenic cardiomyopathy and multisystemic disorder caused by LAMP2 gene mutations resulting in LAMP2 protein deficiency. Male DD patients (pts) develop severe progressive hypertrophic cardiomyopathy (HCM), left ventricular (LV) dysfunction and arrhythmias resulting in mortality at a median age of 19-20 years (y). **Methods:** This open-label, single-dose, phase 1 trial enrolled male DD pts with pathogenic LAMP2 mutations and HCM in two age groups: ≥15 y (n=5) and 8-14 y (n=2). Pts received IV infusion of RP-A501, an adeno-associated virus serotype 9 encoding a normal copy of the human LAMP2B isoform (AAV9.LAMP2B) at 6.7 x 1013 GC/kg (low dose) or 1.1 x 1014 GC/kg (high dose). Transient immunomodulation (IM) included prednisone, rituximab, and sirolimus (for the most recently treated pediatric pts). **Results:** Between June 2019 and March 2022, 7 males (5 adult, 2 pediatric) with DD age 11.7 - 21.1y (median 18.3y) received RP-A501 (N=5 low dose and N=2 high dose). All pts were NYHA Class II at baseline. IM compliance was confirmed in 6/7 pts. All pts are alive and stable at 36 months (m) follow-up. One adult pt with baseline LV systolic dysfunction had progressive heart failure believed related to DD progression and required heart transplant at 5m post RP-A501. Follow-up for the 6 pts with baseline LVEF >40% was 24-36 months (adult pts) and 6-12 months (pediatric pts). All RP-A501- or IM-related adverse events (AEs) were manageable and reversible. A single RP-A501-related SAE of grade 4 thrombotic microangiopathy and renal failure requiring transient dialysis (with full recovery from both) was reported in 1 adult pt in the high dose cohort. No RP-A501 or steroid-related SAEs have been observed to date in the pediatric pts. On baseline endomyocardial biopsy, LAMP2 expression was grade 0 (negative staining by immunohistochemistry) in all patients; 100% (N=6/6) of evaluable pts had cardiac LAMP2B transgene expression within 6m of therapy with reduced LV mass (14-48% decrease from baseline) per echocardiogram. Pts evaluable beyond 6m had stabilized or improved BNP (N=6/6) and troponin (N=6/6) by 6-12m, and stabilized/improved LV wall thickness (N=5/5) and NYHA Class (N=5/5) by 12-18m. These findings persist up to 36m post RP-A501. Improvements/stabilization in BNP diverge markedly from natural history, including those observed in an ongoing prospective study (NHS, UCSD: NCT03766386). In untreated patients of similar age, NPs increased over 3-30m. In this prospective NHS, no patient had improved NYHA class over 6-24 months, in contrast to the NYHA improvements observed following RP-A501. **Conclusions:** Results from this phase 1 trial in DD demonstrate that B- and T-lymphocyte directed immunomodulation enables safe IV RP-A501 gene therapy administration, resulting in cardiomyocyte transduction, LAMP2B expression, improved autophagy, and improved/stabilized serologic, echocardiographic and clinical parameters associated with prognosis in HCM. These data support activation of a phase 2 clinical trial.

10 Clinical Dose-Response Relationship and Safety Profile of rAAVrh8-HexA/HexB

Brown[8], Miguel Sena-Esteves[2], Florian Eichler[5]

[1]Horae Gene Therapy Center, UMass Chan Medical School, Worcester, MA,[2]UMass Chan Medical School, Worcester, MA,[3]Neurosurgery, UMass Chan Medical School, Worcester, MA,[4]Washington University, St. Louis, St. Louis, MO,[5]Center for Rare Neurological Diseases, Massachusetts General Hospital, Boston, MA,[6]MGH Institute for Health Professions, Massachusetts General Hospital, Boston, MA,[7]Mass General Brigham, Boston, MA,[8]Neurology, UMass Chan Medical School, Worcester, MA

Tay-Sachs Disease (TSD, HEXA mutation) and Sandhoff disease (SD, HEXB mutation) result in lysosomal storage of GM2 gangliosides with severe neurodegenerative consequences. Infantile TSD and SD are fatal within the first several years. Juvenile-onset patients regress after age 2 and also have poor outcomes. Previously, a two-vector rAAVrh8 gene therapy (rAAVrh8-HexA/HexB) showed bioactivity and partial phenotypic correction in animal models and in a trial in 2 SD infants. At the time of presentation, 7 patients (4 infantile and 3 juvenile) will have been treated with bilateral intrathalamic delivery (BiTh) to exploit axonal transport, along with intracisternal/intrathecal (CSF) injection. Patients were treated with rituximab, corticosteroids and sirolimus, the latter two for 3- and 6 months post. Three dose levels were tested: a starting BiTh dose (STD) of 180 mcl (5.87E+12vg BiTh; 1.42E+14vg total), a low-dose (LD) of 360 mcl (1.17+E13vg BiTh; 1.95E+14vg total), and a mid-dose (MD) of 720 mcl (2.35E+13vg BiTh; 2.18E+14 total). Among infants, one each will have been treated at the STD, LD and two at the MD levels, while among juveniles, 2 were LD and 1 was MD. Follow-up ranges from 2 to 24 months. Outcomes included safety, CSF biochemistry, MRI/MRS/DTI and neurodevelopmental observations. CSF HexA enzyme levels showed a consistent dose-related increase in TSD patients after gene therapy [Figure], while CSF GM2 decreased. Study procedures were well tolerated. Injection-related MRI changes partially resolved on later scans. Infants showed partial stabilization, including preservation of oral feeding, and improvement of myelination in the striatum and parietal lobes. Serious adverse events (SAEs) included infections (including one fatal C. diff infection at 5.5 months post-therapy) and seizures (disease-related). In juveniles, dystonic posturing worsened after dosing in all 3 patients treated. The demonstration of a clear dose-response in CSF HexA levels confirms the feasibility of combined BiTh and CSF injection for GM2 gene delivery.



AAV Capsid Biology

11 Identification of Host Factors Critical for rAAV2.5T Transduction of Polarized Human Airway Epithelia

Siyuan Hao[1], Kang Ning[1], Zehua Feng[2], Cagla Aksu Kuz[1], Ziying Yan[2], Jianming Qiu[1]

[1]University of Kansas Medical Center, Kansas City, KS,[2]University of Iowa, Iowa City, IA

rAAV2.5T was selected from the directed evolution of an AAV capsid library in human airway epithelium (HAE) cultured at an air-liquid interface (ALI). The capsid gene of rAAV2.5T is a chimera of the N-terminal unique region of AAV2 VP1 (VP1u) and the VP2 and VP3 regions of AAV5 with a single A581T mutation. We conducted two rounds of genome-wide CRISPR screens of rAAV2.5T transduction in HeLa-S3 cells using the Brunello gRNA library. This study identified that KIAA0319L (AAVR), GPR108, and WRD63 are critical host factors for AAV2.5T transduction in HeLa cells. We next investigated the role of these host factors in rAAV2.5T transduction of the polarized HAE-ALI cultures, in which the genes encoding these host factors were knocked out individually. AAVR was identified as the proteaceous receptor of various AAVs to infect cells, including AAV2 and AAV5. However, we found that although AAVR was essential for rAAV2.5T transduction in polarized HAE-ALI cultures, the apical entry of rAAV2.5T was independent on AAVR, suggesting that another proteaceous receptor may also be used to mediate rAAV2.5T entry of HAE-ALI. GPR108, a G protein-coupled receptor, is known as an essential host factor for transduction of rAAV2, but not for rAAV5. On the other hand, we observed that GPR108 knockout aborted the rAAV2.5T transduction in HAE-ALI; however, the application of doxorubicin (DOX) reinstalled the transduction of rAAV2.5T in the GPR108-KO HAE-ALI cultures. DOX is an FDA approved chemotherapy agent for cancer treatment. It is a DNA topoisomerase II inhibitor and also demonstrates inhibition of proteasome activity. Application of DOX increased rAAV2.5T transduction in HAE-ALI cultures by >100-fold. Mechanistically, DOX enhanced rAAV2.5T transduction was primarily mediated by altering the intracellular trafficking pathway of the vectors, but not the inhibition of proteasome-dependent degradation. Importantly, we identified that a sequence of 14 amino acids at AAV2 VP1u determined the rAAV2.5T dependence of GPR108 for transduction. We further confirmed that AAV2 VP1u specifically interacted with the cytosolic portion of GPR108, which likely facilitates rAAV to be released from trans-Golgi network (TGN), and the use of DOX assists rAAV to escape the TGN and enter the nucleus while GPR108 is absent. In summary, rAAV2.5T utilizes AAVR and GPR108 for productive transduction in HAE-ALI, but it does not solely use AAVR for vector entry. DOX facilitates rAAV2.5T to escape the TGN through a GPR108 independent pathway for nuclear import.

12 AAV2's Defective Trafficking in the Absence of the AAV-Receptor is Due to a Block in Endosomal Escape

Marti Cabanes[1], Sophia Liao[1], Maddison Knight[1], Renina Navarro[1], Angus Johnston[2], Leszek Lisowski[1]

[1]Children's Medical Research Institute, Westmead, Australia,[2]Monash Institute of Pharmaceutical Sciences, Parkville, Australia

Seven years have elapsed since the paradigm-shifting discovery of KIAA0319L, an essential receptor for adeno-associated virus infection, a protein since then named AAVR. However, the understanding of the mechanistic function of this protein in the transduction pathway of AAV has lagged. Viral overlay assays and resolved cryo-electron microscopy structures of the AAV2-AAVR complex performed by independent laboratories suggest that AAV2 physically interacts with AAVR. Multiple labs have also confirmed a complete lack of functional transduction - understood as transgene transcription and translation - in the absence of AAVR. This suggests the presence of a block in the transduction pathway of AAV2. In this work, we aimed to reveal the nature of such block, in the context of AAV2 transduction, in the absence of AAVR. Our study, performed in HuH-7 naïve and in-house generated HuH-7 AAVR-KO cells, suggests that AAV2 vectors can still physically enter cells lacking AAVR, as demonstrated by the presence of intracellular vector genomes and A20 antibody signal, which recognizes intact AAV2 capsids. However, in the case of AAVR-KO cells, this vector uptake led neither to RNA (as shown by RNA-FISH) nor to, understandably, protein expression. In contrast, transgene translation and expression were readily detectable in naïve HuH-7 cells already 24h post-transduction. To understand whether the block in transduction occurred upstream or downstream of the nuclear entry, we used transmission electron microscopy (TEM) to detect rAAV2 particles in naïve and AAVR-KO HuH-7 cells. To our surprise, we observed clear signs of nuclear envelope breakdown in naïve cells, which is consistent with the mechanism of nuclear entry described for other parvoviruses. We observed no such signs in AAVR-KO cells, suggesting the pathway block in AAVR-KO cells was upstream of nuclear entry. Realizing that the AAV2 phenotype in AAVR-KO cells mimics the well-studied phenotype of AAV2 virions lacking the VP1 capsid protein, we next investigated whether a defective endosomal escape could be a driver behind the observed block of AAV2 transduction in AAVR-KO cells. We could detect A20 signal (intact capsids) in both naïve and AAVR-KO cells, but when studying the VP1-unique (VP1u) exposure in transduced cells, we could only detect A1 signal, which recognizes the VP1u region, in naïve HuH-7 cells. The currently accepted theory is that endosomal acidification leads to the exposure of the PLA_2 domain present in the VP1u region that is required for endosomal escape. Thus, our data suggest that either AAVR regulates such acidification or that acidification *per se* is

not sufficient, intracellularly, to mediate the conformational change in the AAV capsid. To study this, we used pH dependant fluorescent lifetime imagining microscopy (pHLIM) to quantify the sub-cellular pH of the individual endosomal vesicles accurately. Preliminary data in naïve and AAVR-KO showed no major differences in the pH in both cell lines. Hence, this work challenges the commonly accepted theory that endosomal acidification is the only required step for VP1u exposure and opens the possibility for the AAVR-AAV2 interaction to be essential for such a process. The absence of this hypothesized interaction in HuH-7 AAVR-KO cells would trap the vectors in the endosomal vesicles, which would be consistent with the observed lack of functional transduction AAV2 in this knock-out line.

13 Modifying Immune Responses to Adeno-Associated Virus (AAV) Vectors by Capsid Engineering

Martin Bentler[1], Romain Hardet[2], Moritz Ertelt[3], Dorota Kaniowska[4], Daniela Rudolf[4], Florian W. R. Vondran[5], Clara T. Schoeder[3], Marion Delphin[6], Julie Lucifora[6], Michael Ott[7], Ulrich T. Hacker[8], Sahil Adriouch[2], Hildegard Büning[1]

Adeno-Associated Virus (AAV) vector-based gene therapy may be impaired by *de novo* immune responses towards the AAV capsids or encoded transgene products. With the aim of reducing potential innate immune responses in cells infected with AAV, we generated a capsid-engineered AAV vector displaying an immune modulatory peptide on its capsid that is known to interfere with innate immune signaling. Insertion of this peptide did neither affect capsid assembly nor production efficiency. The new capsid variant, termed AAV2.MB, outperformed AAV2 in terms of transduction efficacy in human monocyte-derived dendritic cells (moDCs) and in primary human hepatocyte (PHH) cultures. In line with our hypothesis, AAV2.MB and AAV2 differed in triggering innate immune response activation in human primary cells. Specifically, induction of the expression of type I interferons was lower in moDCs treated with AAV2.MB. Importantly, AAV2.MB vector administration either intravenously or intramuscularly resulted in a markedly reduced $CD8^+$ T cell response against the AAV vector-encoded EGFP transgene product. Beyond that, humoral responses against AAV capsids measured by anti-AAV2 IgG2a antibodies were mitigated and delayed in AAV2.MB-injected mice independent of the route of administration. To conclude, by incorporating an immune-modulatory peptide into the AAV2 capsid we could modify the activation of innate as well as adaptive immunity in response to AAV2 vectors.

14 Structural and Kinetic Characterization of Anti-AAV9 Monoclonal Antibodies Derived from Patients Post-Zolgensma Treatment

Jane Hsi[1], Mario Mietzsch[1], Austin R. Nelson[1], Paul Chipman[1], Jenny Jackson[2], Peter Schofield[2], Daniel Christ[2], Joanne Reed[3], Neeta Khandekar[4], Grant Logan[4], Ian E. Alexander[4], Robert McKenna[1]

[1]University of Florida, Gainesville, FL,[2]Garvan Institute for Medical Research, Sydney, Australia,[3]Westmead Institute for Medical Research, Sydney, Australia,[4]Sydney Children's Hospitals Network, Westmead, Australia

The utilization of adeno-associated virus (AAV) as a gene transfer vehicle has become increasingly feasible as a clinical option in recent years. Following the FDA approval of Zolgensma®, an AAV9 based biologic to treat children under the age of two with spinal muscular atrophy (SMA), there is a growing interest in expanding AAV9 usage due to its ability to transduce cardiac and skeletal muscle, liver, pancreas, eye, and its capability to cross the blood-brain-barrier to transduce the central nervous system (CNS). However, the presence of pre-existing neutralizing antibodies (NAbs) against AAV9 capsids in a large percentage of the population could reduce the efficacy of AAV9 gene therapy and may lead to the exclusion of patients from treatment. A strategy to circumvent the immune response of a patient for AAV-mediated therapeutic gene delivery is the development of engineered vector capsids by either directed evolution or rational design that are then able to escape antibody recognition. In order to pursue this strategy, the interactions of the NAbs to the capsid binding need to be characterized. Previously, our lab as well as others have generated mouse monoclonal antibodies targeting the AAV9 capsids to simulate the immune response against the capsid and map the major antigenic regions. However, this approach has faced criticism as mouse-derived antibodies may not fully mimic the behavior of human-derived antibodies. Here, we present the structural and kinetic characterization of human monoclonal antibodies that were obtained from patients that received Zolgensma®. Specifically, we have determined the binding sites of 21 antibodies obtained from three patients to the AAV9 capsid by cryo-electron microscopy and three-dimensional image reconstruction. Our data shows that the 2-fold capsid surface is the antigenically dominant region as approximately three quarters of the antibodies bind there. The binding interactions and kinetics for these antibodies were analyzed using biolayer interferometry and compared to the previously developed murine antibodies. All the antibodies neutralize AAV9 transduction, and some also cross-react and neutralize a range of different AAV serotypes. Additionally, there is a strong correlation between Fab binding affinity and the IC50 values for the corresponding mAb. Structural and kinetic comparisons of human and murine antibodies will be presented along with antibody escape variants.

15 Co-Identification and Characterization of Host and Viral Protein Interactomes during AAV Transduction by Two Different Proximity Labeling Methods

Jisun Lee[1], Guangping Gao[1,2], Jun Xie[1,2]
[1]Horae Gene Therapy Center, UMass Chan Medical School, Worcester, MA,[2]Co-responding Authors, Worcester, MA

Recombinant adeno-associated viral vectors (rAAV) are considered promising vehicles for gene therapy. However, high dose of AAV administration and insufficient transduction efficiencies still pose difficulties on therapeutic applications. Efficient transduction is determined by the life cycle of AAV and more significantly the molecular interactions between the viral vectors and the host proteins. A better understanding of the cellular proteins involved in AAV transduction throughout the transduction pathway of AAV will lead to improved efficiency of AAV-derived vectors. The proximity-dependent biotin identification method allows detecting protein-protein interactions with a promiscuous biotin ligase fused to a bait protein. These biotinylated proteins can be selectively isolated by biotin-streptavidin capture and identified by mass spectrometry. We grafted two types of biotin ligase, BioID2 or TurboID onto the surface of AAV2 capsid. BioID2 is a smaller biotin ligase, and the major disadvantage is its slow kinetics, which necessitates labeling with biotin for 18-24 hours. By contrast, TurboID is greater in size but enable the labeling in 10 minutes. Both engineered AAV2 capsids can biotinylate un-biotinylated substrates just like a purified biotin ligase. During AAV transduction in HEK 293 cell, biotin and ATP were added to the culture medium. Twenty-four hours post infection, proteins were then selectively isolated by streptavidin-coated beads for mass spectrometry analysis. Finally, we found four host proteins which showed increased AAV2 transduction in HEK 293 cells and HeLa cells after knock-down by siRNA treatment. Furthermore, specific combinations of two host siRNAs showed higher transduction efficiency in AAV2-infected HeLa cells, compared to a single siRNA treatment. This was also observed in multiple serotypes including AAV1, AAV3b, AAV5, and AAV9. Those four host proteins are not involved in the attachment of AAV to the cells, internalization, nuclear import, and genome release (uncoating). And yet, knock-down of the host proteins significantly increased luciferase transcript through recruiting transcriptional machinery onto the AAV vector genome. Our findings will advance our understanding of the molecular interaction between the host proteins and AAV during transduction, and consequently contribute to improving the efficacy of AAV transduction.* G.G., and J.X are co-corresponding authors

16 Multiplexed Characterization of AAV Cellular Tropism and Promoter Expression in Large Animals Using Single-Cell RNA Sequencing

Alex Araki[1], Martin Borch Jensen[1], Chase Bowman[1], Chris Carrico[1], Linda Chio[1], Atray Dixit[1], Caroline Duwaerts[1], Daniel Fuentes[1], Ian Driver[1], Vinay Kartha[1], Akela Kuwahara[1], Carmen Le[1], Francisco LePort[1], Hikaru Miyazaki[1], Wyatt Morgan[1], Dimitry Popov[1], Frank Sachse[1], Neety Sahu[1], Smitha Shambhu[1], Christopher Towne[1], Rachael Watson Levings[2]
[1]Gordian Biotechnology, South San Francisco, CA,[2]University of Florida, Gainesville, FL

In order to develop the best AAV vector for gene delivery, it is important to identify a serotype that is specific to a cell-type of interest and engineer the payload so that it is capable of high transgene expression in relevant disease contexts. Existing AAV serotype screening methods based on AAV genome detection do not provide information on vector functionality nor levels of transgene expression. Other methods relying on bulk next-generation sequencing of barcoded genomes do not confer cell-type resolution within a target tissue. We have developed a platform using expressed barcodes combined with single-cell sequencing that allows for high-throughput multiplexed screening of functional AAV expression across multiple cell types within different organs of relevant animal models including mouse, horse, pig, and non-human primates. Using this screening platform, we are able to identify an optimal cell-type specific AAV serotype and run head-to-head comparisons of regulatory elements to identify promoters for high expression. As an example of this platform, we identified AAV serotypes capable of transducing chondrocytes and synovial cells for the treatment of osteoarthritis (OA). 13 serotypes, each at a dose of 1E12 vg, were pooled and injected into osteoarthritic horse joints (n = 4 joints). 4 weeks after injection, the joint tissue was assessed for GFP expression and processed. Positively transduced chondrocytes and synovial cells were run through the 10x Genomics single-cell system. Following next-generation sequencing, we processed our data to match cell-types with functional internalized AAV genome barcodes. We identified several serotypes with up to 32.8x higher transduction in chondrocytes as compared to AAV2.5, a serotype currently used in clinical trials of OA. Follow-up injection of our chondrocyte-specific and synovial-specific serotypes at doses ranging from 1E12 to 8E12 vg into non-diseased and OA joints (n = 11 joints) phenotypically confirmed the the results of our screen and resulted in transduction percentages in a range of 1 - 5% and 0.5 - 15%, respectively. We used the same screening approach to optimize regulatory elements for a gene of interest for the highest relative number of transduced cells and level of expression across different cell-types within multiple tissues. A pooled library of 47 combinations of enhancers, promoters, introns, and poly-A signals was tested in mouse lungs (n = 10) and livers (n = 9). From the resulting data, we were able to identify a ubiquitous enhancer-promoter-intron combination with active transcripts and expression detectable in twice as many cells as a ubiquitous CMV promoter. Continuing the expansion of our platform's capabilities, the above methods have been combined to identify serotypes and promoters for a heart failure pig model. The top 3 serotypes (from 17 serotypes) and the top 3 promoters (from 47 combinations) were identified and validated

in a mouse model transcriptomically and histologically. These vectors along with single-stranded and self-complementary variants were injected in a heart failure pig model (n = 3 pigs) to achieve successful gene expression. Taken together, this work shows the broad-ranging ability of our platform to produce optimal AAV vectors for gene delivery. Through the combination of single-cell RNA sequencing with transcriptomic readouts of barcoded libraries, we are able to identify cell-type specific serotypes and highly expressing regulatory elements in relevant animal models for disease.

17 A New Class of AAVR Binders: Structure of a Goat Adeno-Associated Virus (AAVGo.1) Complexed with the Human Adeno-Associated Virus (AAVR) Receptor

Edward E. Large[1], Mark Silveria[2], Onellah Weerakoon[1], Tommi White[3], Michael S. Chapman[2]

[1]Biochemistry, University of Missouri, Columbia, MO,[2]University of Missouri, Columbia, MO,[3]Crop Science, Bayer, Chesterfield, MO

Adeno-associated viruses (AAVs) are compact (~250 Å diameter) non-pathogenic viruses that are useful for gene therapy. Viral capsid structure modulates cellular entry. AAV is first anchored to cells using glycan attachment factors, then cell entry is mediated by the Adenovirus Associated Virus Receptor (AAVR) and several potential co receptors. Most AAV serotypes, including AAV2, bind AAVR using the second of five AAVR polycystic kidney disease (PKD) repeat domains (PKD2) whereas the distantly related serotype AAV5 binds PKD1. The two modes of binding (PKD2 vs PKD1) have been visualized using cryo-EM: PKD2 binds to a capsid area distinct from the PKD1-binding region. In order to examine the full potential diversity in AAVR-capsid interactions an investigation of the goat parvovirus, AAVGo.1, was initiated. Goats are the most distant relatives of human hosts for which there is known cross-species AAV susceptibility. Virus like particles of AAVGo.1 were produced using Sf9 cells and purified using cesium chloride gradient ultracentrifugation. Various AAVR domains were expressed in E. coli and purified using FPLC. ELISA assays were used to detect receptor binding and also for neutralizing antibody binding comparisons between AAV5 and AAVGo.1. Virus receptor complexes were then visualized using cryo-EM. Cryo-EM structures of both AAVGo.1 (2.9 Å resolution) and AAVGo.1 bound to human AAVR (2.4 Å resolution) were solved. AAVGo.1 is most similar to AAV5 and also binds to PKD1 but with a rotation of ~1 Å compared to PKD1 bound to AAV5. Therefore, AAVGo.1 becomes the second member (alongside AAV5) of a distinct class of AAV in terms of their mode of AAVR binding (to the PKD1 domain). The majority of virus-receptor interactions are conserved within each class and this has important implications for vector engineering.

AAV Vectors - Product Development Manufacturing: Downstream

18 Exploring the Robustness and Throughput of Size Exclusion Chromatography of Recombinant AAVs

Szabolcs Fekete[1], Mateusz Imiolek[1], Matthew Lauber[2]

[1]Waters Corporation, Geneva, Switzerland,[2]Waters Corporation, Milford, MA

Adenoassociated virus (AAV) gene therapies have advanced over the past decade to become a promising class of therapeutics capable of treating intractable diseases. Establishing an AAV as a well characterized drug product is however a major undertaking because they are inherently heterogeneous, containing full, partially filled, and empty capsids as well as aggregates, fragments and process-related impurities. As with the antibody pipeline, liquid chromatography (LC) assays have emerged to provide CQA measurements and to aid drug product engineering, process development, formulation, and release testing. With that, there is a need to continue exploring the capabilities of these new LC assays, learn their limits and make new insights about their robustness. Size exclusion chromatography (SEC) is one of the most important techniques being adopted. It is favored not only for its size variant profiling but because it can be readily coupled with multiple wave-length UV, fluorescence (FL), multiangle light scattering (MALS) and refractive index (RI) detectors so that multiple physicochemical measurements can be extracted from a single run. With current practices, analytical SEC for AAV analysis makes use of ≥ 5 µm diameter 300 to 1000 Å pore size packing materials and large volume columns made from stainless steel hardware. This means that analyses can be time consuming, use significant amounts of sample and be plagued by non-specific interactions that can impair the quantitation of important impurities. As a result, we are exploring separations of AAV2, AAV5 and AAV9 using the above starting points and systematically demonstrating the effects of using high efficiency 2.5 micron packing materials and low adsorption column hardware. Enthalpy contributions and solute retention will be reported along with an investigation into the potential for shear force effects to impact critical measurements. Moreover, a new simple experimental design will be employed for a method robustness check using an approach that requires only 8 quick experiments. It is hoped that these SEC studies will provide new insights on robustness and throughput considerations that the field can more broadly apply in support of the burgeoning AAV pipeline.

19 Novel Repression System for Gene Expression Regulation during Recombinant Adeno-Assoiciated Virus and Lentiviral Vector Manufacturing

Jiali Yang, Liping Zhang, Jia Xu, Peimin Ma, Ruiju Yang, Guodong Jia, Weiran Shen, Xinglin Yang

OBiO Technology (Shanghai) Corp., Ltd., Shanghai, China

Ubiquitous promoters are widely used for gene expression by viral vectors. However, the same gene also expresses in vector packaging cells. Gene of interest (GOI) could be toxic or disruptive to viral vector

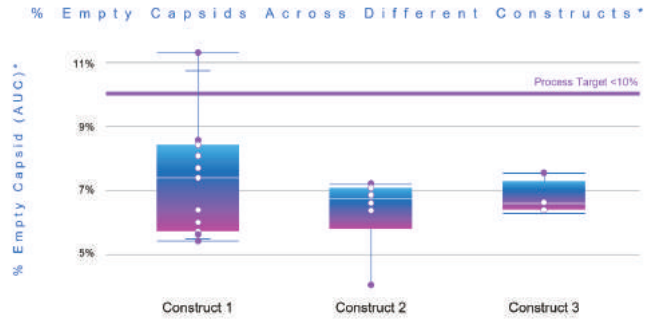
packaging, resulting in either low yield or poor quality of vectors during manufacturing. There were several potential solutions to this challenge. Tet-on inducible or tissue-specific promoters could be used, yet the application is restrictive to meet different needs. There were studies using RNAi-based technology to silence GOI expression. However, this system may not be widely applicable to all GOI expressions. Some research used the TRiP system for exogenous protein translation inhibition, but it has no control over RNA encoding genes. In this study, we developed a gene expression regulation system, which overcomes the defects mentioned above. The CuO-Cymr repression system includes a short DNA element, which could insert into a ubiquitous promoter. The element responses to a repressor which is constructed into the manufacturing cell line. The induction results in significant gene silencing. The leaky expression is minimal compared with other inducible systems. Importantly, it is applicable to different GOI and regulates the expression of both protein and RNA. We evaluated the system in toxic gene packaging by recombinant adeno-associated virus or lentiviral vectors. Both vectors achieved high yield by packaging toxic genes, otherwise, vectors could be barely produced. The inducible system has no changes over gene expression or function for downstream applications of the viral vectors.

20 Ahead of the Game: A Scalable Purification AEX Platform Capable of Achieving <10% Empty Capsids

Ashish Sharma, Alex Meola, Kyla DeSanty, Alice Oliveira Aguiar, Thomas Thiers, Zaid Junaid, Carlos Chong, Luke Mustich, Shanshan Zhou, Michael Mercaldi

Process Development, Oxford Biomedica Solutions, Bedford, MA

Control of empty capsids is a significant challenge for the manufacture of AAV therapeutics. The elevated presence of empty capsids in AAV Drug Product may cause undesirable safety issues and the level must be controlled to ensure patient safety. The purification process for AAV can be designed to remove empty capsids to limit exposure to patients. The traditional approach has been to use gradient ultracentrifugation. Gradient ultracentrifugation can separate empty from full capsids by exploiting their relative differences in density and can work well in small scale setting, but can be challenging to implement and control in a manufacturing setting. Furthermore, as AAV bioreactor titers increase, ultracentrifugation becomes more challenging to effectively scale up. To meet the growing clinical and commercial demands of AAV, alternative approaches that can scale up and deliver comparable levels of empty capsids need to be developed. Many organizations and manufacturers have adopted anion exchange chromatography as the preferred process of choice to ultracentrifugation. However, a limited number of these methods can deliver the same level of empty capsids as ultracentrifugation which leave therapeutic developers with having to choose between yield and product quality. Our presentation will introduce an Anion Exchange chromatography step (AEX) that delivers on both yield and product quality, by achieving <10% empty capsids, a high yield of 67-88% vector genomes, and is scalable to 2000L. The AEX step consistently produces <10% empty capsids across multiple constructs with the same capsid. It also delivers the same level of purity across other major serotypes including, but not limited to AAV1, AAV2, AAV6, AAV8 and AAV9. Reproducible operational success at the 50L, 500L, and 2000L scales (N=23) with comparable product quality and yield has been possible due to the isocratic nature of the step. This makes the platform manufacturing friendly, automatable, and very robust.



In our talk, we will describe how the AEX platform was developed, implemented for multiple serotypes and constructs, scaled-up and compared to ultracentrifugation. The plug and play applicability and workflow will also be reviewed. Furthermore, we will discuss the scalability of this step and how it helps to streamline manufacturing operations, reduce Cost of Goods (CoGs) and enable straightforward late-stage process characterization and commercial manufacturing. Finally, we will outline the value proposition offered by the AEX platform; a robust, efficient manufacturing step that can be executed at any scale and consistently delivers high product quality. The use of this AEX step can lead to higher productivity manufacturing and enable therapeutic developers to treat indications with larger patient populations in a safe and economical manner.

21 Impact of Downstream Buffer pH and Ionic Strength on rAAV Capsid Stability

Vijesh Kumar, Ohnmar Khanal, Mi JIn

Technical Development, Downstream and Drug Product Development, Spark Therapeutics, Philadelphia, PA

A production process consisting of suspension cell culture and chromatographic purification is becoming increasingly popular for large-scale manufacturing of rAAV vectors for gene therapy. Before the preparation of the rAAV drug product in the formulation buffer, rAAV vectors face a series of downstream purification buffers across different unit operations like lysis, filtration, chromatography, and tangential flow filtration. The downstream processing of rAAV vectors can take 3- 7 days. During this time, the rAAVs are exposed to environments of different pH ranging from 9.0 to 3.0. They may also be held in a particular environment for over 24 hours to accommodate the processing timeline. Moreover, downstream processing buffers also span an extensive range of ionic strength (10 mM -500 mM) and may include additives such as metal ions and surfactants. Exposure to unfavorable ionic strength and pH buffers can lead to various degradation issues. In particular, chromatography operations require low ionic strength buffers and harsh pH conditions. In this work, we systematically evaluated the stability of AAV capsid in predefined buffer components ranging from pH 3 to 9 and ionic strengths of 50 to 300 mM, along with commonly used purification additives. The rAAVs were incubated in various buffers for 0, 2, 6, 12, and 24 hours. They were then analyzed on analytical anion exchange (AEX), hydrophilic

interaction liquid (HILIC), and size chromatography exclusion (SEC) chromatography to monitor the changes in the product profile. The AEX result indicated lower ionic strength impacts AAV capsid stability more significantly than pH. Furthermore, empty and full capsids showed different stability profiles. Buffers with 50-120 mM ionic strength significantly changed the AEX peak profile, particularly in the mid-pH range. Given that the above pH and ionic strength ranges are most commonly utilized during chromatographic operation, assessing their stability and solubility is critical. Based on our study, we recommend strategies to limit the exposure of AAVs to unfavorable buffer conditions as needed, such as the implementation of inline dilution during product loading onto AEX and the adjustment of pH and IS after chromatographic elution.

22 Challenging the Bind and Elute Convention: A Novel Approach to Partitioning Method for Full rAAV Capsid Enrichment Using AEX Chromatography

Tamara Zekovic, Paul Greback-Clarke, Jacob Smith, Jordan Hobbs, Robert Tikkanen, Eva Graham, Eric Vorst

Asklepios BioPharmaceutical, Inc., Durham, NC

Two of the largest hurdles in the downstream purification of recombinant Adeno-Associated Virus (rAAV), at present, are variable distribution of empty and full capsids produced in each bioreactor batch and that empty capsids co-purify with genome containing (full) rAAV vectors during chromatographic separation. Several publications have detailed methods of separating empty and full recombinant rAAV particles by strong anion exchange chromatography (AEX) (Dickerson et al., J.F. Wright et al.). To date, these reported methods have relied upon a bind and elute strategy to achieve the high degree of chromatographic resolution required to separate empty and full capsids. These gradient-based elution methods typically are very sensitive to variability in load composition and mobile phase composition and require a tightly controlled fractionation strategy, all of which pose a challenge to robust scale-up. This presentation will detail a novel method of enriching full genome containing rAAV over AEX that addresses the challenges of process robustness and scalability. Modulating the mobile phase composition during the AEX load enables the flowthrough or "partitioning" of empty capsids while selectively retaining full rAAV vectors. Minimizing empty capsid binding simplifies the elution strategy, enabling better process control, which can be a significant benefit during tech transfer and scale up. Furthermore, the partitioning technique is robust to changes in starting material (serotype, transgene, vector titer, and empty/full distribution in upstream samples). Using this method, we have demonstrated full capsid enrichment at levels comparable to those obtained by the standard industry practice of density gradient ultracentrifugation across a range of scales and multiple serotypes including 2, 2i8, 8, 9.

23 Preserving High Transduction Efficiency - Serotype Agnostic Purification of Adeno-Associated Virus Using Adsorbents Functionalized with In Silco Discovered Peptide Ligand

Shriarjun Shastry, Stefano Menegatti, Wenning Chu

Chemical and Biomolecular Engineering, North Carolina State University, Raleigh, NC

Preserving the transduction efficiency of adeno-associated virus (AAV) is crucial in gene therapy and gene editing applications. High transduction efficiency leads to greater therapeutic efficacy and better patient outcomes. On the other hand, low transduction efficiency can lead to insufficient therapeutic gene expression and, therefore, ineffective treatment. Additionally, preserving transduction efficiency is also important in optimizing the safety of AAV-mediated gene therapy, as it reduces the amount of virus needed to be administered, minimizing potential adverse effects. Adeno-associated virus receptor (AAVR) is an important factor in the transduction efficiency of AAV. AAVR is a cell surface protein that is required for AAV to enter target cells and deliver its genetic payload. By identifying the specific cell types and tissues that express AAVR, researchers can optimize the targeting of AAV to the desired cells and increase the efficiency of transduction. Furthermore, understanding the regulation of AAVR expression and its interaction with other cellular components can lead to the development of novel strategies for enhancing AAV transduction efficiency. Additionally, the A20 antibody is an important component in the use of AAVs for gene therapy. AAVs are commonly used as vectors for delivering therapeutic genes to treat various diseases, but their use can be limited by the immune response generated against the virus. The A20 antibody specifically targets the A20 protein, which is known to play a role in regulating the immune response. By blocking the activity of the A20 protein, the A20 antibody can enhance the transduction efficiency of AAVs, thereby increasing the effectiveness of gene therapy. In this study, we have tackled the issue of AAV stability by proposing a methodology to purify AAV Serotype 2 (AAV2) from Human embryonic kidney (HEK293) cell lysate using peptide-based adsorbents, with mild elution conditions that will prevent capsid structure alteration, which is typically caused by reduction of pH and hence preserving the transduction efficiency. Docking studies were performed with the VP1 sequence of AAV2 against the sequences of AAVR and A20 antibodies. Eight different peptides were discovered via Insilco modeling. These were then synthesized on the Toyopearl NH2-750F resin bead. Further, binding efficiency, selectivity, and recovery in the purification of AAV2 using the Insilco-discovered peptides were evaluated. 20 mM Bis-Tris, 25 mM NaCl buffer at pH 7.0 maximizes the capture of AAV2 on the peptide-based adsorbents. A 10 ml injection of HEK293 clarified lysate on a 0.5 ml column yielded AAV recoveries of up to 70% with great selectivity, using mild elution conditions such as a buffer containing 1.0 M Magnesium chloride at pH 6.0. These recoveries were hugely comparable to the commercially available resins, where the capsids are eluted in a low pH (2.0 - 2.2) environment. HEK293 host cell protein (HCP) logarithmic removal value (LRV) of 2.2 - 2.8 was achieved by the peptide-based resins compared to an LRV of 2.8 obtained from the AAVX and AVB Sepharose HP resins. Bind and elute studies on pure AAV1, AAV5, AAV6, AAV8, AAV9, and AAVrh10 samples also indicated the ability

of some peptide-based resins to capture these serotypes effectively. Collectively, these results demonstrate the potential for an alternate selective chromatographic process for purifying AAV2 and potentially other AAV serotypes from HEK293 clarified cell lysate in a neutral pH environment, thus preserving the transduction efficiency.

24 IsoTag AAV - An Innovative, Scalable, Non-Chromatographic Method for Streamlined AAV Manufacturing

Michael Dzuricky
Isolere Bio, Durham, NC

Purification of adeno-associated viruses (AAVs) is a rate-limiting step of therapeutic development which impacts the cost, safety, and efficacy of the final product. Traditional separation processes - filtration accompanied by affinity capture - are the industry standard for primary contamination clearance but are inefficient, costly, and impractical when applied to gene therapy viral vectors. Isolere Bio, Inc. has developed IsoTag-AAV, a purification process that combines filtration and affinity separation into a single processing step via the novel mechanism of liquid-liquid phase transition. Briefly, AAV capsids can be sequestered and concentrated into IsoTag-AAV droplets away from contaminants and then subsequently released from the droplets in a user-triggered manner for collection of pure product. The entire process can be performed with a standard tangential-flow filtration (TFF) machine and commercially available using hollow fibers between 0.22 and 0.65-micron pores. IsoTag-AAV is remarkably robust, capable of >98% capture across a wide range of serotypes (2, 5, 8, 9 and rh10), platform across a 3-log range in titer (5E10-1E13 vg/ml) and can be completed in under 4 hours regardless of starting culture volume. Our process yields highly pure AAV whose *in vitro* infectivity is comparable or exceeds AAV purified by affinity chromatography. IsoTag-AAV actually improves upon traditional affinity yields and product quality with minimal optimization. A head-to-head comparison of IsoTag-AAV purification and traditional affinity purification at the 1L scale. This comparison showed yield improvements up to 20% unoptimized and comparable purity in half the time. Process cost modeling showed that IsoTag-AAV can reduce cost of goods for a commercial AAV program by as much as 50%. In conclusion, IsoTag™ AAV offers improved yields and comparable purity to traditional chromatography methods in a TFF process that scales linearly to streamline process development, scale up and manufacturing, accelerating time to the clinic

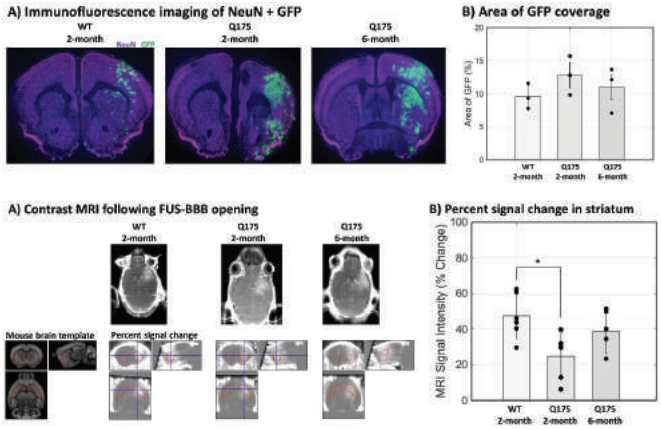
Synthetic/Molecular Conjugates and Physical Methods for Delivery of Gene Therapeutics I

25 Focused Ultrasound for Improved Delivery of AAV Vectors to the Brain for the Treatment of Huntington's Disease

Nick Todd[1], Yongzhi Zhang[1], Lilyan Garrett[2], Alvin Yao[3], Kai Shing[4], Kimberly Kegel-Gleason[4]
[1]Brigham and Women's Hospital, Boston, MA,[2]Northeastern University, Boston, MA,[3]Harvard University, Boston, MA,[4]Massachusetts General Hospital, Boston, MA

Background The goal of this study is to use the technology of focused ultrasound (FUS) to improve the delivery of gene therapies to the brain for the treatment of Huntington's disease. Pulsed FUS combined with systemically circulating microbubbles can achieve non-invasive, transient and spatially targeted opening of the blood-brain barrier (BBB) to facilitate delivery of normally non-penetrant agents into the brain. FUS is applied through the intact skull, can be focused to a region of only several millimeters, and can reach both cortical areas and sub-cortical structures. Gene therapies that knock down expression of the mutant Huntingtin protein are promising approaches to treat Huntington's disease. However, all gene therapies for brain disorders face the interrelated challenges of delivering the therapy across the BBB, and achieving an adequate therapeutic exposure at the targeted site while minimizing toxicity in healthy brain tissue and other organs. FUS-BBB opening may be an approach to improving the delivery of gene therapies over more invasive methods of intrathecal injection or direct neurosurgical injection currently used. **Methods** This study compares FUS-mediated delivery of an AAV9 capsid with green fluorescent protein (AAV9-GFP) in three mouse groups (N=6 per group): 2-month old wild type (WT) mice, 2-month old Q175 mice (mouse model of Huntington's disease), and 6-month old Q175 mice. FUS-BBB opening was targeted to the right striatum. Microbubbles were given by tail vein injection (Definity, 20 µL/kg) and FUS sonications were applied at 10 ms bursts and 1 Hz repetition frequency over 120 seconds. AAV9-GFP was given by tail vein injection immediately after FUS treatment (7.0e11 vg/mouse or ~2.8e10 vg/g) and contrast MRI images were acquired to quantify the extent of BBB disruption. Mice were sacrificed 3 weeks after treatment for immunohistochemistry. Brains were sectioned with Vibratome LEICA VT 1000 S and striatum sections were selected for fluorescent staining with GFP + [NeuN, GFAP, Iba1]. Sections were imaged using fluorescence microscopy and processed in MATLAB to quantify area of transfection. **Results** Figure 1 shows quantification of BBB opening based on contrast MRI images that are coregistered to a mouse brain template, converted to percent signal change and pixel values averaged over the full volume of striatum. One-way ANOVA indicates a significant main effect over the mouse groups ($F = 5.26$, $p = 0.019$, n=6 per group), with post-hoc comparison showing significant difference between WT and 2-month Q175 mice ($p = 0.015$) and a non-significant trend of difference between 2-month and 6-month Q175 mice ($p=0.14$). Figure 2 shows immunofluorescent imaging results from the first three mice in each group that have been processed to date. Significantly more GFP signal is seen in the FUS-targeted right

hemisphere compared to the non-targeted left hemisphere. Statistics to determine significant differences between mouse groups will be performed once all data sets are processed.



26 Liver-Specific Targeting CRISPR/Cas9 mRNA LNPs Achieve Long-Term FVIII Expression in Hemophilia A Mice

Chun-Yu Chen[1], Xiaohe Cai[1], Carol H. Miao[2]

[1]Seattle Children's Research Institute, Seattle, WA,[2]Seattle Children's Research Institute, Seattle, WA

Deficiency of X-linked factor VIII (FVIII) gene which participates in the intrinsic pathway of the coagulation cascade leads to a serious bleeding disorder, hemophilia A (HemA). Current treatment of HemA patients is routinely infused with FVIII protein several times every week as prophylactic treatment, which is costly and inconvenient. Gene therapy represents a very promising alternative treatment method. Combination of lipid nanoparticle (LNP) technology and CRISPR/Cas9 technique allow *in vivo* gene correction of the mutant FVIII. We aimed at optimizing *in vivo* delivery efficiency of mRNA encapsulated LNPs to repair the mutant FVIII gene and help HemA patients regain endogenous FVIII expression. Since FVIII protein is mainly and naturally made in liver sinusoidal endothelial cells (LSECs), we investigated various formulations of LNPs that can target LSECs. To examine the *in vivo* transfection efficiency of LSECs, we encapsulated luciferase (Luc) mRNA and GFP mRNA into MC3-based LNPs and delivered into mice, respectively. The efficacy of Luc mRNA LNPs and GFP mRNA LNPs was evaluated using *in vivo* imaging systems (IVIS) and immunofluorescent staining of the liver sections, respectively. Results suggested that this MC3-based LNP formulation can target both hepatocytes and LSECs *in vivo*. An immunodeficient hemophilia A (NSG HA) mouse model that contained frameshift-mediated premature stop codon in exon 1 of FVIII gene was used in this study. According to the *in vitro* gene editing data, we selected two efficient sgRNAs (mF8sgRNA and NSGHAsgRNA) for *in vivo* gene editing of mutant FVIII. We encapsulated Cas9 mRNA with each sgRNA into LNPs and intravenously deliver the LNPs to NSG HA mice, respectively. Endogenous FVIII activity was evaluated by aPTT assay and improvement of coagulation activity was examined by rotational thromboelastometry (ROTEM) assay. The Cas9 and FVIII-targeting sgRNAs LNP-treated NSG HA mice showed FVIII expression (1-7%) for more than 6 months. Moreover, we isolated the hepatocytes and LSECs from treated mice and the gene editing efficiencies of these two major liver cell types were verified by deep sequencing. The results showed that total percentages of frameshift mutation are 4.75% and 3.1% in hepatocytes and LSECs, respectively. Among all the frameshift mutations, percentages of one base deletion which can correct the frameshift-mediated nonsense mutation in NSG HA mice are 3.71% and 2.45% in hepatocytes and LSECs, respectively. All the data suggested that our LNP formulations can deliver mRNA into both hepatocytes and LSECs *in vivo*. Furthermore, combined with CRISPR/Cas9 technology, we have corrected the mutated FVIII gene in LSECs and regained the FVIII activity in NSG HA mice. This gene editing protocol shows the potential to persistently achieve therapeutic levels of FVIII gene expression for hemophilia A treatment.

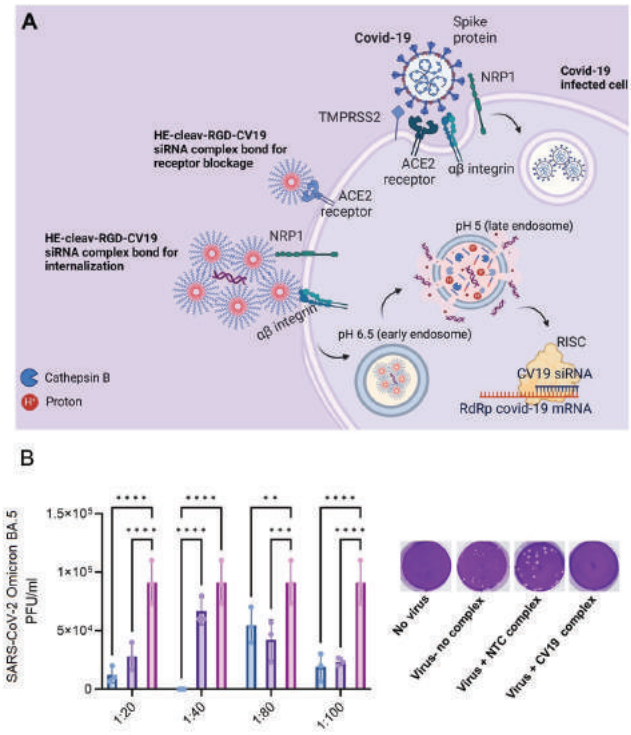
27 A Novel Multitargeted Peptide-siRNA Complex for Simultaneous Inhibition of SARS-CoV-2 Host Cell Entry and Intracellular Viral Replication

Martina Tuttolomondo[1], Stephanie Thuy Duong Pham[1], Mikkel G. Terp[1], Niels Langkjær[2], Christina Baun[2], Helge Thisgaard[2], Yaseelan Palarasah[1], Henrik Ditzel[1]

[1]Department of Cancer and Inflammation Research, University of Southern Denmark, Odense C, Denmark,[2]Department of Nuclear Medicine, Odense University Hospital, Odense C, Denmark

Although several successful vaccines have been developed against SARS-CoV-2, responsible for the COVID-19 pandemic, novel variants develop quickly and escape the vaccine protection while an effective and specific SARS-CoV-2 inhibitor is still missing. A promising approach is to silence a viral mRNA by administering a siRNA against the RNA-dependent RNA-polymerase (RdRp). Due to their limited blood stability and intracellular bioavailability, siRNA molecules must be combined with a vehicle. Cell-penetrating peptides are flexible vehicles that can be designed to allow spontaneous siRNA encapsulation and specific receptor binding. Peptides containing the RGD moiety interact with integrins and have been employed to target cancer cells. SARS-CoV-2 primarily enters the host cells by the interaction of viral spike protein with human angiotensin-converting enzyme 2 (ACE2). Moreover, human neuropilin-1 (NRP1) and some human integrins are also involved in the virus cell entry. We designed a novel RGD-containing self-assembling peptide (HE-cleav-RGD) to block SARS-CoV-2 by a combination of mechanisms (Figure 1A). The peptide interacted *in vitro* with recombinant viral spike receptor binding domain (spike RBD), human ACE2, human neuropilin-1, and spike-binding human integrins ITGAV and ITGA2. Moreover, the interaction of spike RGB with ACE2, ITGAV, and ITGA2 was displaced by the addition of HE-cleav-RGD. Furthermore, HE-cleav-RGD spontaneously encapsulated siRNA and protected its RNase degradation in serum. In Vero cells, GAPDH siRNA-HE-cleav-RGD complex allowed efficient GAPDH silencing in a dose-dependent manner that was inhibited by the addition of chlorpromazine (chlatrin inhibitor) and dynasore (dynamin inhibitor), suggesting that complex uptake occurs by receptor-mediated endocytosis. Further, immunocytochemical staining of Vero cells revealed colocalization of a fluorescent siRNA-HE-cleav-RGD complex with ITGAV, suggesting that the internalization was triggered by integrin binding. Finally, an

RdRp-targeting COVID-19 siRNA was complexed with HE-cleav-RGD and administered to Vero cells infected with ancestral or omicron BA.5 SARS-CoV-2. Plaque assay revealed that non-targeting siRNA complexed with HE-cleav-RGD (NTC siRNA-HE-cleav-RGD) allowed partial SARS-CoV-2 replication due to the inhibition of SARS-CoV-2 cell entry by the peptide. When HE-cleav-RGD is combined with an RdRp-siRNA (COVID-19 siRNA-HE-cleav-RGD), up to 100% inhibition of viral replication was observed at a siRNA-peptide molar ratio 1:40 (Figure 1B). Interestingly, SPECT scan of mice administered with I^{125}-labelled HE-cleav-RGD peptide revealed substantial lung accumulation. Altogether, our results suggest that HE-cleav-RGD peptide may be employed to develop promising anti-COVID-19 therapeutics.



28 Isolation of Natural and Biologically Active EV-AAVs for Brain Gene Delivery

Carina Henriques[1], Miguel Lopes[1], Patricia Albuquerque[1], David Rufino-Ramos[1], Laetitia Gaspar[1], Diana Lobo[1], Ana Carolina Silva[1], Rafael Baganha[1,2], Sónia Duarte[1], Casey A. Maguire[3], Magda Santana[1], Luis Pereira de Almeida[1,2,4], Rui Jorge Nobre[1,2,5]

[1]Center for Neuroscience and Cell Biology, Coimbra, Portugal,[2]ViraVector–Viral Vector for Gene Transfer Core Facility, University of Coimbra, Coimbra, Portugal,[3]The Massachusetts General Hospital, Charlestown, MA,[4]Faculty of Pharmacy, University of Coimbra, Coimbra, Portugal,[5]5Institute for Interdisciplinary Research (III), University of Coimbra, Coimbra, Portugal

Adeno-associated viral (AAV) vectors are one of the preferred options for delivering genes to the central nervous system (CNS). Recent studies have shown that they can also be secreted along with extracellular vesicles (EVs) during production. This combination, known as EV-AAVs, improves AAV transduction in various organs, including the brain. This is due to the fact that EVs are naturally formed cell vesicles that can transport biomolecules and circulate without being targeted by the immune system. Despite the remarkable results obtained in previous reports, only AAV serotypes with already known ability to cross the blood-brain barrier have been used.In this work, we aimed at developing a size exclusion chromatography (SEC) protocol for the isolation of natural and biologically-active EV-AAVs from any AAV serotype for non-invasive gene delivery to the CNS. We also sought to compare EV-AAVs isolated by differential centrifugation (UC) and SEC. The EV-AAVs were produced following the standard protocol for AAV production and subsequently isolated by UC and SEC. Characterisation was performed by western blotting, nanoparticle tracking analysis (NTA), qPCR and transmission electron microscopy (TEM), while infectivity was evaluated *in vitro* and *in vivo.*The results indicated that SEC provides a higher recovery of natural EV-AAVs compared to UC (about four times higher), free from cell-contaminating proteins and with fewer solo AAVs. The SEC-purified EV-AAVs were also more infectious *in vitro* than solo AAVs. Upon intravenous injection in mice, SEC-purified EV-AAVs were able to cross the blood-brain barrier and the blood-cerebrospinal fluid barrier without AAV's contribution, and to successfully transduce mouse brains.In conclusion, SEC-purified EV-AAVs have the potential to be an effective gene delivery vector for the treatment of brain disorders.

29 Shuttle Peptides-Mediated Local RNP Delivery of Editing Complex in the Sensory Organs of the Inner Ear and Retina *In Vivo* in Adult Mice

Wan Du[1], Xue Cheng[2], Qin Liu[3], Wei Wei[1], Rossano Butcher[3], David Guay[2], Zheng-Yi Chen[1]

[1]Department of Otolaryngology-Head and Neck Surgery, Harvard Medical School/Massachusetts Eye and Ear, Boston, MA,[2]Feldan Therapeutics, Quebec, QC, Canada,[3]Department of Ophthalmology, Harvard Medical School/Massachusetts Eye and Ear, Boston, MA

Genetic hearing loss and blindness are prevalent with limited treatment options. Despite the tremendous progress in the development of editing therapy for hearing loss and blindness, the ability to deliver the editing complex into the inner ear and retina remains the major challenge to realizing the potential. For viral vectors, issues like immunogenicity, genome integration and long-term effect remain a safety concern. In addition, with the more complex editing strategies including base editing and prime editing, multiple components need to be packaged into multiple AAVs, further limiting their efficiency. We have developed an amphiphilic S10 shuttle peptide and demonstrated delivery efficiency of CRISPR-associated nuclease ribonucleoprotein (RNP) to the respiratory tract of mice. In this study, we screened additional peptides of different charges and lengths to evaluate the application of shuttle peptides to deliver editing RNP complex into the sensory organs of the inner ear and retina in adult mice by local injection *in vivo*. The shuttle peptide-RNP formulation was delivered locally into the inner ear through the round window membrane (RWM) and retina by subretinal injection in adult Ai14 mice with tdTomato (tdT)

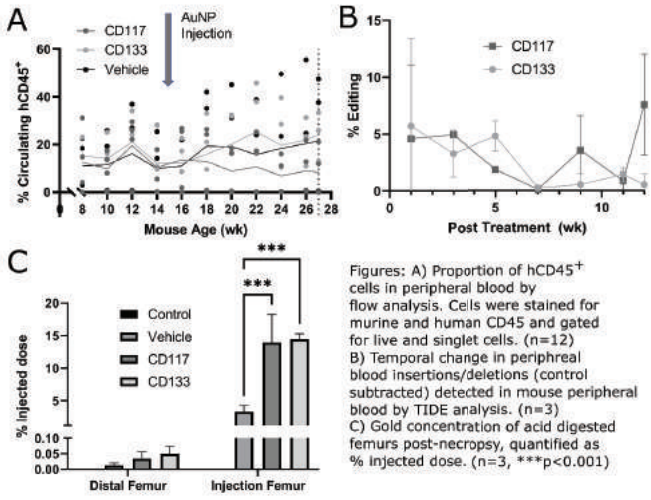
reporter. We identified shuttle peptides capable of RNP delivery into multiple inner ear sensory epithelial cell types and retinal cells with efficient editing. In the inner ear, the shuttle peptides mediated efficient delivery and editing in the supporting cell subtypes throughout the entire cochlear turn. Damage to outer hair cells was detected as a result of the delivery. In the retina, the shuttle peptides mediated efficient delivery and editing in the retinal pigment epithelial (RPE) cells and Muller cells, including those at a distance from the injection site. Muller cells at the injection site were also edited after injection. Using a shuttle peptide mixed with fluorescent cargo Cy5-NLS for the delivery into the inner ear, we detected Cy5 labeling in the majority of inner ear sensory epithelial cell types in adult mice, suggesting further modifications may target more inner ear cell types. The identification of shuttle peptides capable of efficient *in vivo* RNP delivery of editing agents in the mature mammalian inner ear and retina opens a new avenue to develop editing therapy for human hearing loss and blindness.

30 Hematopoietic Stem and Progenitor Cell Specific Antibodies and Intraosseous Administration Enhance Delivery of a CRISPR Nanoformulation

Reza Shahbazi[1,2], Daniel Douglas Lane[1], Patricia Lipson[1], Karthikeya Gottimukkala[1,3], Rachel Cunningham[1,3], Molly Ellena Cassidy[1], Youngseo Jwa[1], Jennifer E. Adair[1,3]

[1]Translational Science and Therapeutics, Fred Hutchinson Cancer Center, Seattle, WA,[2]Indiana University School of Medicine, Indianapolis, IN,[3]Department of Laboratory Medicine and Pathology, University of Washington, Seattle, WA

Hematopoietic stem and progenitor cells (HSC) have been a target for CRISPR gene editing (CGE) to treat multiple diseases. State of the art for HSC CGE occurs *ex vivo*, however, these methods remain challenging for global dissemination. *In vivo* delivery of CGE could facilitate global access but is inhibited by the rare and diffuse composition of HSC throughout the bone marrow niche. We previously described a layered gold nanoformulation to deliver CRISPR *in vitro* without electroporation (CR-AuNP)[1]. Here we sought to test this CR-AuNP *in vivo* in a humanized murine model of hematopoiesis[2]. One method to access HSC *in vivo* is to administer mobilizing agents, which reversibly increase HSC concentrations in peripheral blood. Initial experiments in mice (n=3) showed no toxicity associated with a single intravenous injection of CR-AuNP under mobilization, but only transient CGE (5.0 ± 2.5%) in peripheral blood leukocytes at 2 weeks after administration. To improve HSC-specific editing, we designed actively targeted CR-AuNPs, consisting of a conjugated targeting moiety. Optimal HSC targeting moieties were selected by winnowing a set of 22 known antibodies, aptamers and ligands for observed internalization by confocal microscopy within 1 hour of addition to primary human CD34$^+$ HSC. Three antibodies (αCD133:7, αCD117:104D2 and αCD90:5E10), two known aptamers (A15, B19), and one ligand (SCF) were identified for further testing. Whole bone marrow from six biological replicates was analyzed by flow cytometry to determine moiety specificity. αCD133 and αCD117 showed the highest specificity of 56.9 ± 7 and 66.4 ± 1% of CD34$^+$/CD38$^-$ cells, respectively, vs. 6.87 ± 0.25 and 1.17 ± 0.18% of total CD34$^-$ cells and were then loaded onto CR-AuNP via electrostatic binding. The resulting particle had a hydrodynamic diameter of 114.3 nm with a polydispersity index of 0.147 by dynamic light scattering. These particles were injected intraosseously into one femur of humanized mice (n=12), to increase local concentration within the bone marrow. Mice did not show any signs of toxicity by weight measurements or behavior by daily visual inspection. αCD117-CR-AuNP resulted in peripheral blood CGE of 4.6 ± 6.5% at week 2 as measured by Sanger sequencing and TIDE analysis, which persisted to 7.55 ± 4.5% at 12 weeks post injection (Figure B). Gold tracing by inductively-coupled plasma mass spectrometry at necropsy showed 14.2 ± 0.81% of Au dose within the injected femur ($p<0.001$ over bare AuNP control), with enhanced retention of targeted CR-AuNP in the distal femurs (Figure C). This data suggests CR-AuNP is well-tolerated *in vivo*, active targeting and intraosseous injection increases bone marrow retention, and this combination is associated with persistent CGE of peripheral blood leukocytes up to 12 weeks after administration in humanized mice.



Figures: A) Proportion of hCD45$^+$ cells in peripheral blood by flow analysis. Cells were stained for murine and human CD45 and gated for live and singlet cells. (n=12) B) Temporal change in peripheral blood insertions/deletions (control subtracted) detected in mouse peripheral blood by TIDE analysis. (n=3) C) Gold concentration of acid digested femurs post-necropsy, quantified as % injected dose. (n=3, ***p<0.001)

31 NHEJ Gene Editing of Hemophilia A Mice Show Therapeutic Levels of FVIII Following Ultrasound Mediated Gene Delivery of CRISPR/Cas9 Plasmid

Savannah M. Lawton[1], Meng-Ni Fan[1], Ting-Yen Chao[1], Chun-Yu Chen[1], Ellen Xu[1], Xiaohe Cai[1], Carol H. Miao[2]

[1]Seattle Children's Research Institute, Seattle, WA,[2]Seattle Children's Research Institute, Seattle, WA

Hemophilia A (HA) is a blood coagulation disorder, where an individual does not produce functional factor VIII (FVIII) protein. Treatment of this disease relies on repeated injections of FVIII, which is both costly and inconvenient for the patient. Correction of the mutation responsible for HA through CRISPR/Cas9 gene editing is a potentially permanent rescue of FVIII protein production that could avoid multitudinous treatments. We have previously

demonstrated that ultrasound mediated gene delivery (UMGD) can be a safe and effective non-viral method of targeting liver sinusoidal endothelial cells (LSECs), the native production site of FVIII, *in vivo*. In this study, we investigated the efficacy of combined ultrasound and microbubbles to successfully deliver CRISPR/Cas9 plasmids to HA mice for restoration of FVIII through gene editing. For the gene editing animal model, we used immunodeficient HA (NSG HA) mice with a 5 base pair deletion in FVIII exon I. RN18 microbubbles (MBs) and Cas9 plasmid containing an exon 1 targeting sgRNA (mF8sgRNA) were injected into the mouse portal vein for 30s, while simultaneously a pulsed, therapeutic ultrasound (US) transducer at 1.1 MHz frequency and 14 Hz PRF treated the liver surface for 60 s at 50 W, 150 µs PD. This US condition has previously been demonstrated to predominantly transfect LSECs. The FVIII activity was determined via the aPTT assay at various timepoints over 90 days, and whole blood clotting was evaluated via ROTEM. Livers were sectioned, stained, and imaged to examine production of FVIII mRNA using RNAscope© Multiplex Fluorescent staining assay. Successful gene editing was verified by DNA sequencing. Factor VIII activity levels for treated NSG HA mice, n=7, averaged 5% over 90 days (Figure 1). Increased production of FVIII mRNA was detected in the liver sections of treated mice compared to untreated naïve mice, in addition to colocalization of FVIII and Lyve-1 (LSEC marker) signals indicating targeting of LSECs. The ROTEM assay showed an improvement in clotting time and clot formation time (Figure 2), signifying therapeutic correction of the severe HA phenotype. DNA sequencing confirmed successful induction of indels with an editing efficiency of approximately 4.3%. UMGD successfully delivered a CRISPR/Cas9 plasmid to livers of NSG HA mice to induce a mutation in the target site, resulting in therapeutic levels of FVIII expression. This indicates UMGD is a potentially effective non-viral technique for delivering gene editing tools *in vivo* for the treatment of HA.

Figure 1. NSG HA mice treated with UMGD had hFVIII activity levels of approximately 5% over 90 days

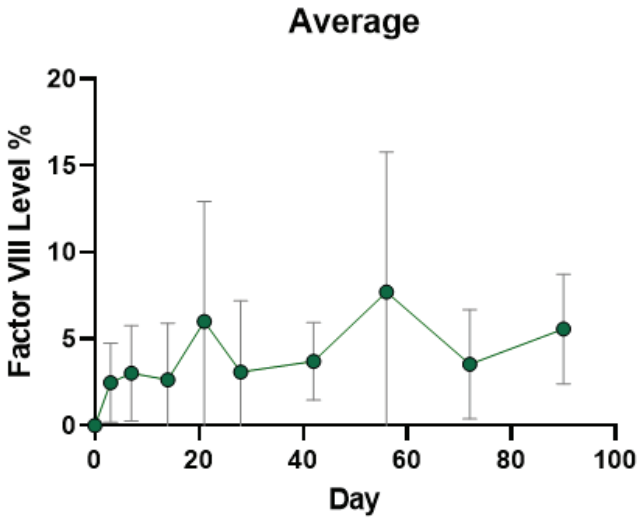

Figure 2. ROTEM blood clotting assay done in wild type BL6 mouse, untreated NSG HA mouse and UMGD treated NSG HA mouse displaying clotting time (CT) and clot formation time (CFT)

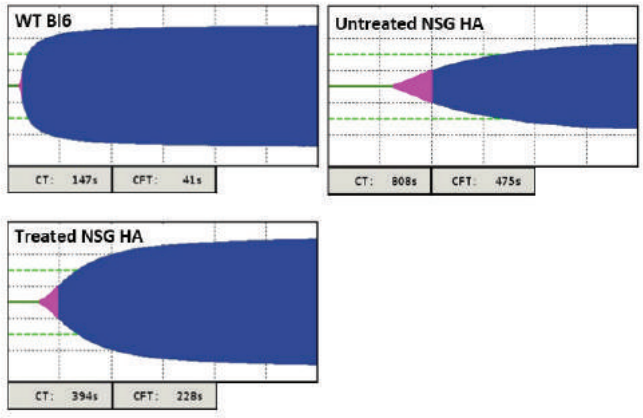

Epi-/Genetic Editing and New Methods to Target the Nervous System

32 Zinc Finger Transcriptional Regulator Mediated Repression of *SCN9A* as a Therapeutic Approach for Painful Peripheral Neuropathies

Mohammad Samie, Toufan Parman, Mihika Jalan, Jisoo Lee, Patrick Dunn, Jason Eshleman, Josh Holter, Sarah Hinkley, Alicia Goodwin, Dianna Vidales, Dan Chung, Luke Workley, Kenneth Kennard, David Ojala, Matt Tiffany, Sandeep Yadav, Bryan Zeitler, Jason Fontenot, Amy Pooler

Sangamo Therapeutics, Inc., Richmond, CA

Painful peripheral neuropathies are caused by severe and permanent damage to peripheral sensory or motor neurons and are estimated to affect several million patients in the US alone. Given the high unmet need and lack of effective treatments, there is an urgent need to develop novel therapeutics for the treatment of chronic painful peripheral neuropathies. The voltage-gated sodium channel Nav1.7, encoded by the *SCN9A* gene, is involved in a spectrum of inherited human pain disorders. Loss or gain of function mutations in *SCN9A* result in insensitivity or hypersensitivity to pain, respectively, highlighting the central role of Nav1.7 in pain transmission to the brain. Development of selective and efficacious Nav1.7 inhibitors has been challenging due to similarities in protein sequence and structure among the Nav channels. We hypothesized that lowering Nav1.7 via selective repression of the *SCN9A* gene using engineered zinc finger repressors (ZF-Rs) would reduce the expression of Nav1.7, and therefore reduce neuropathic pain. To evaluate the feasibility of this approach, ZF-Rs specifically targeting the mouse *Scn9a* gene were designed and assessed *in vivo* in a neuropathic pain spared never injury (SNI) mouse model. AAV-mediated ZF-R delivery resulted in up to 70% bulk repression of *Scn9a* in mouse dorsal root ganglion (DRG) tissue. *Scn9a* repression was associated with significant reduction in pain one month post-treatment as measured by increased mechanical and cold allodynia threshold in the SNI model of neuropathic pain. The repression of *Scn9a* was

not associated with neuroinflammation or neuronal loss in DRGs. To identify human ZF-R candidates, a library containing more than 300 ZF-Rs targeting the human *SCN9A* gene was designed and screened in human neuronal cells lines. Lead ZF-Rs were packaged into AAV and tested in human iPSC-derived GABAergic and iPSC-derived sensory neurons *in vitro*. We identified ZF-Rs that repressed *SCN9A* by more than 90% over a wide dose range with no detectable off-target activity as measured by global transcriptome analysis, including selective repression of Nav1.7. Candidate human ZF-Rs are being evaluated for pharmacology and safety in nonhuman primates. Taken together, our results support the development of AAV-delivered ZF-Rs for the treatment of painful chronic neuropathic indications.

33 Delivery of BDNF through a Pluripotent Stem Cell-Based Platform Ameliorates Behavioral Deficits in a Mouse Model of Huntington's Disease

Sridhar Selvaraj[1], Danielle A. Simmons[2], Tingshuo Chen[2], Gloria Y. Cao[2], Talita S. Camelo[2], Tyne L. M. McHugh[2], Selena Gonzalez[2], Renata M. Martin[1], Juste M. Simanauskaite[2], Nobuko Uchida[3], Frank M. Longo[2], Matthew H. Porteus[1]

[1]Pediatrics, Stanford University School of Medicine, Stanford, CA,[2]Neurology and Neurological Sciences, Stanford University School of Medicine, Stanford, CA,[3]ReGen Med Division, BOCO Silicon Valley, Palo Alto, CA

Huntington's disease (HD) is a life-threatening neurodegenerative disease that occurs due to an autosomal dominant mutation of CAG trinucleotide repeat expansion beyond 35 repeats in exon 1 of the Huntingtin (*HTT*) gene. The expanded CAG repeats encode for a mutant HTT with an abnormally long polyglutamine tract. This mutant HTT forms toxic aggregates in the brain which inhibit neuronal function and survival to cause neurodegeneration. Striatal medium spiny neurons (MSN) are the most affected and neuronal subpopulations of the cerebral cortex are affected to a lesser extent. Current treatments for HD are only palliative and do not stop or reverse the neurodegeneration. Studies in animal models have shown that viral vector or cell-based delivery of secretory neuroprotective (NP) factors ameliorates HD-associated neurodegeneration. However, host immunity against viral vectors and transplanted allogeneic or xenogeneic cells poses a significant barrier for clinical translation of this approach. To address this, a pluripotent stem cell (PSC)-based delivery platform could be utilized due to the feasibility of deriving large scale therapeutically relevant non-immunogenic autologous cell types. The goal of this study is to test the feasibility of using a PSC-based platform to deliver NP factors in the brain to treat HD. Here, we have tested the therapeutic potential of delivering BDNF and NT-3 NP factors using a PSC-based platform in the R6/2 HD mouse model. For this, we have used a previously generated H9 embryonic stem cell line expressing a rapamycin-inducible safety switch transgene. For the expression of NP factors, we performed gene targeting in PSC at the HBB locus, a safe harbor for neural cell types. For this HBB gene targeting, we used gene editing with Cas9 ribonucleoprotein (RNP) and AAV6 based homology directed repair donor template delivery to express NP factors from a constitutive promoter. Post-gene editing, we isolated single cell PSC clones with bi-allelic gene targeting of BDNF, NT-3 and confirmed the protein secretion *in vitro*. Using previously described differentiation protocols, we derived neural and striatal progenitors from the gene edited PSC for the delivery of NP factors in the brain. To assess the therapeutic potential, we performed intra-striatal transplantation of the PSC derived neural and striatal progenitors in the R6/2 HD mouse model following antibody-based immunosuppression. Post-transplantation, motor and cognitive functions were assessed through nest building, rotarod, marble bury, open field and social memory behavior tests. Neural progenitors with and without NT-3 expression ameliorated deficits in some of the behavior tests when compared to the vehicle injected R6/2 mice. Neural progenitors expressing BDNF significantly ameliorated the deficits in all the behavior tests indicating improved motor and cognitive functions. Striatal progenitors expressing BDNF moderately ameliorated various behavioral deficits. Upon histology analysis, we found that the transplanted neural and striatal progenitors can differentiate into post-mitotic neurons expressing NeuN marker *in vivo*. Importantly, we have validated the feasibility of activating the safety switch to eliminate the transplanted cells in the brain following intraperitoneal injection of rapamycin. Thus, delivery of BDNF through PSC derived neural progenitors could an effective therapeutic intervention for HD and the applicability of safety switch enhances the safety of this approach.

34 RNA Editing Therapy in a Humanized Mouse Model of MECP2 Duplication Syndrome and Non-Human Primates

Xiaoqing Wu[1], Dong Yang[1,2], Linyu Shi[1], Hui Yang[1,2]

[1]HuidaGene Therapeutics Co., Ltd., Shanghai, China,[2]Center for Excellence in Brain Science and Intelligence Technology, Chinese Academy of Sciences, Shanghai, China

Background: MECP2 duplication syndrome (MDS) is a rare, fatal childhood neurodevelopmental disorder with progressive neurological regression such as loss of motor skills and speech, predominantly affecting boys and accounting for about 1% of X-linked cases of intellectual disability. MDS is caused by the duplication of the methyl-CpG binding protein 2 (*MECP2*) gene which locates at the chromosome Xq28. To date, there is no effective treatment for this devastating disease. **Methods**: We tested the treatment efficacy of AAV delivering the system of high-fidelity Cas13Y (hfCas13Y, a high-efficiency and high-fidelity RNA editor) and gRNAs targeting MECP2 (gMECP2) (AAV-hfCas13Y-gMECP2), in postnatal day 0-1 male humanized MDS mice (from the Jackson Laboratory) via intracerebroventricular (ICV) injection (Fig. 1A). Additionally, we validated the knockdown efficiency of *MECP2* in the brain of wild-type non-human primates (NHPs) via ICV administration of AAV-hfCas13Y-gMECP2 (Fig. 1H). The behavioral tests were performed in humanized MDS transgenic mice injected with AAV-hfCas13Y-gMECP2 and their controls, including accelerating rotarod, open field, elevated plus maze, and 3-chamber social tests. **Results**: The hfCas13Y and *MECP2* gRNAs were stably expressed in brain regions of mice and monkeys where the pathological changes of MDS mainly occur. Furthermore, the expression of MECP2 was knocked down to 40-60% and almost reversed to the normal level (wild-type mice level) in the brain of humanized MDS mice (Fig. 1B,C). Importantly, the accelerating rotarod shows that the prolonged latency to fall from the rotating rod decreased in AAV-hfCas13Y-gMECP2

treated MDS mice (Fig. 1D). The open field test shows that the MDS mice displayed reduced exploratory behavior, which could be rescued by the treatment of AAV-hfCas13Y-gMECP2 (Fig. 1E). Moreover, the elevated plus maze test shows that the anxiety-like behavior of MDS mice was increased compared with wildtype (WT) mice, and it could be reversed to normal level (WT mice) by the administration of AAV-hfCas13Y-gMECP2 (Fig. 1F). In the 3-chamber social test, the MDS mice showed less communication behaviors, which could be rescued to normal level by the treatment of AAV-hfCas13Y-gMECP2 (Fig. 1G). Similar to the humanized MDS mice and in the brain of monkeys, the MECP2 knockdown efficiency was more than 20 % in 40 % brain regions, and among which the highest one reaches 70% compared with the control (Fig. 1I). In addition, there was no *in vivo* toxicity (including nerve, liver, and kidney injury) observed in the humanized MDS mice and monkeys injected with the high dose of AAV-hfCas13Y-gMECP2 administration. **Conclusions:** Since the AAV we used is able to cross the blood-brain barrier and to infect neurons efficiently, our findings provide a strong foundation and promising approach for the clinical application of AAV delivering hfCas13Y-gMECP2 in MDS, which may potentially improve the motor and behavioral impairment in patients with MDS.

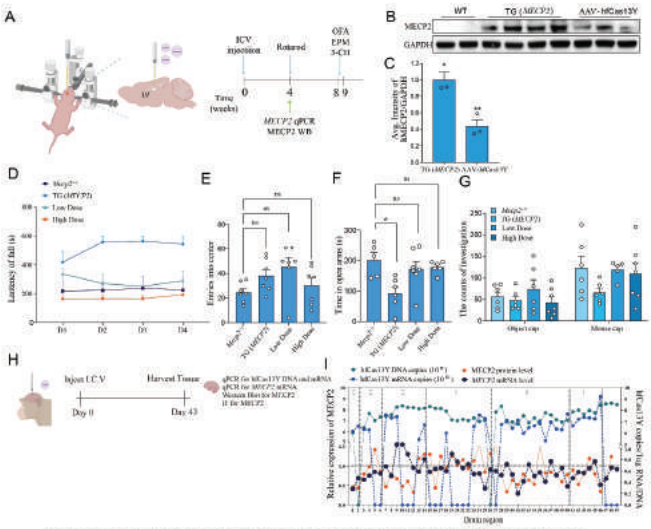

Figure 1. The treatment effect of AAV-hfCas13Y-gMECP2 in the male humanized MDS mice and the WT monkey

35 The Interplay between Central Nervous System and Peripheral Organs: The Lesson from the Treatment of Canavan Disease with rAAV Gene Therapy

Jie Wang[1], Anoushka Lotun[1], Danning Li[1], NhatAnh B. Nguyen[1], Morgan Mooney[1], Guangping Gao[1,2], Dominic J. Gessler[1,2]

[1]Horae Gene Therapy Center, UMass Chan Medical School, Worcester, MA,[2]Co-corresponding author, Worcester, MA

Mutations in the Aspartoacylase (ASPA) gene lead to a lethal neurodegenerative condition called Canavan disease (CD), which is characterized by progressive neurodegeneration with dysmyelination and accumulation of N-acetylaspartate (NAA), the only substrate of ASPA in oligodendrocytes. In the CD knock-out (KO) mouse model, with the most severe disease pathology and early death at around postnatal day (P) 27, we previously showed complete disease prevention with systemic delivery of ASPA by recombination adeno-associated virus 9 (rAAV9ASPA). However, central nervous system (CNS)-restricted gene therapy by intracerebroventricular (ICV) injection could not completely prevent the phenotypes compared to those with intravenous (IV) treatment despite similar brain biomarkers in both groups and equivalent ASPA enzyme activity. Therefore, we hypothesized that peripheral organs, such as liver, could mediate this effect. We used neuro-metabolomics and transcriptomics to explore this connection to analyze the brain and peripheral organs (serum) in WT and CD mice. Two key findings were the elevation of ketone body β-hydroxybutyrate (bOHB) and several inflammation markers in the CNS. We hypothesized that treatment of peripheral organs might modulate CNS metabolism and immunopathology. To test this hypothesis, we treated neonatal CD KO mice with rAAV9ASPA with cell-type specific promoters: neurons, astrocytes, oligodendrocytes, heart, liver, and skeletal muscle. To our surprise, mean overall survival was substantially improved in the liver-restricted group without normalized brain NAA levels. Interestingly, despite liver-restricted restoration of ASPA protein, the liver function was only partially rescued, i.e., bOHB pathway, compared to the wildtype mice, suggesting that extrahepatic factors contribute to the biochemical liver profile. Due to bOHB's known function in epigenetic regulation, we next tested if bOHB modulates histone modifications in the CNS and found that liver-restricted ASPA expression normalized several histone modifications by bOHB and acetyl-CoA in the brain and liver - a finding we are currently investigating. bOHB and epigenetic mechanisms are important modulators of the immune response, and our transcriptomics data indicated differential expression of several genes in the CNS immune response. Furthermore, interrogation of several of these genes showed that liver-restricted expression changed some proteins profiles in the brain, suggesting that liver treatment has CNS immune modulatory effects that might modulate the disease progression favorably In sum, this study provides novel insight into the disease-modifying role of peripheral organs on CNS pathology in Canavan disease rAAV gene therapy through biochemical and immunomodulating function with possible implications for other CNS-targeting gene therapies.

36 Gene Editing Strategies to Treat Spinocerebellar Ataxia Type 1

Kelly Fagan[1], Ellie Carrell[2], Beverly L. Davidson[2]

[1]University of Pennsylvania, Philadelphia, PA,[2]Children's Hospital of Philadelphia, Philadelphia, PA

Spinocerebellar ataxia type 1 (SCA1) is an autosomal dominant neurodegenerative disease that causes progressive loss of motor coordination, respiratory issues and eventual death. SCA1 is caused by expansion of the polyglutamine repeat region in the ATXN1 gene. Although mATXN1 is expressed ubiquitously, it affects primarily Purkinje cells (PCs). There are currently no treatment options for SCA1. We hypothesize that CRISPR-Cas editing of ATXN1 will reduce mutant ATXN1 and be therapeutically beneficial For Cas9, we designed two different strategies to reduce ATXN1; the first uses a single guide RNA (gRNA) to target near the exon-exon junction to induce nonsense mediated decay and the second approach employs a dual guide system to delete the CAG repeat region. In

cultured cells, the single guide approach reduced ATXN1 mRNA levels by 40-45% ($p \leq 0.02$) and protein by approximately 20% ($p \leq 0.01$) and the dual guide approach reduced levels of mRNA and protein levels by 70-75% ($p < 0.001$) and 45-65% ($p \leq 0.03$), respectively. For the dual guide strategy, DNA editing assessed by Sanger sequencing confirmed full length deletions at the expected size in vitro. For testing in vivo, SCA1 mice, expressing mutant human ATXN1 were injected with recombinant AAVs (rAAVs) expressing the optimized gRNAs from each strategy and spCas9. The viruses were co-delivered into neonatal mice with an intracerebroventricular injection for transduction of PCs. Both the exon-exon strategy and the dual guide strategy reduced mRNA ATXN1 levels by 55% ($p < 0.001$) and 40% ($p < 0.001$), respectively, compared to saline injected controls. Oxford Nanopore sequencing after in vivo delivery confirmed full length deletions. Further analysis is underway to more fully define the editing events and to assess the efficacy of the single and dual guide editing approaches on mice behavior and neuropathological readouts. In another strategy, we developed approaches for CRISPR-based RNA knock down using RfxCas13d. RfxCas13d is an RNA specific nuclease that binds to target mRNA and cleaves the sequence complementary to the gRNA. RfxCas13d guides designed to target ATXN1 transcripts reduced ATXN1 mRNA by 50% ($p < 0.001$) in cells and in short term pilot studies in B05 mice, reduced ATXN1 mRNA by 10% reduction ($p = 0.001$). Cumulatively, our work contrasts and compares several editing strategies for reduction of ATXN1 for SCA1 therapy.

37 Single-Cell RNA-Sequencing to Evaluate rAVV Transduction in the CNS and Its Therapeutic Implications for Canavan Disease Gene Therapy

Jie Wang[1], Peiyi Guo[1], Alper Kucukural[2], Elisabet C. Mandon[1], Guangping Gao[1,3], Dominic J. Gessler[1,3]

[1]Horae Gene Therapy Center, UMass Chan Medical School, Worcester, MA,[2]Department of Bioinformatics and Integrative Biology, UMass Chan Medical School, Worcester, MA,[3]Co-corresponding author, Worcester, MA

Gene therapy using recombinant adeno-associated virus (rAAV) vectors has rapidly emerged as one of the leading approaches for treating various inherited disorders of the central nervous system (CNS). Although the successful use of rAAV-based gene therapy in clinical trials are promising, two central questions remain poorly understood. 1) How effective are different cell types transduced via intravenous delivery in the CNS? and 2) Do successfully transduced cells exert therapeutic benefits on untreated cells in the CNS? We used Canavan disease (CD) as a model system to narrow this knowledge gap. CD is a lethal leukodystrophy caused by mutations in the ASPA gene, which encodes the enzyme aspartoacylase (ASPA). ASPA is mainly expressed in oligodendrocytes in the brain, metabolizing N-acetylaspartate (NAA) into L-aspartate and acetate. First, using the CD knock-out (CD KO) mouse model, mice treated intravenously at neonatal age with rAAV9-based gene therapy that we previously demonstrated can completely prevent the disease. Mice were sacrificed several weeks later to determine rAAV transduction and therapeutic efficacy in cellular resolution. We used a modified protocol to successfully isolate cells from the brains of treated (Tx), untreated (UT), and wild-type (WT) control mice and performed single-cell RNA-sequencing (scRNA-seq). In detail, we obtained 62,538 cells (WT: 18,155; CD-UT:20,297; CD-Tx:24,096) in total, with a mean 1906 transcripts detected per cell, using the 10X Genomics Chromium platform. With Seurat analysis, all of the primary cell types of the brain were captured on the Uniform Manifold Approximation and Projection (UMAP) plots, including excitatory neurons, inhibitory neurons, astrocytes, oligodendrocytes, microglia, endothelial cells, fibroblasts. Further analysis revealed that all major cell types are successfully transduced and transcribed ASPA, including oligodendrocytes in the CD-Tx group. Moreover, we compared the differences between oligodendrocytes with or without transgene expression and the differences for each cell type among the WT, UT, and Tx groups to understand the functional consequences of ASPA transduction. This analysis allowed us to 1) reveal the transcriptomic differences for each cell type in the brain between WT, UT, and Tx groups, providing insight into the molecular mechanisms underlying CD; 2) "visualize" the therapeutic response to rAAV9-based gene therapy, and 3) assess the safety of this therapeutic approach by characterizing microglial response to rAAV9 and 4) demonstrating the transduction efficacy of rAAV9. Together, this study provides a comprehensive preclinical assessment of rAAV9 in the CNS after neonatal delivery and highlights the therapeutic relevance for Canavan disease, which could provide further insight to overcome the challenges of CNS-directed rAAV gene therapy.

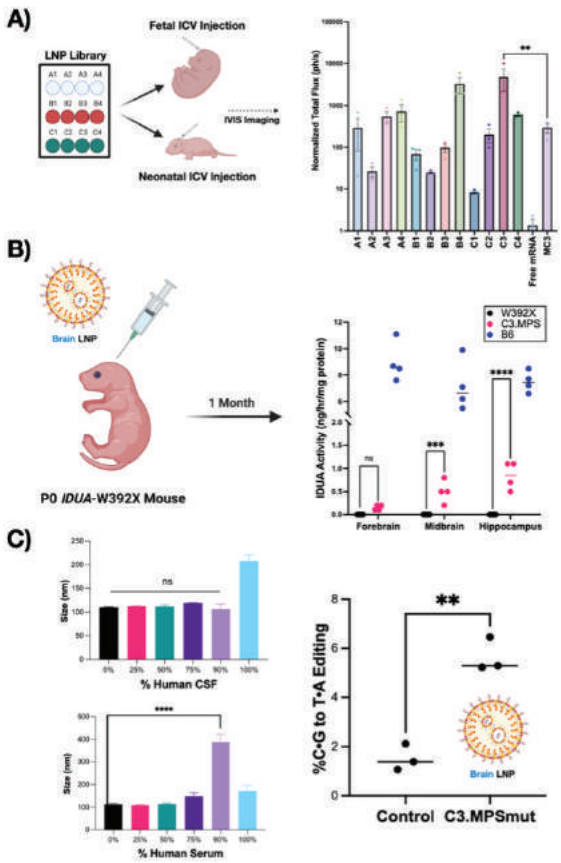
38 Ionizable Lipid Nanoparticles for Therapeutic Base Editing of Congenital Brain Disease

Rohan Palanki[1], Sourav Bose[2], Apeksha Dave[3], Valerie L. Luks[1], Michael Mitchell[1], William Peranteau[4]

[1]University of Pennsylvania, Philadelphia, PA,[2]Children's Hospital of Philadelphia, Philadelphia, PA,[3]CHOP, Columbus, OH,[4]The Children's Hospital of Philadelphia, Philadelphia, PA

Introduction: Congenital neurologic diseases affect 1% of children at birth and account for 40% of pediatric hospitalizations. Editing the genome perinatally and correcting pathogenic mutations prior to disease onset represents a novel therapeutic strategy that could reduce neurodevelopmental symptoms associated with these disorders. A key challenge for translation of mRNA-based gene therapies is safe and effective intracellular delivery. While ionizable lipid nanoparticles (LNPs) are efficacious, biocompatible nucleic acid delivery vehicles, LNPs have not yet been engineered specifically for the delivery of nucleic acids to the perinatal brain environment. Here, we screened a diverse library of LNPs *in vivo* to target the fetal and neonatal mouse brain, optimized LNPs in cells of neural origin *in vitro*, engineered an LNP-base editing platform to correct the biochemical phenotype of mucopolysaccharidosis type-1 (MPS-I) in the neonatal mouse brain, and exhibited proof-of-principle delivery and safety in a fetal NHP and patient-derived brain tissues. **Materials and Methods:** LNPs encapsulating *luciferase* mRNA were formulated as described previously, characterized, and screened in BALB/c fetuses (E18) and neonates (P0) via intracerebroventricular (ICV) injection. The top performing LNP was optimized in a neuroblastoma cell line and primary murine MPS-I cells for excipient ratio, N:P ratio, and adenine base editor (ABE) to guide RNA (sgRNA) ratio. Optimized LNPs were combined with a base editing platform for murine MPS-I and injected ICV in MPS-I neonates.

After 1 month, mice were analyzed for on- and off-target editing, biochemical pathway rescue, and safety via cytokine panel and anti-PEG IgM response. Finally, optimized LNPs were injected ICV into a fetal NHP, assessed for stability in human cerebrospinal fluid (CSF), tested in patient-derived neurons, and used to base edit the human gene involved in MPS-I *ex vivo* in human precision cut brain slices. **Results and Discussion:** Our library screen revealed a novel LNP that mediates a 17-fold increase in mRNA expression in the fetal brain in comparison to an industry standard with similar results observed in the neonatal brain (Fig. 1A). LNPs optimized *in vitro* facilitated low-level brain editing *in vivo*, mediated biochemical rescue of disease - 7 to 13% of normal enzymatic activity - in the neonatal MPS-I mouse brain (Fig. 1B), and did not induce an innate or humoral immune response. Brain-optimized LNPs successfully transfected periventricular tissue of a fetal NHP, were stable in human CSF (Fig. 1C), transfected 90% of patient-derived neurons without toxicity, and facilitated base edits in human brain tissue. **Conclusions:** Our novel LNPs are highly effective at mRNA delivery to both the fetal and neonatal mouse brain. After optimization of formulation parameters *in vitro*, our LNP LNP-base editing platform demonstrated therapeutic efficacy and safety in a mouse model of MPS-I. These LNPs have high potential for clinical translation, since they transfected the fetal NHP brain in vivo, showed stability in human CSF, and are non-toxic and highly effective in transfecting patient-derived tissues. In the future, the LNPs developed in this study can be broadly applied for perinatal mRNA therapeutics targeting the CNS.



AAV Library Technology

39 Parallel Engineering and Recombination of Adeno-Associated Virus Variable Regions Enables Multisite Library Production

David Goertsen, Viviana Gradinaru

Division of Biology and Biological Engineering, California Institute of Technology, Pasadena, CA

Generation of diversified adeno-associated virus (AAV) capsid libraries and subsequent selections of variants has yielded exciting vectors with distinct tropism. However, one limitation of current engineered variants of AAV is that much of the surface-exposed variable regions from the parent are included in the final product, which could cause variants to maintain the receptor binding interactions of their ancestral sequence and contribute to neutralization by the immune system. While mutating surface-exposed loops iteratively allows for gradual alteration of the tissue tropism away from the parent sequence[1], this creates some dependency on previous mutations and restricts the accessible protein landscape for the capsid. With the aim of obtaining AAV capsids with minimal parental sequence present in the prominent surface-exposed loops, we engineered all three surface-exposed regions of the AAV9 capsid by 7-mer substitution. By screening capsid libraries for production, we mutated each of three surface-exposed variable regions of the three-fold axis prior to selection, enabling a wider search of the protein landscape. We then combined these pre-selected libraries for each site to yield capsids with all prominent, surface-exposed residues mutated. Using this approach, we engineered two capsid libraries, containing 14 and 21 amino acid substitutions, respectively, and found that our parallel strategy boosted production and yielded diversified libraries.

1. Goertsen, D., Flytzanis, N. C., Goeden, N., Chuapoco, M. R., Cummins, A., Chen, Y., ... & Gradinaru, V. (2022). AAV capsid variants with brain-wide transgene expression and decreased liver targeting after intravenous delivery in mouse and marmoset. Nature neuroscience, 25(1), 106-115.

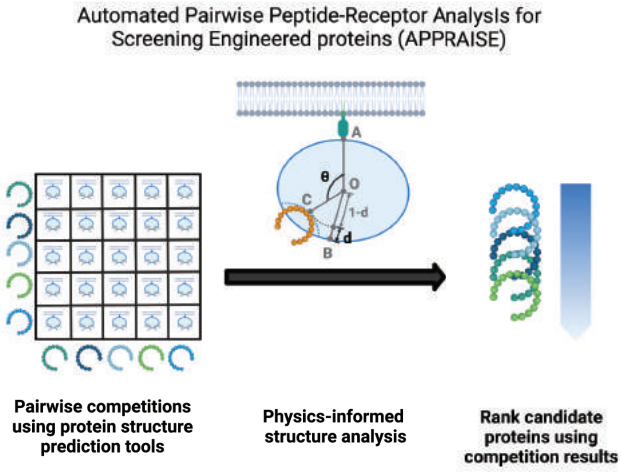
40 APPRAISE: Fast, Accurate Ranking of Engineered Proteins by Receptor Binding Propensity Using Structure Modeling

Xiaozhe Ding, Xinhong Chen, Erin E. Sullivan, Timothy Shay, Viviana Gradinaru

California Institute of Technology, Pasadena, CA

Deep learning-based methods for protein structure prediction have achieved unprecedented accuracy. However, the power of these tools to guide the engineering of protein-based gene & cell therapeutics remains limited due to a gap between the ability to predict the structures of candidate proteins and the ability to assess which of those proteins are most likely to bind to a target receptor. Here we bridge this gap by introducing Automated Pairwise Peptide-Receptor AnalysIs for Screening Engineered proteins (APPRAISE), a method for predicting the receptor binding propensity of engineered proteins. After generating models of engineered proteins competing for binding to a target using an established structure-prediction tool such as AlphaFold2-multimer or ESMFold, APPRAISE performs a

rapid (under 1 CPU second per model) scoring analysis that takes into account biophysical and geometrical constraints. As a proof-of-concept, we demonstrate that APPRAISE can accurately classify receptor-dependent vs. receptor-independent engineered adeno-associated viral (AAV) vectors, as well as diverse classes of engineered proteins such as miniproteins targeting the SARS-CoV-2 spike protein, nanobodies targeting a G-protein-coupled receptor, and peptides that specifically bind to transferrin receptor and PD-L1. When used to screen a library of 100 AAV variants, high-throughput APPRAISE (HT-APPRAISE) correctly predicted an AAV variant with a distinct sequence from previously known receptor binders to be a top receptor binder. The results of both in vitro and in vivo experiments showed that the top AAV variant has strong receptor-dependent transduction. We made APPRAISE accessible through a web-based notebook interface using Google Colaboratory (http://tiny.cc/APPRAISE). With its high accuracy, interpretability, and generalizability, APPRAISE has the potential to expand the utility of current structural prediction methods and accelerate protein engineering for gene & cell therapies.



41 *In Vivo* AAV Capsid Selection at Spatial and Single-Cell Resolution

Ashley B. Robbins[1,2], Paul T. Ranum[2], Yonghong Chen[2], Megan S. Keiser[2], Luis Tecedor[2], Beverly L. Davidson[2,3]

[1]Neuroscience Graduate Group, University of Pennsylvania, Philadelphia, PA,[2]Raymond G. Perelman Center for Cellular and Molecular Therapeutics, Children's Hospital of Philadelphia, Philadelphia, PA,[3]Department of Pathology & Laboratory Medicine, University of Pennsylvania, Philadelphia, PA

Differential regional and cellular vulnerability is a hallmark of neurodegenerative disease and a challenge for brain-targeting gene therapies. The development of novel adeno-associated viruses (AAVs) with tropism for disease-affected regions and cell types is crucial to therapeutic efficacy. AAV selection methodologies have given rise to a new class of engineered AAV vectors capable of improved gene delivery. Current AAV selection methods yield tissue-level enrichment readouts by way of universal promoters, or cell-type enrichment information via cell-type-specific promoters, over multiple rounds of enrichment. While this approach has proven fruitful, current methods are not capable of resolving transduction status in heterogenous cell populations across distinct tissue regions. Existing approaches for the detection of cell-type-specific tropism of engineered AAVs via single-cell RNA sequencing are low-throughput and/or cost-prohibitive for profiling many regions and biological replicates, in part, due to reliance on droplet-based single-cell or nuclei partitioning. To overcome these limitations and implement a scalable method for highly multiplexed profiling of regional and cell-type-specific AAV tropism, we utilized a combinatorial indexing method for single-cell transcriptome sequencing (Rosenberg et al. 2018). Top hits from a previous peptide-modified AAV screen, identified for widespread transduction of deep brain structures, were selected for a proof-of-principle experiment. A mixed pool of 62 top-performing capsids was delivered via direct injection to the striatum or thalamus of adult mice (N=2 mice per injection site). Tissue was collected from the site of injection, as well as other interconnected brain regions (cortex and hippocampus). In total, 12 tissue samples were processed simultaneously, from four mice and four brain regions, for multiplexed single-nuclei RNA sequencing. Custom computational pipelines were developed for the integration and analysis of AAV transduction profiles in the context of single-cell transcriptomes. Here we demonstrate successful capture of the regional and cellular origin of AAV transduction events. We then associate each event with the delivering capsid variant, allowing us to resolve which capsid variants transduced which cell types and in which tissue regions. In addition, we demonstrate the use of this technology to track AAV biodistribution across cellular networks and anatomical regions, a use case that can be applied to numerous biological contexts. This approach has many advantages for scalability. As of now, a single experiment can be expanded to profile ~150,000 cells or nuclei, from hundreds of biological samples, and can be used to assess 10s to 100s of AAV capsid variants simultaneously. Furthermore, our method requires no specialized equipment and can be applied across tissues and species.

42 Antibody Conjugated AAV Vectors for Efficient and Specific Skeletal Muscle Directed Gene Delivery across Species

Poulami Samai, Michael Stec, Valerie Le Rouzic, Naveen Khan, David Golann, Clarisse Lou Jose, Samvitha Cherravuru, Ammar Tareen, Mark Sleeman, Sven H. Moller-Tank, Christos Kyratsous, Leah Sabin

Regeneron Pharmaceuticals, Tarrytown, NY

Adeno-associated virus (AAV) is a leading viral vector used in in vivo gene replacement therapyand gene editing in preclinical and clinical studies. Although AAV has many advantages as a genetherapy vector, selective transduction of specific tissues after systemic delivery remains achallenge. Many AAV capsids preferentially transduce the liver after systemic injection, whichlimits the efficiency of transduction in other tissues and cell types. This is particularly challengingfor skeletal muscle as it comprises up to 40% of total body mass. To achieve therapeutic efficacyexceptionally high virus doses (>1E+14 vg/kg) are required. Several safety concerns associatedwith high dose systemic AAV therapies have been observed in some recent clinical trials,highlighting the need for more efficient AAV vectors that can achieve efficacy at lower doses.Although capsid library-based

selection approaches are a powerful method to identify novelcapsids with desired properties, the translatability of such capsids between species remains aconcern. We aimed to develop a species agnostic AAV retargeting approach that utilizes rational capsid engineering and monoclonal antibodies to redirect viral particles to skeletal muscles. We utilize a protein tagging system to covalently conjugate antibodies to surface-exposed variableloops on the viral capsid. The capsid can be further engineered through the introduction of pointmutations in the amino acid residues that serve as primary determinants of vector tropism. Formuscle targeting, we identified a protein, CACNG1, that is specifically expressed in skeletalmuscle. We also created humanized mice that are genetically modified to express the humanCACNG1 protein. We then generated panels of monoclonal antibodies raised against the humanCACNG1 protein to test in our retargeting platform. Here we demonstrate that AAV particles canbe retargeted to skeletal muscle in an antibody-dependent manner both in vivo and in vitro. Thepanel of CACNG1 Ab-retargeted AAV9 in vitro showed substantially enhanced reporter transgeneexpression in human skeletal muscle cells as well as mouse myotubes. The retargeted capsidsdisplay enhanced skeletal muscle delivery and marked liver detargeting compared to AAV9, astandard wildtype capsid used for muscle delivery in human clinical trials. The retargeted capsidsalso demonstrate enhanced delivery in mouse models of disease such as Duchenne musculardystrophy (D2-mdx) compared to AAV9. To demonstrate the cross-species translatability of ourplatform, we show that our antibody-targeted muscle-specific capsids outperform AAV9 whencompared head-to-head in non-human primates using a barcoded library approach. The extentof liver detargeting as well as the relative efficiency of the panel of antibodies tested were similarbetween rodents and cynomolgous monkeys, demonstrating the translatability of our platform.

43 Generative Networks Create Novel Receptor Targeted AAVs with Only 1,200 Training Examples

Andrew J. Barry, Fatma Elzahraa Eid, Ken Y. Chan, Qin Huang, Jencilin Johnston, Benjamin E. Deverman

Broad Institute of MIT and Harvard, Cambridge, MA

Introduction: Searching vast sequence spaces for protein variants with enhanced biological functions of interest can be challenging when only a small percentage of variants meet these criteria. We investigated the feasibility of applying SeqDesign[1], a Wavenet-based generative neural network, to nominate adeno-associated virus (AAV) capsid variants given only a small sample of known high-performance candidates. **Methods:** Libraries of AAV9 capsid variants modified with 7-amino acid insertions at the surface exposed loop VIII were subjected to functional assays to evaluate their (1) production fitness and (2) ability to bind to a specific human brain endothelial cell surface protein in vitro. The data were used to train different generative models, which were assessed by the diversity and performance distribution of their predicted variants. **Results:** *Training size optimization:* We trained Wavenet models on 20k, 10k, 5k or 1k production-fit sequences and evaluated their performance using our previously established production-fitness model.[2] The predicted fitness of generated capsids decreased at 1,000 training sequences (Fig 1A). *Generating receptor targeted AAVs:* We trained a Wavenet model to predict variants capable of binding to a specific human protein present on the human CNS vasculature. We used 1,200 high-performance candidates identified in an in vitro target protein binding assay[3] for training. Wavenet's outputs were diverse; minimum self-Hamming distances were 1: 62%, 2: 30%, 3: 7.4%, 4: 0.4%. The output was novel compared to the training examples; training-to-generated minimum Hamming distances were 1: 16%, 2: 38%, 3: 37%, 4: 8.4%, 5: 0.04% (Fig 1B). *Validating generated capsids:* We designed a validation library using the receptor targeted variants generated by Wavenet. Wavenet performed well in the critical right-tail prediction task; its best outputs performed as well as variants previously measured in vitro (Fig 1C). **Conclusion:** We demonstrated that Wavenet could generate a highly diverse set of variants that were production-fit and bound the target human receptor. Importantly, in contrast to other ML models, Wavenet generated a larger number of rarer, ultra-high performing receptor targeted variants, which are prime candidates for further development as gene delivery vectors.

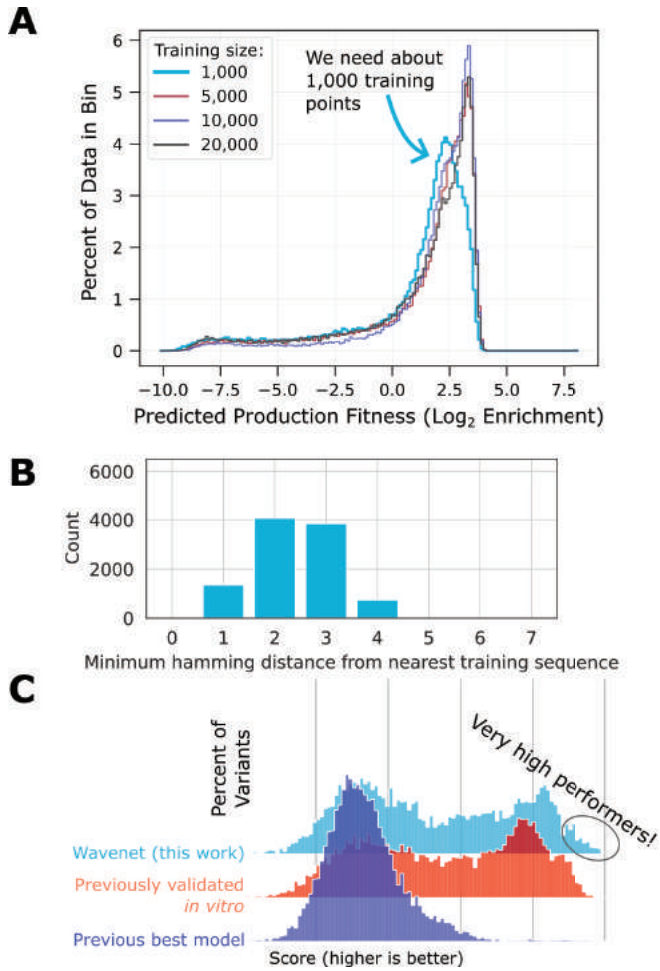

Figure 1. Wavenet model predicts high performing capsids given top examples from in vitro screens. (A) We trained Wavenet to generate production-fit variants with various amounts of training data and used

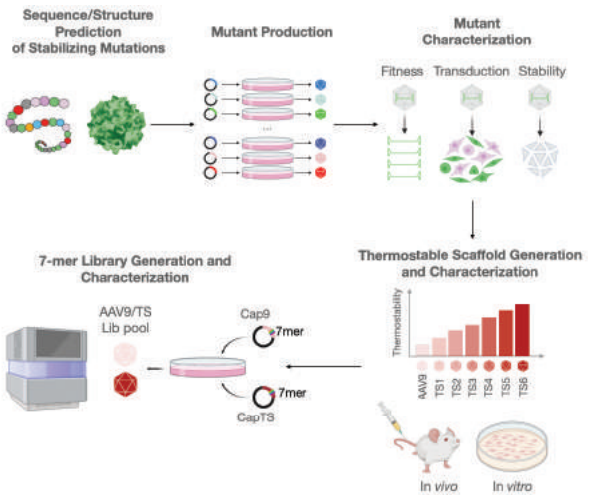
an existing model[2] to predict the production fitness of the output. **(B)** Sequence novelty as measured by the minimum hamming distance between Wavenet's output and the training set. **(C)** Wavenet was trained on top receptor targeted examples and its outputs were manufactured and tested for their ability to bind the target protein in vitro.

44 Development of Stabilized AAV Capsids for Vector Engineering

Simon Pacouret, Fatma Elzahraa Eid, William Donahoe, Ken Y. Chan, Jason Wu, Qingxia Zheng, Casey Keyes, Pamela Brauer, Albert Chen, Yujia A. Chan, Benjamin Deverman

Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, MA

Adeno-associated virus (AAV) vectors are promising candidates for gene therapy, as illustrated by the recent FDA or EMA approvals of Luxturna, Zolgensma and Valoctocogene Roxaparvovec. One challenge in AAV capsid engineering is to enhance tropism and antibody evasion characteristics without compromising VP protein folding, capsid assembly, genome packaging and other key biological functions. Indeed, we find that loop VIII insertions, which have been used to enhance blood-brain barrier (BBB) crossing, are typically highly destabilizing. We hypothesize that AAV capsid evolvability is constrained by its stability, and that the mutational tolerance of the AAV capsid can be increased via the introduction of stabilizing, compensatory mutations. We identified and individually tested seven stabilizing mutations, which increased the AAV9 capsid melting temperature (Tm) by 1-7°C, without any major impact on production fitness or in vitro transduction phenotypes. We demonstrated that these mutations could be combined to fine tune the AAV9 capsid thermal stability (Tm = 77°C), reaching melting temperatures between 77-93.4°C without compromising production titers, in vitro transduction, or the ability to cross the BBB after systemic administration in mice. To determine whether AAV9 capsids bearing a combination of these mutations had increased mutational tolerance, we generated peptide-modified capsid libraries within AAV9 or a highly stabilized capsid variant and screened these libraries for production fitness. This work informs the development of novel AAV capsids with increased mutational tolerance for AAV engineering.



45 *In Vivo* Targeting of HSCs by Capsid-Engineered AAV Vectors

Nadja Meumann[1], Stefan Radtke[2], Xabier Perez Garmendia[1], Sabrina Just[1], Angela Fornell Gutierrez[1], Moritz Ertelt[3], Clara Schoeder[3], Anne-Sophie Kuhlmann[2], Chris W Peterson[2], Hans-Peter Kiem[2], Hildegard Büning[1]

[1]Institute of Experimental Hematology, Hannover Medical School, Hannover, Germany,[2]Clinical Research Division, Fred Hutchinson Cancer Research Center, Seattle, WA,[3]Institute for Drug Discovery, University Leipzig Medical School, Leipzig, Germany

In vivo targeting of hematopoietic stem cells (HSCs) by adeno-associated viral (AAV) vectors would open up a number of relevant therapeutic options. We therefore performed a high-throughput AAV peptide display library screen in non-human primates (NHP) for variants targeting CD34+ cells. A set of capsid variants recovered from the isolated NHP CD34+ cells was investigated as barcoded (BC) eGFP vectors in CD34+ humanized NSG mice (i.v., n = 6-7/pool, 5 d). While FACS analysis detected moderate GFP signals in PBMCs and bone marrow (BM)-derived CD34+ cells, NGS analysis of mRNA BCs identified various capsids with dominant mRNA expression in hCD34+ cells (% of total BC reads: 20-64 %). In line, several variants mediated superior ex vivo transduction of hCD34+ cells (eGFP+ cells 70-80 %). To study possible mechanisms behind the improved tropism, the above-mentioned CD34+-selective capsids were compared for their uncoating efficiency in a BC.eGFP vector pool in hCD34+ NSG mice (n= 6-7, 5 d) with AAV6 and AAV2 as controls. Here, NGS analysis focused on uncoated vector genomes in CD34+ cells, PBMCs, and liver. Thus, before NGS, isolated genomic DNA was subjected to T5 exonuclease treatment to deplete linear vector DNA (encapsidated) and rescue circular concatemeric vector DNA (uncoated). Substantial differences between candidates were observed leading to identification of two capsids, Var24 and Var30, for further analysis. In an ongoing NHP study for efficient CD34+-targeting, Var24 and 30 are compared to AAV2 and AAV6 as BC.eGFP vectors. Furthermore, relevant capsid features of Var24 and 30, such as stability, 3D structure, and immune escape (Var30), were confirmed to be altered compared to parental serotype, AAV2, and may contribute to improved CD34+ cell targeting. In conclusion, we successfully performed a CD34+ cell-targeted AAV library screen for AAV2 capsid variants in an NHP model and confirmed the species-independent tropism of several promising capsids for hCD34+ cells in humanized NSG mice and ex vivo. A number of capsid candidates is worth further investigation. In particular, Var30, with its highly efficient and specific in vivo tropism for hCD34+ cells, represents a strong candidate to equip vectors for gene therapeutic delivery to HSCs.

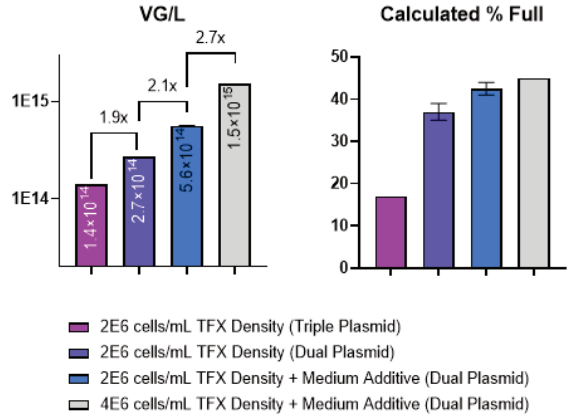
AAV Vectors - Product Development Manufacturing: Upstream

46 Development of a Novel Plug-and-Play Upstream Process Offering Scalable, High-Yield Production of High-Quality AAV Vectors

Klaudia Szymczak, Marissa Stanvick, Richard Gilmore, Eli Wiberg, Divya Tsiros, Shannon Wallace, Chase Rebidue, Jin Yin

Oxford Biomedica (OXB) Solutions, Bedford, MA

With accelerating development of novel AAV-based drug candidates the demand for high vector yields and quality has increased substantially. Improving productivity of AAV vector is critical not only to deliver adequate amounts of therapeutics to treat patients but also to bring down the cost of manufacturing per individual. To address those challenges, OXB Solutions has established a new upstream process which results in over 10-fold higher bioreactor titers with 2-fold higher percent of full capsids, and yields more than 1E15 vector genomes (vg) per L . Importantly, such productivity increase allows for coverage of 10 times more patients with ~90% decrease in production cost per individual. This significant gain in AAV titers was achieved through a combination of process changes including implementation of our novel dual plasmid system, increasing transfection cell density along with optimization of plasmid quantities, adopting a post-transfection additive, and improving bioreactor parameters (see Figure). Replacing triple plasmid constructs with the new dual configuration resulted in up to a 2-fold higher productivity and was responsible for the observed doubling of the calculated percent of full capsids. Changing transfection cell density from 2E6 to 4E6 cells/mL along with optimization of the plasmid amount per cell resulted in up to 3-fold greater AAV titers. After optimizing the final concentration and timing of addition, the additive also significantly improved the efficiency of our process with up to a 3-fold gain in generated vectors. Finally, screening of bioreactor parameters using a DoE approach identified an ideal pH setpoint which was associated with additional titer improvement. Importantly, all the increases caused by the introduced process modifications were confirmed through downstream steps and no impact on product quality was observed except for the substantial gain in percent of full capsids. In addition to high productivity, our process also demonstrates strong reproducibility among at least 9 different AAV serotypes (clades A, B, E and F) reaching bioreactor titers close to or above 1E15 vg/L, and in most cases achieving over 50% of full capsids in affinity-purified product. This reproducibility was also confirmed among various genes of interest (GOI) including GFP, luciferase, and 7 other disease-targeting genes. Finally, we successfully scaled the new process from 2L to 50L and 500L vessels, all of which demonstrated comparable titers and consistent product quality with >90% full capsids in anion-exchange chromatography (AEX)-purified product plus low levels of plasmid- and host-cell-derived impurities. Altogether, a combination of our high-performing upstream process with efficient downstream methods creates a powerful platform for AAV manufacturing yielding over 1E17 total vector genomes in the final drug substance formulation from only one 500L bioreactor. As an innovation-driven company, OXB Solutions continues to improve its platform and is currently developing a next-generation upstream process utilizing perfusion to grow and transfect cells at even higher densities. Our preliminary studies at 2L scale consistently show that this cutting-edge strategy leads to a notable increase in productivity with vg titers over 2.5E15 vg/L.



47 Analysis of Mechanisms Driving Improved Adeno-Associated Vector Production by the Addition of Small Molecules

Nicholas Dietrich, Samantha Lasater, Joseph Rabinowitz, Jennifer Israel

Kriya Therapeutics, Inc, Research Triangle Park, NC

With the recent successes in recombinant adeno-associated virus (rAAV) mediated gene therapy, there is strong interest within the field for production process improvements to drive down costs and improve quality. Here, we take a mechanistic approach to understand the transcriptomic underpinnings of production yield using imidazole-based small molecules, which we discovered impacted production efficiency during the packaging process. To understand the baseline transcriptomic dynamics during vector production, and the subsequent changes upon small molecule addition, we used the triple transfection method to package AAV-GFP and collected total mRNA across multiple timepoints for untreated and treated samples. Using Illumina mRNA-seq, we then analyzed transcriptomic changes through time and across treatment groups. Our baseline RNA-seq results revealed significant, time-dependent changes in host cell gene expression, providing insight into expression dynamics associated with early vs late stages of vector production. We identified hundreds of differentially expressed genes after 24 hours of transfection for both small molecules, and thousands of differentially expressed genes 48 hours after transfection. Further, small molecule addition resulted in large-scale alterations to the baseline host cell transcriptome, revealing many critical gene pathways that likely underlie production efficiency, including many signaling pathways. Collectively, our results characterize gene expression dynamics operating during distinct phases of vector production and highlight pathways likely underlying production and proper generation of full and functional rAAV molecules.

48 A Modified Triple Transfection Method Produces High-Quality AAV Vectors with Much Reduced Plasmid Demand

Hao Liu, Yue Zhang, Mitchell Yip, Lingzhi Ren, Jialing Yang Liang, Jote Bucha, Nan Liu, Ailing Du, Jiaming Wang, Hao Chang, Oh Hyejin, Chen Zhou, Ruxiao Xing, Mengyao Xu, Mengtian Cui, Xiupeng Chen, Jisun Lee, Jinchen He, Jun Xie, Phillip WL Tai, Guangping Gao#, Dan Wang#

Horae Gene Therapy Center, The University of Massachusetts Chan Medical School, Worcester, MA

Triple transfection of HEK293 cells is the most widely used method for producing recombinant adeno-associated virus (rAAV). It involves three plasmids co-transfected to cells at roughly equal molar ratio: a helper plasmid that delivers certain genes of adenovirus (pAd-Helper), a trans plasmid that expresses AAV rep and cap genes (pTrans), and a cis plasmid that harbors a therapeutic transgene cassette flanked by AAV inverted terminal repeats (pCis). Although triple transfection has gained tremendous success, emerging issues arise when it is increasingly used to produce clinical-grade rAAV and scrutinized by advanced technologies, such as high cost of goods for GMP plasmid and alarming levels of plasmid backbone DNA detected in purified rAAV. Here, we describe a modified triple transfection method that improves the quantity and quality of rAAV batch with a greatly reduced demand of plasmid. We recently combined AAV-based gene delivery and suppressor tRNA-mediated stop codon readthrough to develop AAV-NoSTOP (Wang J., et al. *Nature* 2022), an in vivo gene therapy approach that targets pathogenic nonsense mutations. As we attempted to expand the AAV-NoSTOP toolbox, we failed to package certain suppressor tRNA genes into rAAV by standard triple transfection. Mechanistically, we found that expression of the suppressor tRNAs from pCis in HEK293 cells interfered with rep/cap expression from pTrans. Surprisingly, reducing the amount of transfected pCis to 1% allowed for rep/cap expression and afforded successful rAAV production. These results prompted us to carry out a series of comparative studies, which demonstrated that reducing pCis to 1% of that used in standard triple transfection was broadly applicable to both single-stranded and self-complementary vector genomes, various reporter transgenes and capsids, and different production scales. The resulting rAAV yield was comparable or slightly reduced compared with that obtained from standard triple transfection. Besides using much less plasmid, another advantage of using 1% pCis is the improvement of vector DNA purity. Specifically, PacBio sequencing showed that it significantly reduced read-through and reverse-packaged vector DNA that contained the pCis plasmid backbone (from 4.4% in standard triple transfection to 0.7%), which may cause undesired RNA expression and innate immunity in transduced tissues. Finally, in vivo studies in mice showed that rAAV produced using 1% pCis had superior transduction efficiency in a transgene-, serotype- and tissue-specific manner. In summary, we developed a modified triple transfection method that is easy to implement, cost-effective, and able to produce rAAV of high purity and potency. (#Co-corresponding authors)

49 Adenovirus L4 22 and 33K Proteins Are Essential for Episomal Amplification of Integrated rep/cap Genes and rAAV Production from Stable AAV Packaging Cells

Weiheng Su[1], Ryan Cawood[1], Leonard W. Seymour[2]

[1]OXGENE, Oxford, United Kingdom,[2]University of Oxford, Oxford, United Kingdom

Recombinant adeno-associated virus (rAAV) is the vector of choice for in vivo gene therapy, however, efficient production of rAAV at scale remains challenging. rAAV packaging and producer cell lines have been explored extensively and are promising approaches for scalable rAAV manufacture. rAAV production from these cell lines is induced by infection with wild-type adenoviruses to promote amplification of integrated rep-cap genes (100 to 1000-fold), essential to supply sufficient Rep and Cap proteins for rAAV replication. This amplification effect is dependent on a cis-acting replication element (CARE). Adenovirus proteins that play a role in mobilizing CARE-dependent amplification of AAV rep-cap remain to be fully defined. We recently described a new helper adenovirus entitled TESSA, wherein the Major Late Promoter (MLP) was modified *in situ* to enable promoter self-repression for contaminant-free manufacture of rAAV. TESSA provided efficient helper functions to enable rAAV replication when the rep-cap genes were provided *in trans* but, interestingly, was unable to support rep-cap amplification and rAAV production from stable packaging cells. Here we show that expression of the adenovirus L4 22-33K unit is essential for rep-cap amplification and rAAV production using an rAAV packaging cell line HeLaRC32. Our results suggest a model wherein, normally, high levels of 22-33K are expressed from adenovirus MLP to support the replication of adenovirus and amplification of AAV rep-cap genes in the packaging cells. However, repression of the MLP from TESSA, and titration by replicating adenoviral genomes, restricted sufficient 22-33K proteins required to support rep-cap amplification. Importantly, siRNA-knockdown of the adenovirus DNA-polymerase or the use of a temperature-sensitive DNA-polymerase mutant in TESSA (TESSA-E1-tsDNA) significantly decreased adenovirus genome replication, thereby recovering rep-cap amplification for efficient rAAV replication. Our results further elucidate the intricate kinetics between CARE-dependent rAAV replication and adenoviral helper functions with implications for improving rAAV manufacture from stable cell lines.

50 A Combined Transcriptomics and Compound Screening Approach to Increasing AAV Productivity in Gene Therapy Process Development

Maria Choi-Ali, Jenny Shupe, Hooman Hefzi

Biogen, Cambridge, MA

Viral vectors such as adeno-associated virus are the choice of gene delivery vehicle for Gene Therapy applications, and transient transfection using suspension cell culture remains the most widely used production platform in the industry. There is interest in continuously improving AAV productivity during the production process to meet high clinical and commercial product demands, as well as advancing fundamental understandings of AAV production

biology. Both transfection and AAV production may induce cellular stress responses including anti-viral response, which may result in reduced AAV productivity. Media additives targeting specific pathways are hypothesized to offset these cellular stress responses, and thus improve AAV production. In this work we have used transcriptomics to separate and understand the time-course cellular stress responses to both transfection and AAV production and screened small molecule compounds targeting the identified pathways. The supplementation of these compounds in production medium was further optimized using high-throughput 24-deep well and Ambr15 screening formats and confirmed in lab scale bioreactors. This combined approach of transcriptomics followed by targeted compound screening resulted in a greater than two-fold improvement in AAV productivity.

51 Development of AAV Continuous High Production Technology by FF Original Flow Electroporation Method

Takashi Yakushiji, Michiko Edo, Nozomu Tonoike, Yuka Kobayashi, Takayoshi Kuwabara, Yoichi Nagai
Fujifilm, Kaisei-machi, Ashigarakami-gum Kanagawa, Japan

The purpose of this study is to develop a technology for high production of AAV based on the triple transfection method using HEK293 cell. At present, a high dose is required in hemophilia etc., but it is difficult in principle to respond to high production with the PEI-TT method. Therefore, we are working on a technology that can achieve both high productivity and high quality by adopting a PEI-free production method that combines perfusion culture and FF original continuous flow-type electroporation technology. In this report, we will report the verification results of the technology to obtain 10L culture medium with a AAV titer of 1E+15vg/l by working on continuous production at 1L culture scale for 1 month.

52 Synthetic Cell Lines for Recombinant AAV Production

Min Lu, Zion Lee, Yu-Chieh Lin, Wei-Shou Hu
Department of Chemical Engineering and Materials Science, University of Minnesota, Minneapolis, MN

Recombinant adeno-associated virus (rAAV) is one of the most commonly used vehicles for gene therapy due to its effectiveness in *in vivo* gene delivery, long-term persistency, and safety. In general, a very large dosage of rAAV is required in clinical applications, hence manufacturing is anticipated to be carried out in large scale to meet the demand. Current rAAV production relies on multiple plasmid transfections or helper virus infections, which pose challenge in large-scale manufacturing. Additionally, rAAV produced in current manufacturing processes often has large fractions of empty viral particles without the payload. Innovations in viral vector manufacturing are called for to increase vector titers and enhance vector quality. Our aim is to bring into being a cell line which has all the essential genetic elements for the synthesis of rAAV vectors that can be inducibly expressed to generate the recombinant virus. Since the production does not require any plasmid transfection or virus infection, the process is simple and scalable. Additionally, through tuning of the inducer concentration profile, we can control the expression dynamics of different viral components and modulate the full-to-empty particle ratio of the vector to enhance the quality of the product. We have taken a synthetic biology approach to establish rAAV producing cell lines by replacing native transcriptional regulation of viral genes with inducible promoters, organizing the essential viral genes into genetic modules, and integrating those modules independently into HEK293 cell genome. The genome module contained a rAAV genome encoding GFP; the replication module encodes the Rep68 protein and helper proteins of adenovirus; and the packaging module provided capsid proteins and the Rep52 protein. After transfection, cells with these three modules integrated into host genome were screened for rAAV productivity. To facilitate screening, we also developed an assay cell line harboring *rep* and helper genes but has no viral genome nor *cap* gene for titration of infectious rAAV. We successfully isolated four producers that can generate infectious rAAV with high titers upon induction. By optimizing the inducer ratio and induction timing, better titers with high full particle content were achieved. Transcriptomics and targeted proteomics were adopted to quantify both cellular and viral transcripts and proteins. Time-course profiles of viral transcripts and proteins revealed different viral gene expression dynamics of each cell line, and their possible influence on rAAV titers and quality. These understandings led to further modification of cultural conditions to enhance the productivity. Taken together, utilizing a systems design and synthetic biology approach, a scalable and controllable rAAV production system was demonstrated. This work exemplifies the crucial role of synthetic biology to engineer next-generation gene therapy manufacturing platforms.

Immunotherapy, Oncolytic Viruses, and Cytokines

53 UB-VV200 is a Novel Surface-Engineered Lentiviral Product Candidate for *In Vivo* Engineering of Universal TagCAR T Cells for the Treatment of Solid Tumors

Alyssa Sheih, Nanda Coelho, Kathryn Michels, Anna Ting, Susana H. Lopez, Kelsey Lynch, Kristen Mittelsteadt, Ruth Chenault, Alissa Brandes, Don Parrilla, Anai M. Perez, Mason Muhonen, Jessica Freeman, Sarah Gould, Alessandra M. Sullivan, Shon Green, Rich Getto, Andrew M. Scharenberg, Byoung Ryu, Laurie Beitz, Ryan Larson
Umoja Biopharma, Seattle, WA

Despite the promising clinical efficacy of CAR T cells in hematologic malignancies, tumor heterogeneity and the immunosuppressive tumor microenvironment (TME) are key challenges that limit efficacy of CAR T cells in solid tumors. Additionally, complex ex vivo CAR T manufacturing and the need for lymphodepletion limit its widespread application. To overcome these challenges, our integrated platform includes a surface-engineered lentiviral vector drug product, UB-VV200, designed to specifically engineer T cells in vivo to express a universal anti-fluorescein CAR (TagCAR) and a synthetic cytokine receptor for selective small molecule- controlled in vivo expansion of TagCAR T cells. TagCAR T cells are designed

to be used in combination with TumorTags, which are bispecific adaptors comprised of fluorescein linked to a tumor-targeting ligand. UB-TT170 is a TumorTag that specifically targets folate receptors (FRα and β). FRα is upregulated on many tumor cell types while FRβ is expressed on immunosuppressive tumor-associated macrophages, which allows UB-TT170 to simultaneously target the tumor and TME. To promote selective, high avidity binding to T cells, UB-VV200 surface engineering includes an anti-CD3 single chain variable fragment (scFv) and costimulatory molecules. Here, we show that UB-VV200 binds selectively to T cells and activates them to facilitate efficient transduction in a dose-dependent manner in vitro. TagCAR T cells mediated antigen-specific cytolytic activity and cytokine release against FRα+ MDA-MB-231 tumor cells when cocultured with UB-TT170. Resulting TagCAR T cells selectively expanded through activation of the synthetic cytokine receptor. When administered in vivo, UB-VV200 efficiently generated TagCAR T cells in non-activated PBMC-humanized NSG mice bearing FRα+ MDA-MB-231 tumors. There were no acute toxicities associated with UB-VV200 administration. In vivo generated TagCAR T cells proliferated in an antigen-dependent manner in the presence of UB-TT170 and cleared established tumors. In the absence of UB-TT170, TagCAR T cells alone did not exhibit expansion or anti-tumor activity. Overall, we have demonstrated that UB-VV200 can engineer TagCAR T cells in vivo and that UB-TT170 can direct TagCAR T cells to eliminate FRα+ tumor cells. These data support development of UB-VV200 in combination with TumorTags as a new therapeutic approach against solid tumors.

54 TNT: Talimogene Laherparepvec (An Oncolytic Virus Expressing GM-CSF), Nivolumab and Trabectedin for Advanced Leiomyosarcoma: A Phase 2 Study *[NCT# 03886311]*

Neal Chawla[1], Nadezhda Omelchenko[2], Elan Younesi[2], Victoria Chua-Alcala[2], Ania Moradkhani[2], Don Brigham[3], Sant P. Chawla[2], Erlinda M. Gordon[3,4]

[1]Medical Oncology, City of Hope, Duarte, CA,[2]Medical Oncology, Sarcoma Oncology Center, Santa Monica, CA,[3]Medical Oncology, Aveni Foundation, Santa Monica, CA,[4]Medical Oncology, Sarcoma Oncology Research Center, Santa Monica, CA

Background: Intratumoral injection of Talimogene Laherparepvec (TVEC) has a local oncolytic effect and evokes a cytotoxic immune response. The combination of Trabectedin (T) and Nivolumab (N) is a safe and effective therapy in soft tissue sarcoma (STS). This study aims to determine the safety and efficacy of adding TVEC to the combination of T and N in advanced leiomyosarcoma (LMS). **Objectives: Primary:** To assess progression-free survival (PFS). **Secondary**: (1) To evaluate the best overall response, (2) PFS rate at 6 and 9 months, (3) Overall survival (OS) rate at 6, 9, and 12 months, (4) Incidence of conversion from unresectable to the resectable tumor, and (5) Incidence of treatment-related adverse events (TRAEs). **Patients and Methods:** Eligible patients included patients ≥ 18 years of age with locally advanced unresectable or metastatic LMS, measurable disease by RECIST v1.1, and at least one accessible tumor for TVEC intratumoral injection. N (3 mg/kg q2 weeks), T (1.2 mg/m2 q3 weeks), and TVEC (1x10e8 PFU/ml q 2 weeks depending on tumor size) were administered. A starting dose of TVEC (1x10e6 PFU/ml) was initially given, followed by a total dose of 1x10e8 PFU/ml q 2 weeks depending on tumor size) three weeks later. **Results: Efficacy:** Per protocol, there were 11 evaluable subjects (Modified Intention to Treat [mITT] patients who had completed at least one treatment cycle and had a follow-up CT scan). The median number of prior lines of therapy was 4 (range 1-8). Best Overall Response (BOR) by RECIST v1.1 = 2 PR, 9SD (BOR Rate 18.2%). The disease control rate (PR+SD) at week 6 was 100%. The median PFS was 7 months (range: 3- 18; Trabectedin alone for LMS= 4.3 mos; Dacarbazine alone = 1.6 mos); 6-month PFS rate, 55%; median OS 18.2 months (range: 4- 32); 6-month OS rate, 91%. Response was not related to PD-L1 positivity but both patients with PR were ER+/PR+ and had uterine LMS. There were 15 evaluable subjects for OS analysis under the Intention-to-Treat (ITT) population who received at least one dose of study drug. The median OS was 12 (range 0-32) months; 6-month OS rate, 60%. **Safety:** Eight of 15 (53.3%) patients experienced at least one ≥ Grade 3 treatment-related adverse event (TRAE). The ≥ Grade 3 TRAEs include anemia (n=3), thrombocytopenia (n=3), neutropenia (n=1), increased ALT (n=1), increased GGT (n=1), decreased LVEF (n=1), dehydration (n=1), hyponatremia (n=1). There were no new safety signals noted in this study. **Conclusion:** These results suggest that (1) By indirect comparison, the combination regimen using Talimogene laherparepvec, Nivolumab & Trabectedin may be more effective as second/third-line/fourth therapy for advanced leiomyosarcoma with manageable toxicity, (2) Response is not related to PD-L1 positivity and (3) The best responders are patients with HR+ uterine LMS.

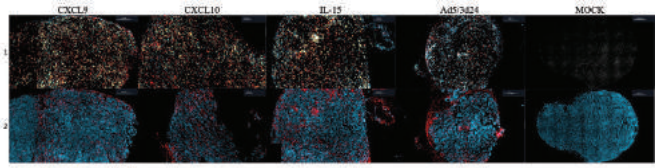
55 Cytokine Encoding Adenoviruses Advance T cell Recruitment to Cancerous Tumors of Renal Cell Carcinoma

Michaela Feodoroff[1], Firas Hamdan[1], Manlio Fusciello[1], Sara Feola[1], Gabriella Antignani[1], Salvatore Russo[1], Jacopo Chiaro[2], Teijo Pellinen[3], Katja Välimäki[3], Minna Malmstedt[4], Antti Rannikko[1], Vilja Pietiäinen[1], Mikaela Grönholm[1], Vincenzo Cerullo[1]

[1]University of Helsinki, Helsinki, Finland,[2]University of Helinski, Helinski, Finland,[3]Institute for Molecular Medicine Finland, Helsinki, Finland,[4]HUS, Helsinki University Hospital, Helsinki, Finland

Oncolytic adenoviruses have become commonly used viral vectors for cancer immunotherapy worldwide. Such viruses have shown to work in synergy with checkpoint inhibitors, featuring a potential combination for clinical treatment. Modifications in the viral genome give further potential of such viruses to serve as gene transfer vehicles to target cancer cells of malignant phenotype, while simultaneously triggering the activity of the patient´s immune system. Traditional cancer therapies have prolonged the life of many cancer patients. However, many patients do not benefit from such therapies. This is often due to lack of tumor infiltrated immune cells. Molecular messengers known as cytokines, hold the potential to switch a cold tumor into a hot tumor with increased immune cell infiltration. Consequently, we designed cytokine encoding adenoviruses to facilitate the immune cell infiltration based on their role, mainly, in T-cell attraction. Adenoviruses encoding for CXCL9, CXCL10 and IL-15, respectively, were generated using Gibson Assembly cloning method.

To tackle the lack of relevant preclinical testing platforms for cancer immunotherapy, we use patient derived organoids from clear cell renal cell carcinoma as *ex vivo* models to predict the biological responses elicited in humans. Such patient material and T-cells matching the patient-specific immune profile from freshly isolated PBMCs, are obtained from an ongoing precision medicine study DEDUCER (Development of Diagnostics and Treatment of Urological Cancers), together with the iCAN Digital Precision Medicine Flagship. To advance the clinical relevance of our *in vitro* testing platforms, we use immunodeficient humanized NSG mice as renal cancer models to evaluate the chemotactic effect of human PBMCs *in vivo*. Here, we show the effect of oncolytic adenoviruses armed with CXCL9, CXCL10 and IL-15 cytokines to infect and secrete high amounts of respective protein in tumor cells. Consequently, immune cells are attracted and migrate to the site of infection. Furthermore, we show the presence and localization of migrated intratumoral T-cells in FFPE animal tissue samples using multiplex immunohistochemistry. An increase in the number of intratumoral CD4+ and CD8+ T-cells were observed in all groups treated with armed virus compared to unarmed and MOCK groups, suggesting enhanced immune cell -mediated cancer cell killing. The presence of transgenes was observed to be restricted to the tumor site, indicating local viral spread. In conclusion, our study show that modified adenoviruses can enhance T-cell recruitment to tumor cells both *in vitro* and *in vivo*, highlighting the potential clinical use of modified oncolytic adenoviruses as a therapeutic approach for urological solid tumors.



56 PD-L1 siRNA and Cyclic Dinucleotide Based Immune Reprogramming for Cancer Immunotherapy

Fanfei Meng

Department of Industrial and Physical Pharmacy, Purdue University, West Lafayette, IN

1. Introduction Immunotherapy has shown great therapeutic efficacy in blood cancer treatment, such as leukemia. However, it showed limited therapeutic efficacy in solid tumor treatment, such as melanoma and breast cancer. Several factors contribute to the low therapeutic efficacy of solid tumor treatments, including ineffective drug delivery efficacy to solid tumors, limited tumor neoantigens exposure, and an immunosuppressive tumor microenvironment. Currently, local cancer immunotherapy has attracted much attention, and many local immunotherapy clinical trials have been initiated. The underlying hypothesis is that treating locatable and accessible tumors will stimulate antitumor immunity in situ, resulting in systemic effects against distant tumors. To develop effective local immunotherapy, I have produced a nanoformulation loaded with PD-L1 and/or Cyclic dinucleotide (CDN). The nanoformulation consists of three components: an immunoative polymer 2E' that activates antigen-presenting cells to increase antigen-presenting ability; an immunogenic cell death inducer (ICD) paclitaxel (PTX) that kills tumor cells and exposes tumor neoantigens; PD-L1 siRNA (siPD-L1) inhibiting PD-L1 expression or CDN activating STING signal pathway. I have shown that a single local administration of 2E'/PTX/siPD-L1 or 2E'/PTX/CDN induces strong antitumor immunity, resulting in immediate regression of large established tumors, tumor-free survival, abscopal effect on distant tumors, and the resistance to tumor rechallenge. **2. Methods**An immunoactive polymeric assembly 2E'/PTX/siPD-L1 was developed and visualized by transmission electron microscopy. Cytotoxicity, cellular uptake, pD-L1 silencing, and immunostimulatory effects of 2E'/PTX/siPD-L1 were tested on CT26 colorectal carcinoma and bone marrow-derived dendritic cells (BMDC). Antitumor and immune activation effects of intratumorally injected 2E'/PTX/siPD-L1 and 2E'/PTX/CDN were evaluated in mouse models of syngeneic CT26 tumor and B16F10 tumor. **3. Results** *Characterization:* 2E'/PTX/siPD-L1 showed a spherical shape with an average diameter of 50 nm. 2E'/PTX/siPD-L1 showed selective toxicity to cancer cells. 2E'/PTX/siPD-L1 entered cancer cells and inhibited the PD-L1 expression in cancer cells. Furthermore, 2E'/PTX/siPD-L1 induced the secretion of immunostimulatory cytokines from immune cells and exposure of calreticulin (CRT) on cancer cells.*2E'/PTX/siPD-L1 primes systemic antitumor immunity in poorly immunogenic B16F10 tumors:* 2E'/PTX/siPD-L1 inhibited tumor growth in both treated and untreated distant tumors, yielding the smallest tumor size on both sides compared with other groups. 2E'/PTX/siPD-L1 also induced a significant increase of melanoma antigen-specific T cells compared to D5W or 2E'/PTX/siNeg (negative control siRNA), supporting that 2E'/PTX/siPD-L1 activated systemic antitumor immunity in B16F10 tumor model. *2E'/PTX/CDN eliminates established tumors and develops antitumor immunity in CT26 model:* 2E'/PTX/CDN showed the best antitumor effects: 86% of the treated mice survived tumor-free after a single treatment. When rechallenged with live CT26 cells, none of the tumor-free mice grew tumor for 66 days (duration of observation). These results indicate that the single intratumoral treatment of 2E'/PTX/CDN induced strong antitumor immune memory. However, the surviving animals did not reject unrelated syngeneic 4T1 tumors, indicating that the antitumor immunity was tumor-specific. **4. Conclusion** 2E'/PTX/siPD-L1 showed selective toxicity against cancer cells as compared to immune cells. 2E'/PTX/siPD-L1 and 2E'/PTX/CDN induced potent antitumor immunity by a single intratumoral administration, resulting in immediate regression of large established tumors, tumor-free survival, abscopal effect on distant tumors, and the resistance to tumor rechallenge.

57 Cis-Targeted Cytokines for Specific Stimulation of CAR T Cells

Sara Sleiman[1], Nathan D. Mathewson[2], Feng Shen[1], Kelly D. Moynihan[2], Wei Chen[2], Paul Bessette[2], Chris Kimberlin[2], Danielle Pappas[2], Terrence Park[2], Andy Yeung[2], Ivana Djuretic[2], Saar Gill[1,3]

[1]Center for Cellular Immunotherapies, University of Pennsylvania, Philadelphia, PA,[2]Asher Biotherapeutics, South San Francisco, CA,[3]Division of Hematology-Oncology, Department of Medicine, Perelman School of Medicine at University of Pennsylvania, Philadelphia, PA

INTRODUCTION In vivo behavior of CART cells correlates with improved outcomes, spurring interest in the development of approaches to selectively control their in vivo expansion after infusion. While IL-2

family cytokines can be administered to achieve this goal, cognate receptors for these cytokines exist on multiple types of immune cells, leading to toxicity and the expansion of undesired cell populations (e.g. Tregs). This problem can be addressed by engineering IL-2 variants with biased affinity to IL-2R subunits modestly increasing their selectivity, or by introducing orthogonal cytokine/cytokine receptors. The former system is not specific, and the latter is complicated by the need for genetic modification of cytokine receptors on engineered T cells. To address these challenges, we developed IL-2 or IL-21 fusion molecules that selectively activate CART cells by recognizing an extracellular tag that is an integral component of existing, commercially available CARs. METHODS Cis-targeted cytokine fusions are comprised of (1) a targeting antibody directed against an exogenous tag expressed on the CAR-T surface (truncated non-signaling epidermal growth factor receptor [EGFRt] that is co-expressed with the CAR) and (2) a cytokine mutein with attenuated binding to its cognate receptor. Specifically, IL-2 muteins exhibit diminished binding to IL2Rα/β while the IL-21 mutein has diminished binding to the IL-21R subunit. The fusion molecule targeting arm provides avidity to the attenuated cytokines, resulting in selective activation of the associated cytokine receptors on CAR-Ts. Both molecules were characterized in vitro using primary human CAR T cells. In vivo activity was tested by IV injection of ultra low-dose human CART19 (1 x 10^5) into immunodeficient mice engrafted with a B-ALL cell line. Cis-targeted cytokine fusions were administered i.p. once, one day later. Anti-tumor activity was measured by bioluminescence imaging (BLI) and analysis of peripheral blood were performed weekly to examine the expansion, persistence, and phenotype of the CAR-Ts. RESULTS The specificity of the EGFRt-IL2 molecule was demonstrated by its ability to selectively induce pSTAT5 signaling and EGFRt-IL21 molecule by pSTAT3, resulting in >100-fold preferential STAT activity in CAR-T cells compared to non-CAR cells. In vivo BLI revealed that when a suboptimal dose of CAR-Ts were injected into leukemia-bearing mice, both EGFRt-IL2 and EGFRt-IL21 induced substantial tumor regression (Figure 1). EGFRt-IL2 induced a stronger initial expansion of CART19 in vivo than EGFRt-IL21 (median 964.98 CART19 T cells/μL blood vs 22.98 CART19 T cells/μL blood, p< 0.0001 on day 13). Both therapies were superior to CART19 therapy alone without exogenous cytokine and were well tolerated in mice. CONCLUSION Cis-targeted IL-2 or IL-21 cytokine fusion molecules selectively activate CAR-Ts in vitro and enhance in vivo anti-tumor activity and survival. Temporal control of the cis-targeted cytokines directed by anti-tag antibodies represents a promising approach to enhance CAR T cell therapies.

58 Correlative Results of a Phase 1/2 Study of Pembrolizumab Combined with Blinatumomab in Patients with Relapsed/ Refractory (r/r) ALL

Alan Daniel Macias, Karamjeet Sandhu, Marissa M. Del Real, Kim Young, Asucena L. Beltran, Kenneth Ng, Jianying Zhang, Joycelynne Palmer, Marjorie Robbins, James O'Hearn, Mojtaba Akhtari, Guido Marcucci, Lihua E. Budde

City of Hope, Duarte, CA

Blinatumomab (blina), a bispecific anti-CD19/CD3 antibody, has resulted in improved outcomes in patients (pts) with r/r B-ALL compared to conventional chemotherapy. However, over half of treated pts fail to respond (CR/CRh/PR, 44%) and the majority of responders eventually relapse without consolidation therapy. Upregulation of PD-L1 on leukemic blasts and PD-1 on T cells have been shown to associate with resistance to blina in preclinical and clinical studies. Blockade of the PD-1 pathway represents a reasonable strategy to augment blina efficacy. Thus, we set out to test the combination of pembrolizumab (pembro) and blina in a single arm, phase 1/2 trial (NCT03512405). We investigated preliminary correlative results from samples collected from patient peripheral blood (PB), bone marrow (BM), and serum, including immune cell phenotypes via multi-color flow cytometry (MFC), the TCR repertoire via TCRβ sequencing, and serum cytokine levels via the Luminex Cytokine 30-Plex Human Panel. Pts (≥18 years; ECOG <1) with CD19+ r/r B-ALL received standard blina 9 μg/day on days 1-7 and 28 μg/day on days 8-28 in cycle 1 and on days 1-28 in subsequent cycles. Pembro 200 mg was given on day 15 in cycle 1 and on days 1 and 22 in subsequent cycles. PB and serum samples were collected at pretreatment and on days 1, 8, 15, 22, and 29 of cycle 1, at the end of subsequent cycles, and at standard of care (SOC) times. BM samples were collected before treatment, in the last week of cycles 1 and 2, and at SOC times. We used conventional and spectral MFC to phenotype immune cell populations in PB and BM, including T regulatory (Treg) cells, tumor cells, and T cells. We also quantified the number of CD19 molecules using quantitation beads. Additionally, we used the ImmunoSeq platform to do bulk TCRβ sequencing of PB samples at pretreatment and days 1, 8, 15, 22, and 29 after the first cycle and on day 36 after the second cycle of treatment. Finally, we measured serum cytokine levels using Luminex. As of January 6, 2023, 7 pts were enrolled to phase 1 with one unevaluable, and 12 patients to phase 2. Eighteen evaluable pts received a median of 2 (1-6) cycles of treatment. Thirteen of 18 evaluable pts (72%) achieved flow cytometry MRD negative (MRD-) CR/CRi after a median of 1 (1-2) cycle. Twelve of 18 evaluable pts were still alive at the data cut-off. Flow cytometry analysis showed that PD-1 detection decreased among both responders (n=12) and non-responders (n=5) after pembro administration in T cells from PB, but not among responders (n=12) and non-responders (n=4) in T cells from BM. There was no difference in the percentage of Treg cells in responders vs. non responders in PB and BM. Responders after cycle 1 had higher CD8+ T cells which increased further in PB but not BM following pembro administration. Additionally, we did not detect expression of exhaustion markers in non-responders. We quantitated CD19 levels in B cells at pretreatment and preliminary results suggest CD19 expression levels do not correlate with response. Serum cytokine levels suggest no

differences in levels among responders (n=9) vs. non-responders (n=4). Correlative studies, including bulk TCRβ sequencing analysis is ongoing. Encouraging safety and anti-leukemic activity have been seen in the majority of treated patients (CR/CRi, 72%), and most were MRD-. The phase 2 portion of the trial continues to recruit patients. Preliminary correlative studies suggest PD-1 levels are higher in BM vs. PB from pretreatment and day 29 of cycle 1. Additionally, Treg cells were not elevated in non-responders as has been previously described. The quantitation of CD19 in BM suggests that high CD19 levels are not a prerequisite for response.

59 Epigenetic-Mediated Cancer Rewind Enhances Oncolytic Immunovirotherapy

Salvatore Russo[1], Sara Feola[1], Michaela Feodoroff[1], Jacopo Chiaro[1], Gabriella Antignani[1], Manlio Fusciello[1], Firas Hamdan[1], Riikka Mölsä[1], Lorella Tripodi[2], Lucio Pastore[3], Mikaela Grönholm[1], Vincenzo Cerullo[1]

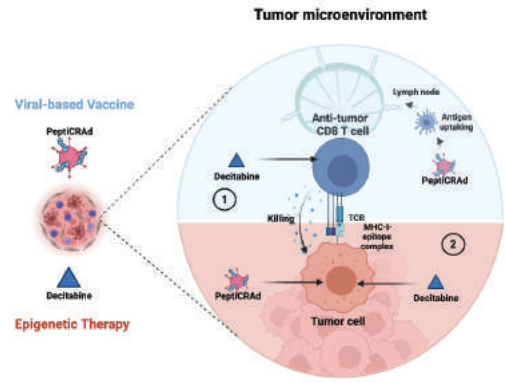
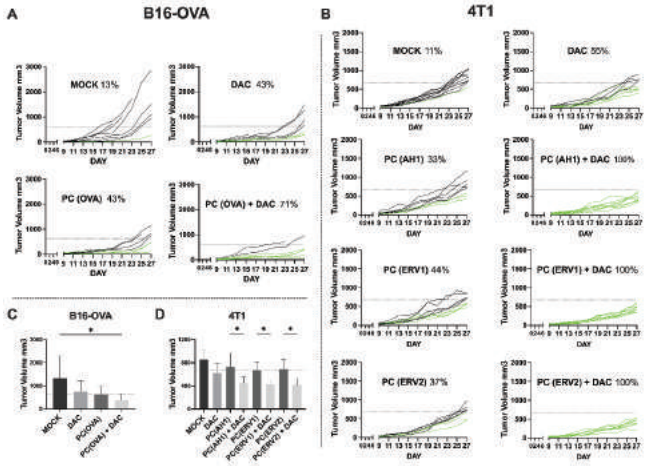
Cancer immunotherapy requires the natural or artificial generation and boosting of a specific anti-tumor CD8+ T cell-driven immune response. To be recognized and killed by effector CD8+ T cells, tumors should have functional and sustained antigen expression within the MHC-I complex of mutated or tumor-associated antigens (TMAs or TAAs); however, upon genetic and epigenetic alterations of the antigen processing and presenting components, cancer cells escape anti-tumor immune response within the tumor microenvironment (TME). As a result, poorly immunogenic tumors are refractory to conventional immunotherapy and oblige patients to severe chemotherapy and radiotherapy regimens. In this context, oncolytic viruses (OVs) and DNA methyltransferase inhibitors (HMAs) represent promising tools to boost cancer immunogenicity by enhancing cancer antigen presentation and improving CD8+ T cell effector functions in-vivo. Because of that, combining these two agents constitutes a potential synergistic strategy to overcome cancer immunotherapy limitations. However, studies applying epigenetic therapy benefits to viral-based immunotherapy are limited so far. In this study, we evaluated FDA-approved HMAs in combination with OVs for boosting tumor immunogenicity in melanoma and triple-negative breast cancer (TNBC). Specifically, we assessed the combined impact on HLA-I surface expression in cancer cell lines and activation of human CD8+ T cells. Then, we tested our approach in cancer-bearing mice where the epigenetic therapy enhanced oncolytic therapy in controlling the tumor growth, remodeling of the TME, and improved specific anti-tumor CD8+ T cell response generation.



Decitabine (DAC) promotes CD8+ T cell activation and boosts tumor immunogenicity in the tumor microenvironment (TME). Synergistically, our viral-based immunotherapy PeptiCRAd reshapes the TME and primes specific anti-tumor CD8+ T cells. The combination of the two agents generates an enhanced anti-tumor immune response.



Tumor growth in a syngeneic mouse model of B16-OVA and 4T1. Mice were treated with PBS (Mock), Decitabine (DAC), Oncolytic vaccine (PeptiCRAd, PC), and PC + DAC. Tumor growth curves for each treatment are shown in (A) and (B); the number of mice in the B16-OVA model was 7; the number of mice in the 4T1 model was 9-10. Tumor size (mm3) at day 27 post-tumor implantation in B16-OVA (C) and 4T1 (D) models. Levels of significance were set at *p<0.05, **p<0.01, ***p<0.001, and ****p<0.0001 (two-way ANOVA with Tukey's multiple comparisons correction to compare individual groups). Single curves represent individual mice for each treatment group. The dotted line represents the tumor volume threshold to define responder mice. Experimental group names are shown together with the relative responder percentage. Bar plot graphs are shown as mean ± SD.

AAV Vectors - Preclinical and Proof-of-Concept In Vivo Studies I

60 AAV Immuno-Gene Therapy Delivers Vectorized Cytokines to Effectively Treat High-Grade Gliomas

Nathalie Clement[1], Sarah Morris[1], Akela Kuwahara[1], Emily Casey[1], Kyounghee Seo[2], Raquel Santos[2], Miko Fogarty[2], Syuan-Ming Guo[3], Shalin Mehta[3], Yael Rossenberg-Hasson[4], Jennifer Clarke[5], Aaron Diaz[5], Joanna Phillips[6], Tomoko Ozawa[2], David Raleigh[7], Nicole K. Paulk[1,8]

[1]Siren Biotechnology, San Francisco, CA,[2]Neurological Surgery, UCSF, San Francisco, CA,[3]CZ Biohub, San Francisco, CA,[4]Institute for Immunity, Transplantation & Infection, Stanford, Stanford, CA,[5]Clinical Neurology, UCSF, San Francisco, CA,[6]Pathology, UCSF, San Francisco, CA,[7]Radiation Oncology, UCSF, San Francisco, CA,[8]Neurologic Oncology, UCSF, San Francisco, CA

High grade gliomas (HGG) are highly refractory to treatment. Innate interferons (IFN) are pleiotropic immunomodulatory cytokines central to the body's basal cancer immunosurveillance and many therapy-induced immunogenic anti-tumor responses. IFNs drive many anti-tumor functions including being anti-angiogenic, increasing tumor MHC-I expression, stimulating apoptosis, enabling DCs to mature and cross prime T cells against tumor antigens, and increasing the proliferation of activated macrophages and NK cells. Delivering gene therapies to the brain with AAV has proven to be safe and effective. However, common delivery routes (intrathecal, intracerebroventricular and intracisternal) are broadly dispersive and non-targeted. Direct intratumoral delivery limits off-target transduction and reduces neurotoxicity risks. Brain cancer patients often undergo surgical resection or biopsy, providing an opportunity to concomitantly infuse AAV directly using Convection-Enhanced Delivery (CED). This precise and highly targeted method allows for significantly reduced vector doses and improved safety. Here we evaluated safety and efficacy of an immuno-gene therapy utilizing AAV9 vectors to express engineered immunomodulatory payloads (IFNα1, IFNβ, IFNγ, and combinations thereof). We first assessed tumorigenesis and intrinsic therapeutic responses to our suite of vectorized IFNs in primary human HGG organoids. PBS, DMSO and AAV-GFP had no effect on tumor or healthy cerebral cells in the organoids, and HGG tumor cells grew uncontrolled. Temozolomide chemotherapy (the current standard of care) significantly decimated healthy cerebral cells and only slightly delayed HGG tumor growth. In contrast, our AAV immuno-gene therapies with 12 different engineered cytokine payloads, rapidly and selectively reduced tumor size. We next tested our payloads *in vivo* in 3 orthotopic HGG mouse models delivered intratumorally via CED. Our AAVs effectively blocked tumor growth, resulting in tumor regression and significantly prolonged survival in human GBM6 xenografts ($P<0.02$-0.001 and 31-60% complete responses (CR)), mouse GL261 allografts ($P<0.0009$), and human patient-derived xenografts ($P<0.04$; 30% CR); ($n = 450$). Evaluation of tumor-bearing mouse brains demonstrated marked tumor changes following treatment. Within 48hrs following treatment, local intratumoral expression of our engineered IFNs led to widespread tumor cell apoptosis, activated microglia, and reactive astrogliosis. Remarkably, by day 7, there was reproducible tumor eradication, no evidence of residual proliferating cells, no engineered cytokine payload expression, and only residual reactive astrogliosis and microglial responses. This was seen at both the protein level by immunohistochemistry, and at the transcript level by RNAscope. To further probe transcriptomic responses, we performed single cell sequencing on syngeneic mouse brain tumors following treatment and demonstrated that tumor cells specifically exhibited a significant upregulation of genes linked to IFN responses (*Ifit1, Ifit2, Ifitm3*), as well as other immune response genes (*Isg15, Bst2, Trim30a*) and were specific to IFN payload expression, not AAV. These transformative results introduce universal AAV immuno-gene therapies as a promising new drug class that we're advancing to the clinic to treat solid tumors.

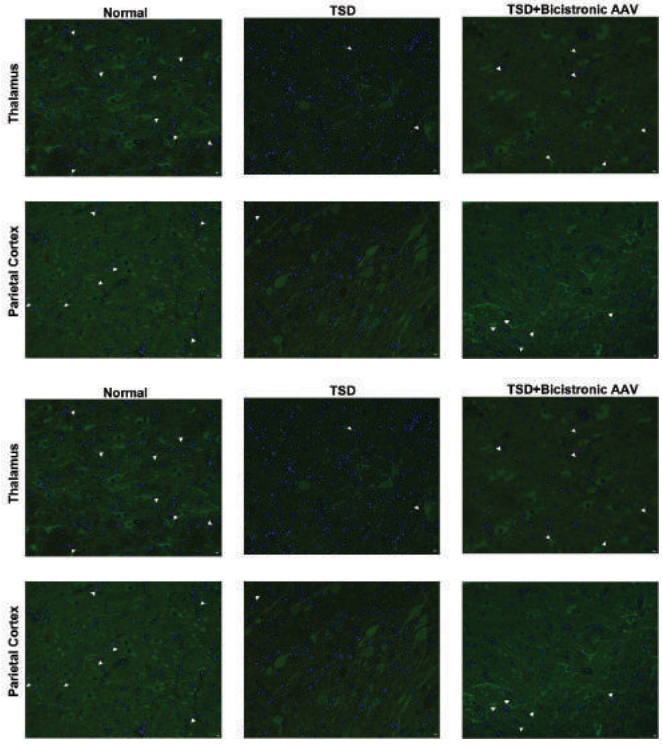
61 Durability of Bicistronic AAV Gene Therapy for Tay-Sachs Disease in the Sheep Model

Toloo Taghian[1], Stephanie Bertrand[2], Abby McElroy[1], Jillian Gallagher[1], Erin F. Hall[1], Hector R. Benatti,[1], Rachel Prestigiacomo[1], William C. Baker[1], Deborah J. Fernau[1], Elise Diffie[3], Amanda L. Gross[3], Rachael Gately[2], Ana Rita Batista[1], Amanda Taylor[3], Jey Koehler[3], Douglas R. Martin[3], Miguel Sena-Esteves[1], Heather L. Gray-Edwards[1]

[1]UMass Chan Medical School, Worcester, MA,[2]Tufts Cummings School of Veterinary Medicine, Grafton, MA,[3]Auburn University, Auburn, AL

Tay-Sachs and Sandhoff diseases (TSD, SD) are fatal neurodegenerative disorders, caused by mutations in alpha or beta subunit respectively, of enzyme Hexosaminidase A (HexA). Hex A deficiency results in GM2 ganglioside storage and subsequent neuronal death. While infantile and juvenile forms are fatal, late onset patients become wheelchair bound in mid-life.Here we update on preclinical efficacy of a bicistronic AAV9 gene therapy in TSD sheep after combination of bilateral ICV, cisterna magna, and lumbar intrathecal cerebrospinal fluid injections (CSF, n=5 long term; n= 4 at 5 months). Survival is currently at 41±18 months, with two sheep ongoing. Neurologic disease was mild at euthanasia for all the deceased sheep who were euthanized due to 1) cervical trauma from ramming at 10 months 2) right sided heart failure at 46 months and 3) metacarpal ligament rupture at 42 months. The remaining two sheep presently have mild neurological disease at 48 and 60 months. The untreated TSD sheep lifespan is ~ 9±0.5 months. Post-mortem: The CSF treatment cohort resulted in above normal Hex A levels (3X-20X) throughout the brain and spinal cord at 4 months and 4 years after gene therapy. GM2 levels in brain and spinal cord returned to normal, except for thalamus and temporal cortex where GM2 levels decreased by 50%. Histopathology in TSD brain showed reduced number and swollen neurons (MAP2 staining) and a reduction of oligodendrocytes (olig2). In CSF AAV9 treated sheep, normalized neuronal morphology and increased number of oligodendrocytes (Fig. 1) was observed. Staining for astrocytes (GFAP) and glia (Iba1) is ongoing, and preliminarily a reduction of gliosis is observed in the in CSF treated cohort. Biomarkers: HexA in CSF of long-term cohort remained in normal range up to 3 years, after which a slow but steady decrease was observed. The inverse was observed where with GM2 in CSF. Interestingly, the CSF treated cohort had serum

anti AAV9 neutralizing antibodies (Nab)>1:10 at time of treatment that increased over period of 4 months for three sheep. Two sheep that showed highest pretreatment titer at 1 and 2 months, had 50% less HexA in CSF. Magnetic resonance spectroscopy and diffusion tensor imaging showed normalization of markers of neuronal health, myelination, microstructural integrity and metabolism. We are moving toward a human clinical trial for juvenile and late onset TSD and SD patients using combined bilateral ICV, cisterna magna and lumbar intrathecal AAV9 injection (1.5E15vg divided across sites). The pre-IND application was agreed upon by FDA and includes a non-GMP AAV in phase I/II clinical trial, a GLP-like non-human primate study (n=6) and a full GLP rat study.**Fig 1**. MAP2 (green) and Olig2 (magenta, arrowhead) IF in thalamus and parietal cortex of normal, untreated TSD sheep and bicistronic AAV treated TSD sheep. Scale bar 5µm.



62 More Than Nine Year Survival of a GRMD Dog after Injection of AAV-Microdystrophin Gene Therapy

Caroline Le Guiner[1], Bodvael Fraysse[1], Isabelle Testault[2], Karim Wahbi[3], Célia Couzinié[1], Oumeya Adjali[1], George Dickson[4], Estelle Creoff[5], Philippe Veron[5], Serge Braun[5]

[1]TaRGeT Lab, Nantes Université, CHU de Nantes, INSERM, Nantes, France,[2]Centre Hospitalier Vétérinaire Atlantia, Nantes, France,[3]Cardiology Unit, Cochin Hospital & APHP, Institut de Myologie, Hôpital Pitié-Salpétrière, Paris, France,[4]Royal Holloway, University of London, Egham, United Kingdom,[5]Généthon, AFM-Téléthon, Evry, France

Duchenne Muscular Dystrophy (DMD) is a X-linked inherited muscle-wasting disease primarily affecting young boys with a prevalence of 1:5,000. The disease is caused by loss-of-function mutations in the gene encoding for the Dystrophin protein and is characterized by systemic, progressive, irreversible and severe loss of muscle function. Among vector systems that allow efficient *in vivo* gene transfer, recombinant Adeno-Associated Virus vectors (rAAV) hold great promise and allow very efficient transduction of skeletal and cardiac muscles. However, full-length dystrophin cDNA exceeds the packaging capacity for a single rAAV gene-delivery cassette. Therefore, truncated versions namely microdystrophins (MD) have been designed and optimized to contain few clinically important regions of the dystrophin protein. In particular, a MD variant, termed MD1, was optimized for mRNA stability and translation efficiency, and packaged in a rAAV8 under the control of a synthetic, muscle- and cardiac-restricted promoter. We previously demonstrated safety and 2-year efficacy of rAAV8-cMD1 (canine MD1) gene therapy after systemic peripheral administration of vector in Golden Retriever Muscular Dystrophy (GRMD) dogs, the canine model of DMD. GRMD dogs received at 2 months of age a systemic intravenous administration of 1E14 vg/kg of rAAV8-cMD1 without immunosuppression. This results in significant and sustained levels of microdystrophin in skeletal muscles and reduces dystrophic symptoms. No toxicity or adverse immune consequences of vector administration were observed for over 2 years after rAAV-MD injection (Le Guiner et al, 2017). This study, among others, paved the way towards a phase 1/2 multicentric clinical trial of single administration by intravenous (IV) route in 6 to 10-year-old ambulant boys with DMD, that was initiated in 2021 by Genethon. Most of the GRMD dogs that were included in our preclinical study were sacrificed few months after injection in order to document the efficacy and the safety of the treatment. However, we maintained one dog for very long-term follow-up. As of today, this dog is still alive, more than 9 years post-vector injection, whereas life expectancy of untreated GRMD dogs rarely exceeds 2 to 3 years. During these 9 years, this very active dog showed stable clinical scores, between 70 and 80 % (a score of 100% being those of healthy golden retriever dogs). Gait improvement, evaluated using Locometrix system, was also preserved during these 9 years, at levels that were very close to healthy dogs scores. All clinical parameters, including cardiac function, respiratory function, digestive function, neurological function, but also blood clinical chemistry and hematology parameters showed no or only minor evolution during this follow-up. This striking preservation of the cardiac function is never seen in our untreated GRMD dogs. No deleterious immune response (against cMD1 or AAV8) was detected either. All the data obtained during this multi-year follow-up will be presented. At a time when several rAAV-MD products are being tested in young DMD patients, such results are of importance to demonstrate that this gene therapy can be sustained for many years, with no decline in clinical improvement.

63 Intravitreal Gene Therapy of Retinitis Pigmentosa (RP) Associated with Mutations in the *CNGA1* Gene (*CNGA1*-RP)

Lena Zobel[1], Victoria Splith[1], Michael D. Bartoschek[1], Volker Geiss[1], Janhavi Pandurangi[1], Dina Otify[2], Verena Mehlfeld[2], Miriam Esgleas[1], Elvir Becirovic[3], Martin Biel[2], Stylianos Michalakis[4]

[1]ViGeneron GmbH, Planegg-München, Germany,[2]Pharmacy, LMU Munich, München, Germany,[3]Ophthalmology, University of Zurich, Schlieren, Switzerland,[4]Ophthalmology, LMU Munich, München, Germany

Pathogenic sequence variants in the cyclic nucleotide-gated (CNG) channel subunit alpha 1 (*CNGA1*) gene cause autosomal recessive retinopathy of the retinitis pigmentosa (RP) type. Treatments for *CNGA1*-RP are currently not available. In this study, we developed and tested a novel intravitreal gene supplementation therapy suitable for clinical translation. The therapy uses a novel recombinant adeno-associated virus (AAV) vector based on the engineered AAV2.NN capsid, carrying a genome that features a human rhodopsin promoter driving rod-specific expression of full-length human CNGA1. AAV2.NN.hCNGA1 was evaluated for potency and safety *in vitro* and *in vivo*. In particular, *in vitro* transgene expression was confirmed at the transcript and protein level in HeLa and HEK293 cells engineered to transactivate expression from the rhodopsin promoter. In addition, transgene expression was established in human retinal organoids grown from hIPSCs. *In vivo* potency testing was performed in the *Cnga1* mutant (*Cnga1*MUT) mouse model of *CNGA1*-RP that lacks expression of the rod CNG channel. Increasing doses of AAV2.NN.hCNGA1 were delivered through single intravitreal injection in 3-week-old *Cnga1*MUT mice and the treatment effect was assessed over a follow-up period of 8 weeks at the level of retinal morphology, retinal function, and transgene expression. We found that intravitreal treatment with AAV2.NN-CNGA1 resulted in efficient expression of the human CNGA1 protein in mouse rods and was able to normalize the expression of the endogenous mouse CNGB1 subunit, which together with CNGA1 forms the native heterotetrameric CNG channel in rod photoreceptors. The treatment led to a dose-dependent recovery of rod photoreceptor-driven function and preservation of retinal morphology in *Cnga1*MUT mice. A GLP-safety study in rabbits applying single intravitreal injection followed by a 6-month post treatment observation period confirmed safety of AAV2.NN.hCNGA1. In summary, these results demonstrate the efficacy and safety of hCNGA1 gene supplementation therapy and support the translation of this approach toward future clinical application.

64 AAV Vaccine in a Preclinical Spontaneous Canine Model of Oral Melanoma

Ester Molina[1], Colin Caine[1], Karina Krotova[1], Hisae Kuoch[1], Antonella Borgatti[2,3,4], George Aslanidi[4,5,6]

[1]The Hormel Institute, University of Minnesota, Austin, MN,[2]College of Veterinary Medicine, University of Minnesota, St. Paul, MN,[3]Clinical Investigation Center, University of Minnesota, St. Paul, MN,[4]Masonic Cancer Center, University of Minnesota, Minneapolis, MN,[5]Hormel Institute, University of Minnesota, Austin, MN,[6]Institute Molecular Virology, University of Minnesota, Minneapolis, MN

Oral melanoma (OM) is a disease with low incidence but high mortality in the US. Early detection is difficult, so metastasis in distant organs is the main cause of death. Standard of care therapy involves intense chemotherapy and radiotherapy, which may cause severe adverse events and it is generally ineffective. In contrast, immunotherapies including cancer vaccines, harness of the immune system of the patients to control and eliminate malignancy, sparing healthy cells and tissues. Similar to mucosal melanoma in humans, canine OM is a very aggressive disease that readily spread to other parts of the body particularly the lungs and lymph nodes with a life expectancy of 6-12 months with standard of care treatments. Like humans, dogs with naturally occurring tumors have an intact immune system and many studies have shown that dogs offer a robust, clinically relevant model to study novel immunotherapies. In current pilot study, we used novel AAV-based vaccination in dogs with spontaneous OM in conjunction with standard of care local therapy. The novel vaccine developed in our lab addressed several limitations of previous AAV vaccines, such as low efficiency and immunogenicity, lack of ability to activate $CD4^+$ T helper cells, and functional impairment of $CD8^+$ T cells caused by persistence of antigen expression at the site of injection. The major innovation of the vaccine is fusion of truncated tumor antigen with MHC class I molecule-trafficking signals, which dramatically increases antigen-specific $CD4^+$ and $CD8^+$ T cell expansion and their killing capabilities. Specifically for dog study we used optimized AAV-based multivalent vaccine carrying pre-melanosome protein gp100, Tyrosinase (Tyr) and tyrosine-related protein 1 (TRP-1) to overcome tumors heterogeneity and their ability to escape immune control by losing expression of targeted antigens. Serum was collected from dogs prior to enrollment for evaluation of anti-AAV neutralizing antibody assays (NAB) and to elucidate the suitability of the candidates for the vaccine treatment. The threshold was set at NAB titter ≤1:8. Four (4) dogs were already enrolled in pilot study with major goal to establish toxicity-less minimal dose at $1x10^{12}$ vg/per dog containing equal load of each of the three tumor antigens. The parameters of the study to determine the success of the treatment were collected at different time points include physical evaluation at the veterinary clinic to assess the general welfare of the dogs, blood biochemistry and hematological analysis. Chest radiographies were taken before and after surgery to follow up for lung metastasis. The peripheral blood mononuclear cells (PBMCs) were collected for immunological assessment of antigen-specific $CD8^+$ T cells by IFN-γ ELISPOT assays. We have documented several important observations. None of the dogs experienced adverse events related to the vaccine. One out of four dogs showed clear evidence of immune response to all three AAV encoded antigens. One dog experienced local recurrence and metastasis 3 months after screening and the other dog displayed pulmonary metastasis 6 months

after screening. The other two dogs are alive at the time of writing with no evidence of recurrence or metastasis. Our study documented for the first time the safety of AAV expression tumor antigens in dogs with spontaneous cancer and general utility of non-mutated shared tumor antigens as targets for cancer vaccination.

65 The Longitudinal Kinetics of AAV5 Vector Integration Profiles in Mice

Ashrafali Mohamed Ismail[1], Evan Witt[1], Taren Bouwman[1], Wyatt Clark[1], Bridget Yates[1], Matteo Franco[2,3], Sylvia Fong[1]

[1]BioMarin Pharmaceutical Inc., Novato, CA,[2]ProtaGene CGT GmbH, Heidelberg, Germany,[3]ProtaGene US Inc., Burlington, MA

Introduction: Recombinant adeno-associated virus (rAAV)-based vectors are used clinically for gene transfer for their ability to effectively transduce human cells. Most rAAV vector genomes persist in cells as extrachromosomal episomes. Vector genomes can integrate into the host genome, but the theoretical risk of tumorigenesis may depend on vector regulatory features. We use a mouse model to investigate the long-term kinetics and integration profiles of an rAAV serotype 5 (rAAV5) vector that mimics key features of valoctocogene roxaparvovec (AAV5-hFVIII-SQ), a gene therapy for severe hemophilia A. **Methods:** We used an rAAV5-human alpha-1 anti-trypsin (hA1AT) vector approximately the same size (~5 kb) and containing the same regulatory elements as valoctocogene roxaparvovec. Mice do not develop antibodies to hA1AT protein, thereby allowing long-term studies. C57BL/6J mice received $6x10^{13}$ vg/kg of vector produced in insect *Spodoptera frugiperda* (*Sf*) and HEK293 cells. Mice were sacrificed at weeks 1, 3, 12, 24, and 57, and DNA and RNA extracted from liver samples. Target enrichment sequencing, common integration site (CIS) analysis, and polyclonal-monoclonal distance (PMD) tools were used to characterize vector integration profiles over time. **Results:** The majority (88.7%-97.4%) of vector genome reads retrieved from *Sf* vector-treated mice contained vector-vector junctions, with high representation of inverted terminal repeats, representing the episomal form of the vector (**Figure 1A**). The average vector integration frequency was 2.68 (SD, 0.77) integrations per 1000 cells, and remained constant up to 57 weeks post-dose (**Figure 1B**). To determine if integration sites (IS) accumulate at specific genomic regions, CIS analysis was performed, which attributes a CIS order based on the number of unique integrations spanning a CIS region. In samples from *Sf* vector-treated mice, 5.46% (357 of 6533 total) of CIS had an order ≥5, suggesting a proportion of these integrations occurred in a non-random manner. Integrations were enriched near the transcription start sites of genes highly expressed in the liver ($P = 1x10^{-4}$), and less enriched for groups of genes with low or no liver expression. We used a PMD index tool to evaluate the diversity of IS across samples. This tool estimates clonality by measuring distance between richness, represented by the number of IS within a sample, and evenness, represented by the relative frequencies of each IS. The *Sf* vector-treated samples clustered near the theoretical maximum for polyclonality, indicating a lack of clonal expansion throughout the study (**Figure 1C**). This provides molecular support for the absence of tumors observed by histology in vector-treated mice. Results from mice treated with HEK293-produced vector confirmed those from *Sf*-produced vector. **Conclusions:** Our longitudinal integration analysis suggests the AAV5-hFVIII-SQ integrations occur within 1 week at a low frequency and do not increase with time. Most importantly, we found no evidence of clonal expansion at a molecular or histological level.

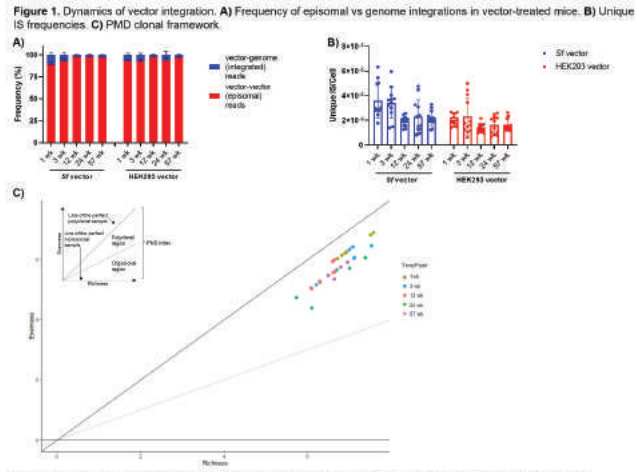

Figure 1. Dynamics of vector integration. **A)** Frequency of episomal vs genome integrations in vector-treated mice. **B)** Unique IS frequencies. **C)** PMD clonal framework.

Based on the properties of Rényi entropies (Rényi, 1961), a clonality plane was constructed considering two extreme components of diversity: richness (total number of IS) and evenness (abundance of each IS). Distance from theoretical maximal polyclonality and monoclonality defines the PMD.
HEK293, human embryonic kidney 293 cells; IS, integration site; PMD, polyclonal-monoclonal distance; *Sf*, Spodoptera frugiperda; wk, week.

RNA Virus Vectors for In Vivo and Ex Vivo Applications

67 Macrophage Inhibitor Clodronate Enhances Liver Transduction of Lentiviral but Not AAV Vectors or mRNA Lipid Nanoparticles *In Vivo*

Sonam Gurung[1], Loukia Touramanidou[1], Dany Perocheau[1], Claudiu Cozmescu[1], Patrick Finn[2], Alexander Cavedon[2], Summar Siddiqui[2], Paolo Martini[2], Lisa Rice[2], Andrea Frassetto[2], John R. Counsell[3], Simon Waddington[4], Paul Gissen[1,5,6], Julien Baruteau[1,5,6]

[1]Great Ormond Street Institute of Child Health, University College London, London, United Kingdom,[2]Moderna Therapeutics, Cambridge, MA,[3]Research Department of Targeted Intervention, UCL Division of Surgery and Interventional Science, University College London, London, United Kingdom,[4]EGA Institute for Women's Health, University College London, London, United Kingdom,[5]NIHR Great Ormond Street Hospital Biomedical Research Centre, London, United Kingdom,[6]Metabolic Medicine, Great Ormond Street Hospital for Children NHS Foundation Trust, London, United Kingdom

Recombinant adeno-associated virus (rAAV) are leading vectors for liver-directed gene therapy. rAAV vectors have been reported with severe adverse events when targeting other organs with high doses. rAAV integration, even at low rate, holds a theoretical risk of insertional mutagenesis. Alternative liver-targeting gene therapy strategies are being developed such as integrating lentiviral (LV) vectors or lipid nanoparticles encapsulating mRNA (LNP-mRNA). For all these strategies to deliver gene therapy, safety is paramount and

administering the lowest minimal effective dose is essential to prevent potential adverse events. Macrophages act as sentinels of the immune system and prime the innate immune response. To maximise safety and increase efficacy, we investigated the potential of macrophage inhibition on liver targeting for two main liver-targeting viral delivery systems, rAAV and LV vector, and with non-viral delivery system, LNP-mRNA. Clodronate is a bisphosphonate which transiently depletes liver and spleen macrophages by 80-90%, following systemic administration. We assessed side-by-side liver transduction after systemic pre-treatment of clodronate liposomes, in both neonatal and young adult wild-type mice for the rAAV (serotype 8) and third generation LV vector modality using GFP. Neonatal and adult clodronate-treated mice showed 10-fold and 2-fold increase of LV-transduced hepatocytes respectively, assessed by immunostaining. Adult clodronate-treated mice showed over 7-fold increased lentiviral vector genome copies (VCN) per cell in the liver. Neonatal and adult mice injected with rAAV did not show any significant difference in transduction in both groups pre-treated with clodronate or not. Similarly, assessing liver GFP protein expression following administration with LNPs encapsulating GFP encoding mRNA, via western blot, did not show difference in the young adult group despite clodronate pre-treatment. This study demonstrates that only LV vector but neither rAAV vectors nor LNPs transfection significantly benefit from systemic clodronate pre-treatment to improve liver transduction. These findings will have translational application for liver-targeted gene therapy programmes.

68 Liver-Directed Lentiviral Gene Therapy is Safe and Curative in Argininosuccinic Aciduria

Loukia Touramanidou[1], Sonam Gurung[1], Hu Yi-Ting[2], Dany P. Perocheau[1], Simon N. Waddington[3], John R. Counsell[4], Adrian J. Thrasher[2], Paul Gissen[1], Giandomenico Turchiano[2], Julien Baruteau[1]

[1]Great Ormond Street Institute of Child Health, University College London, London, United Kingdom,[2]Infection, Immunity and Inflammation Research and Teaching Department, Zayed Centre for Research into Rare Disease in Children, University College London, London, United Kingdom,[3]EGA Institute for Women's Health, University College London, London, United Kingdom,[4]Research Department of Targeted Intervention, UCL Division of Surgery and Interventional Science, London, United Kingdom

The liver-based urea cycle enables nitrogen waste and clearance of neurotoxic ammonia. Argininosuccinic aciduria (ASA) caused by argininosuccinate lyase (ASL) deficiency is the second most common inherited urea cycle defect. Patients present either with neonatal- or late-onset hyperammonaemia, which causes coma and death if untreated, and a high risk of severe cognitive impairment and epilepsy. Curative liver transplantation can be performed in severe cases but requires lifetime immunosuppression. We aimed to test *in vivo* lentiviral gene therapy in neonatal ASL-deficient ($Asl^{Neo/Neo}$) mice. $Asl^{Neo/Neo}$ pups received an intravenous injection of lentiviral vector encoding codon-optimised human *ASL* (LV.coASL) at 4E10TU/kg, versus a control vector encoding GFP at the same dose. LV.coASL-injected animals survived the 12 weeks experiment whilst control mice died within 4 weeks ($p<0.001$). Growth ($p<0.01$), fur coat pattern, ammonia ($p<0.001$), plasma arginosuccinate ($p<0.001$), citrulline ($p<0.01$), and orotate ($p<0.05$) were normalised to those in wild-type mice. Significantly increased ASL expression (+300%; $p<0.01$) and activity (+30%; $p<0.05$) were observed in treated $Asl^{Neo/Neo}$ livers compared to controls. Lentiviral vectors present long-term transgene expression due to their ability to integrate in the host genome. We conducted safety studies to address biodistribution and the presence of genotoxic events driven by the lentiviral vector *in vivo*. 20 neonatal wild-type mice received LV.cohASL vector intravenously versus 20 PBS-injected littermates. No significant difference was shown for survival and liver/body weight ratio. Pathology analysis and dissection of the liver, spleen, and major organs showed no lesions, cysts, or any signs of tumours. Lentiviral biodistribution was predominant in the liver and to a significantly lower extent in the spleen and lungs. This positive outcome was further confirmed by the integration site analysis performed on murine livers at 1 and 9 months after *in vivo* transduction and in human primary hepatocytes at 72 hours after *in vitro* transduction. No clonal dominance was observed so far, and no known oncogenes were over targeted by the lentiviral vectors. Overall, our preliminary studies demonstrated proof of concept of efficacy and safety of *in vivo* lentiviral gene therapy for ASA.

69 Characterization and Cure of a New Mouse Model of alpha-Thalassemia Major

Maxwell Chappell[1], Laura Breda[2], Danuta J. Jarocha[3], Tyler Papp[3], Amaliris Guerra[4], Kandace Gollomp[4], Stavros Glentis[5], Nattiya Teawtrakul[6], Megan Fedorky[4], Antonis Kattamis[5], Abdulmalik Osheiza[4], Valentina Ghiaccio[4], Michael Triebwasser[7], Hamideh Parhiz[8], Stefano Rivella[4]

[1]CHOP, Philadelphia, PA,[2]CHOP, Philadelphiabreda, PA,[3]University of Pennsylvania, Philadelphia, PA,[4]Children's Hospital of Philadelphia, Philadelphia, PA,[5]University of Athens, Athens, Greece,[6]Khon Kaen University, Khon Kaen, Thailand,[7]University of Michigan, Ann Arbor, MI,[8]University of Pennsylvania, Gladwyne, PA

α-Thalassemia (α-thal) is caused by insufficient production of the α-globin protein. In patients with severe α-thal, chronic blood transfusion or allogeneic bone marrow transplantation are required for survival. Alternatively, patients could be treated by autologous bone marrow transplant (BMT) following *ex vivo* transduction with a human α-globin expressing lentiviral vector. However, a proper model system and vector must be established for the development of such a treatment. We created a conditional knockout (cKO) mouse model that has been edited to remove *Hba-a2*, while inserting loxP sites flanking *Hba-a1* ($Hba\text{-}a1^{fl}/Hba\text{-}a2^{ko}$). Homozygous cKO animals ($Hba\text{-}a1^{fl/fl}/Hba\text{-}a2^{ko/ko}$) demonstrate a mild phenotype. To achieve complete deletion of the α-globin genes ($Hba\text{-}a1^{ko/ko}/Hba\text{-}a2^{ko/ko}$) in HSC we developed a novel lipid nanoparticle (LNP) preparation with an antibody to target CD117 and deliver nucleoside-modified mRNA coding for Cre recombinase. Cells showed the expected deletion of the α-globin genes and were injected into myeloablated recipient mice. These chimeras demonstrated a lethal phenotype characterized by abnormal red cells only expressing abnormal hemoglobin (β-chains tetramers/HbH), elevated hematocrit, splenomegaly, and iron deposition in the liver, as well as high levels of erythropoietin in the kidney and low levels of hepcidin in the liver (Fig. 1A). We screened multiple potential erythroid specific lentiviral vectors in both mouse and human cell lines and identified a promising candidate, ALS20αI, which at VCN=1 produced human α-globin protein equivalent to that of a single endogenous

α-globin gene. Myeloablated recipient mice transplanted with Cre-CD117-LNP-treated cKO BM die roughly 7 weeks post-transplant with the expected pathological phenotype. In contrast, mice receiving BM treated with Cre-CD117-LNP and ALS20αI (n=10 and VCN>1) all survived long term (>5-months) with normalization of erythropoiesis and iron metabolism. VCNs were proportional to chimeric hemoglobin (human α/mouse β) levels and concurrently HbH was decreased or absent (Fig. 1B). Secondarily transplanted animals showed persistent expression of the therapeutic gene and the beneficial effects observed in primary transplanted mice. Additionally, we tested ALS20αI in erythroid progenitors derived from CD34 cells isolated from patients with both deletional and non-deletional HbH disease, demonstrating reduction in formation of HbH by HPLC (Fig. 1C). In summary, we have developed a new mouse model for α-thal with a lethal and reproducible phenotype. The features of these animals (hypoxia, persistent and high levels of RBC in circulation) are remarkably similar to patients affected by Bart's Hydrops Fetalis Syndrome (BHFS; no α-chains present), rescued by in utero blood transfusion. These data strongly support the use of ALS20αI for the cure of severe forms of α-thal, as the safe level of 2 copies may be sufficient to rescue patients affected by BHFS, while 1 copy may be sufficient to cure patients affected by HbH disease.

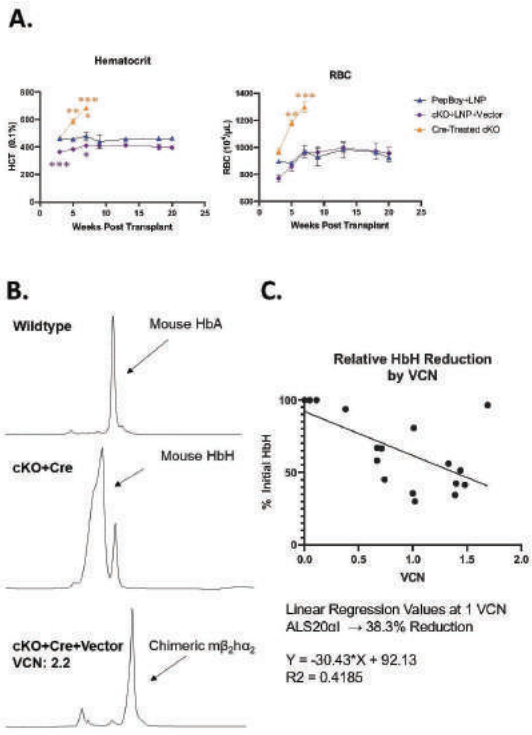

Figure 1: (A) Hematocrit and RBC concentration measured in mice transplanted with Cre-treated cKO HSC, Cre-treated cKO HSC with ALS20αI, and Pepboy HSCs. **(B)** Cation Exchange (CATEX) HPLC chromatograms of the listed groups showing the presence of mouse HBA, HBH, and chimeric hemoglobin. **(C)** Relative reduction of HbH peak area by VCN as measured by CATEX HPLC.

70 Liver-Directed Lentiviral Gene Therapy for ARC Syndrome

Andrei Claudiu Cozmescu[1,2], Loukia Touramanidou[1], Sonam Gurung[1], Dany Perocheau[1], John R. Counsell[3], Rajvinder Karda[4], Simon Waddington[4], Julien Baruteau[1,2,5], Paul Gissen[1,2,5]

[1]Great Ormond Street Institute of Child Health, University College London, London, United Kingdom,[2]NIHR Great Ormond Street Hospital Biomedical Research Centre, London, United Kingdom,[3]Research Department of Targeted Intervention, Division of Surgery and Interventional Science, University College London, London, United Kingdom,[4]EGA Institute for Women's Health, University College London, London, United Kingdom,[5]Metabolic Medicine, Great Ormond Street Hospital for Children NHS Foundation Trust, London, United Kingdom

Arthrogryposis-renal dysfunction-cholestasis (ARC) syndrome is a severe multisystemic autosomal recessive disorder caused mostly by mutations in the *vacuolar protein sorting 33 homolog B* (*VPS33B*) gene. ARC patients display hallmark symptoms including congenital joint contractures, renal tubular acidosis, and neonatal cholestatic jaundice. In the liver, the genetic defect hinders the hepatocytes' ability to secrete several bile components, leading to liver fibrosis, cirrhosis, and terminal-stage liver disease. Whilst liver-directed AAV gene therapy proved efficient in adults with haemophilia, the persistence of AAV expression in the liver of small children may not be sustained long-term due to the episomal nature of the vector. Following breakthrough *ex vivo* treatments of several inherited monogenic disorders, studies on animal models suggest that lentiviral vectors might be safe for *in vivo* use. Thus, we tested the safety and efficacy of an LV.*coVPS33B* lentiviral vector in treating the ARC syndrome's liver phenotype. While *in vitro* tests revealed that lentiviral vector treatment restored *VPS33B* expression and function in a liver cell model, *in vivo* studies in neonate liver-specific *Vps33b*(fl/fl)xAlfp-Cre knock-out mice have uncovered a need for increased hepatocyte transduction for phenotypic improvement. Injections with clodronate-encapsulated liposomes transiently reduce the liver resident Kupffer cell population leading to improved lentiviral vector hepatocyte transduction. Thus, we investigated whether pre-treatment with clodronate could impact the therapeutic outcome in neonatal Vps33b(fl/fl)xAlfp-Cre mice. The mice were fed an 0.5% cholic acid diet at 12 weeks to accelerate phenotype development and sacrificed for analysis a week after. The clodronate-primed mice showed reduced weight loss on the cholic acid diet compared to the mice treated only with the LV.*coVPS33B* vector and improved blood parameters. No safety concerns were identified in 9-months old *Vps33b*(fl/-)xAlfp-Cre mice treated with the LV.*coVPS33B*. These results offer hope for ARC patients and highlight the importance of adequate hepatocyte transduction for lentiviral gene therapy.

71 Improving the Efficiency of *In Vivo* Lentiviral Gene Transfer to Hepatocytes, by Targeting Anti-Viral Pathways, and Application to Familial Hypercholesterolemia

Cesare Canepari[1,2], Michela Milani[1], Francesco Starinieri[1], Anna Fabiano[1], Fabio Russo[1], Rossana Norata[1], Martina Rocchi[3], Biffi Mauro[1], Francesca Sanvito[1], Alessio Cantore[1,2]

[1]San Raffaele Telethon Institute for Gene Therapy, Milan, Italy,[2]Vita Salute San Raffaele University, Milan, Italy,[3]IRCCS San Raffaele Scientific Institute, Milan, Italy

Lentiviral vectors (LV) are attractive tools for *in vivo* gene transfer to hepatocytes, by virtue of integration in the genome of target cells that allows their maintenance upon cell proliferation during liver growth. We previously showed stable LV-mediated liver gene transfer in neonatal and adult mice, in dogs and non-human primates. However, high quantity of highly purified LV are required to treat large animals and potentially humans. Thus, it would be important to improve the efficiency of LV gene transfer into hepatocytes, in order to reduce the doses required to achieve the therapeutic outcome. This is true for both non-cell-autonomous diseases, like hemophilia - a coagulation disorder due to the lack of coagulation factors - but even more for cell-autonomous diseases, like familial hypercholesterolemia (FH) - due to mutations in low-density lipoprotein receptor, (LDLR) - where most of the liver mass needs to be corrected for the therapeutic outcome. To increase the potency of hepatocyte gene transfer, we focused on anti-viral pathways, targeting them before administering LV. We identified interferon response and proteasome activity as possible targets to enhance transduction. A single dose of either an anti-interferon αβ receptor I (IFNARI) antibody, or bortezomib (a proteasome inhibitor) before LV administration increased transgene output of ~5-fold, both in case of LV encoding for coagulation factor IX or coagulation factor VIII. Interestingly, when tested in combination, we did not observe an additive effect of the two compounds. Bortezomib conferred the highest increase in transgene output, possibly indirectly acting also on IFN pathway by reducing the transduction of plasmacytoid dendritic cells, responsible for IFN production *in vivo*. We then evaluated the efficacy of *in vivo* LV gene transfer in a mouse model of FH, *ldlr*$^{-/-}$. Despite LDLR is reported as the main receptor of vesicular stomatitis virus glycoprotein, VSV.G, used to pseudotype LV, we observed efficient gene transfer in *ldlr*$^{-/-}$ mice by VSV.G-LV, with even higher transgene output compared to wild type mice. Since the lack of LDLR enhanced transduction of VSV.G-LV, we attempted to recapitulate the increase in LV-mediated hepatocyte gene transfer in wild type mice, by reducing LDLR amounts on the hepatocytes' membrane. Fasting is known to downregulate LDLR expression. We thus fasted mice for 24 hours before administering LV, and found transgene output to be up to 7-fold higher than in control mice. We tested the combination of the previously identified enhancers and found fasting + bortezomib to confer the highest advantage, with >11-fold higher transgene output, compared to controls. We then moved to the FH therapeutic experiment in *ldlr*$^{-/-}$ mice. When producing VSV.G-LV encoding LDLR, we obtained very low infectious titers, possibly due to LDLR-VSV.G interaction in producer cells. We solved the issue by avoiding LDLR expression during LV production. With these upgraded LV, we treated juvenile *ldlr*$^{-/-}$ mice and obtained long-term LDL normalization, maintained even following a challenge with a high cholesterol diet, and prevented atherosclerosis of the aorta. Here we report some relatively simple and potentially clinically viable interventions allowing to achieve substantial increase in the potency of *in vivo* LV gene transfer to hepatocytes. Interestingly, reduction of the LDLR in the liver increased rather than decreased LV gene transfer. We exploited this favorable feature to successfully treat FH by liver-directed LV gene therapy in the mouse model.

72 Developement of an *Ex Vivo* Gene Therapy for Infantile GM1 Gangliosidosis

Linda Bucciarelli[1], Camilla Fabris[1], Rita Milazzo[2], Alessandra Biffi[3], Valentina Poletti[4]

[1]Department of Pediatric Hematology and Oncology Center, Woman's and Child Health, University of Padova, Padova, Italy,[2]Altheia Science Srl., Milan, Italy,[3]DFCI/BCH Cancer and Blood Disorders Center, Boston, MA,[4]3Dana-Farber/Boston Children's Cancer and Blood Disorders Center, Harvard Medical School, Padua, Italy

GM1-gangliosidosis (GM1, OMIM #230500) is a rare, recessive Lysosomal Storage Disorder (LSD) caused mutations in the *GLB1* gene encoding the β-galactosidase (β-gal) enzyme. The enzymatic deficiency induces multiple mechanism of cell damage that finally led to severe, progressive neurodegeneration and premature death of the patients. LSDs require a therapy providing a prompt and robust enzyme delivery to the central nervous system, possibly associated with reduction of local inflammation. *Ex vivo* Gene therapy (GT), i.e. the autologous transplantation of Hematopoietic Stem/Progenitor Cell (HSPCs) genetically-corrected by lentiviral gene transfer, may represent a valuable therapeutic option for GM1, as proven in at least two clinical studies for other LSDs. To this aim, we developed multiple therapeutic lentiviral vectors (LVs) expressing 1) the murine *Glb1* gene, 2) a codon-optimized sequence of the human *GLB1* gene, alone or 3) in combination with the gene encoding the Metallothionein 1G (MT1G), an immunomodulatory molecule potentially contributing to neuroprotection. LV-transduced cells express dose-dependent, supra-physiological levels of therapeutic enzyme, correctly secreted and uptaken by target human hematopoietic cells. In GM1-patient primary fibroblasts, transduction with the therapeutic LVs, both murine and human, determined a stable metabolic correction, proven by the rescue of storage material as early as two weeks post-transduction, with an average of ≥ 3 vector copies/cell. However, the murine β-gal resulted significantly more active than the human enzyme, likely because of a higher stability as described in the literature. We are currently proceeding with the *in vivo* evaluation of our GT strategy in controlling the disease symptoms in a feasibility and efficacy study performed in Glb1$^{-/-}$ mice, animal model of the disease. Preliminary data suggest that the human β-gal-encoding LV restores ~physiological enzymatic activity levels *in vivo* in murine peripheral blood cells, but not the supra-normal activity proven to be essential for enhancing therapeutic benefit in other LSDs. So far, transplantation of HSPCs transduced with this LV resulted in a partial therapeutic efficacy, determining a delay of disease onset and a partial correction of the neuromuscular phenotype of the affected mice. On the other hand, the therapeutic LV expressing the murine β-gal induced supra-physiological enzymatic activity in GM1 mice, with the potential to more robustly benefit the GM1 symptomatology in the animal model. In summary, the LV expressing

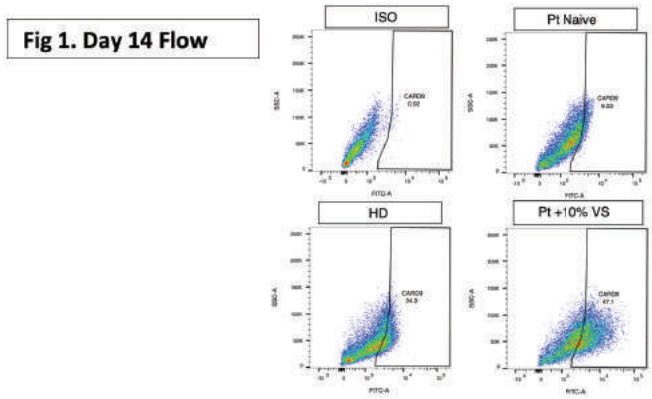
the human β-gal is able to achieve supraphysiological enzymatic activity and correct the biochemical phenotype in GM1 patient-derived primary fibroblasts, while the LV expressing the specie-specific isoform of the enzyme seems to be require to correct the GM1 phenotype in the animal model, and validate our GT approach to the disease.

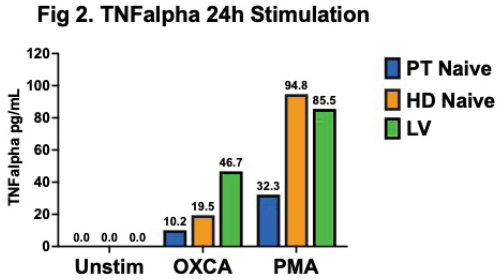
73 Lentiviral Gene Therapy for CARD9 Deficiency

Karissa J. Bever[1], Caroline R. Kreitzer[1], Uimook Choi[1], Andrés F. Zea-Vera[1], Harry L. Malech[1], Michail S. Lionakis[2], Elizabeth M. Kang[1]

[1]Genetic Immunotherapy Section, Laboratory of Clinical Immunology and Microbiology, NIAID, National Institutes of Health, Bethesda, MD,[2]Fungal Pathogenesis Section, Laboratory of Clinical Immunology and Microbiology, NIAID, National Institutes of Health, Bethesda, MD

CARD9 is a critical adaptor protein in the innate immune response to fungal pathogens. CARD9 is phosphorylated downstream of C-type lectin receptors such as Dectin-1 and associates with BCL10 and MALT1 to initiate a signaling cascade resulting in inflammatory cytokine production via NF-KB induction. CARD9 deficiency is an inborn error of immunity characterized by persistent and invasive severe fungal infections of the skin, subcutaneous tissue, mucosal surfaces, and central nervous system. While allogeneic hematopoietic stem cell transplantation can be effective, it is high risk in the context of infection and necessitates a matched donor. The use of a lentiviral vector for *ex vivo* correction of the patients own hematopoietic stem cells(HSC) could be curative while bypassing the need for HLA-matched donors, the use of immune suppressants, and avoiding the risk of graft-versus-host disease. We developed a CARD9 lentiviral vector(LV) and assessed its efficacy in vitro for the treatment of CARD9 deficiency in patient HSCs. CARD9 protein expression was under the control of a constitutive EF-1α promoter. Cryopreserved patient stem cells were thawed and subsequently transduced with 10% diluted vector stock CARD9 LV(2.64e7 IU/mL) at 1e6 cells/mL along with transduction enhancers. Efficacy of the vector was assessed via flow cytometry for CARD9 protein expression, vector copy number(VCN) via droplet digital PCR and colony forming unit(CFU) assay, as well as post-stimulation TNF-α production by ELISA. Following transduction with CARD9 LV, approximately half of CARD9 patient stem cells(PSCs) expressed CARD9 protein as compared to 9% in non-transduced patient and 24% in naïve healthy donor stem cells at fourteen days post-transduction.(Figure 1) CARD9 protein in LV transduced PSCs had increased production of TNF-α in response to Dectin-1 mediated stimulation of the CARD9 pathway as measured via ELISA. Naïve patient monocytes differentiated from HSC showed minimal TNF-α production in response to OXCA stimulation(10.15 pg/mL) while CARD9 LV transduced patient monocytes showed a significant increase in TNF-α production(46.72 pg/mL) even over healthy donor (19.45 pg/mL)($p<0.001$).(Figure 2) Finally, VCN as measured by droplet digital PCR was 1.08 vector copies/cell in the CARD9 LV transduced cells two weeks post-transduction, and 42% of colony forming units from the CFU assay of the transduced cells were positive for vector insertion. Our results demonstrate the production of an effective lentiviral vector for therapeutic replacement of the functional CARD9 gene in hematopoietic stem cells in vitro and show promise for the development of a CARD9 LV gene therapy approach for CARD9-deficient patients. In vivo mouse studies are in progress.





AAV Vectors: Clinical and Non-Human Primate Studies

74 Large-Scale Characterization of the Location and Expansion of AAV Integrations in Macaques and Humans Following *In Vivo* Exposure

Kelly Martins, Qi Zheng, Zhe Zhang, Kanyin Olagbegi, Jenny A. Greig, James M. Wilson

University of Pennsylvania, Philadelphia, PA

Adeno-associated virus (AAV) vectors are a commonly used delivery vehicle for *in vivo* gene therapies due to the lack of pathogenicity of natural AAV infection and the ability of the AAV genome to persist *in vivo* for a long duration. Researchers have reported observations of the integration of naturally occurring AAV (wild-type AAV [wtAAV]), as well as AAV used in gene therapy applications (recombinant AAV [rAAV]) into host genomic DNA, for over two decades. The possibility of rAAV integration has raised concerns for insertional mutagenesis and clonal expansion in mouse and dog studies; however, no concerns regarding pathogenicity have been raised for wtAAV integration. It remains unknown whether rAAV integration is similar to that of non-site-specific wtAAV integration or whether there is an increased risk of locational genotoxicity or expansion in primates. In this study,

we characterized the genomic location, abundance, and expansion of wtAAV and rAAV integrations in the macaque and human genomes following *in vivo* exposure and assessed the translatability of macaque integration studies to humans. Using a modified unbiased next-generation sequencing technique, we identified the location, number, and distribution of genome-wide AAV integration loci from 168 non-human primates (NHPs) and 85 humans naïve to rAAV exposure, and from 79 NHPs treated with rAAVs via gene therapy studies. Our diverse cohort included samples from rAAV studies with different liver-specific promoters/enhancers (including A1AT and TBG), transgenes (including self, non-self, and human), and capsid serotypes (including AAV8, AAVrh10, AAVhu37, and AAV3B) administered at varying doses ($3x10^{12}$ to $1.2x10^{13}$ genome copies/kg), with timepoints after rAAV treatment ranging from 7 days to 15 years post-gene therapy administration. Our results suggest that rAAV and wtAAV integrations exhibit similar, mostly random, integration distribution patterns within the primate genome, with a higher frequency in genomic regions vulnerable to DNA damage. Although rAAV has a higher abundance of unique integration loci, wtAAV integration loci exhibit higher levels of clonal expansion. The striking qualitative and quantitative similarity between our naïve NHP and human cohorts emphasizes the translatability of AAV integration studies performed in NHP models and supports their use in risk assessment studies over other biologically divergent preclinical animal models. Additionally, our data support the use of samples from the large, easily accessible wtAAV-infected population (NHPs and humans) to expedite the development and validation of rAAV integration detection and monitoring tools for clinical applications. This detailed characterization of AAV integration in primates has important translational implications for the safety of rAAV as a gene therapy vector and highlights the clinical translatability of NHP AAV integration data.

75 The Safety and Efficacy of Pre-Treatment with Imlifidase Prior to Adeno Associated Virus (AAV)-Based Gene Therapy in Non-Human Primates with Pre-Existing Anti-AAVrh74 Antibodies

Rachael Potter[1], Sohrab Khan[1], John Snedeker[1], Kaitlin Adegboye[1], Alex Haile[1], Behnam Sayanjali[1], Nicole Pukos[1], Kyle Cochran[1], Jen Ahner[1], Ting Su[1], Nathalie Uzcátegui[2], Yvonne Stenberg[2], Catja Freiburghaus[2], Lena Winstedt[2], Louise Rodino-Klapac[1]

[1]Sarepta Therapeutics, Cambridge, MA,[2]Hansa Biopharma, Lund, Sweden

Duchenne muscular dystrophy (DMD) is an X-linked, neuromuscular disease caused by mutations in the *DMD* gene that prevent the production of functional dystrophin protein. Delandistrogene moxeparvovec (SRP-9001) is a gene transfer therapy designed to compensate for missing dystrophin in DMD by delivering a transgene that utilizes an adeno-associated virus (AAV) vector—AAVrh74—and encodes SRP-9001 dystrophin, a shortened, engineered dystrophin protein that retains key functional domains of the wild-type protein. Despite generally low levels of pre-existing immunity to AAVrh74 in humans, anti-AAV antibodies do occur and can impact the safety and efficacy of gene therapies and preclude their use in otherwise eligible patients. Here, we assessed the ability of imlifidase, a unique endopeptidase that cleaves IgG, to lower anti-AAVrh74 antibodies as a potential means of overcoming or reducing pre-existing immunity. This study of imlifidase in female cynomolgus monkeys was carried out in two parts with a reporter construct. Part 1 assessed a single (Day 1) or once-daily dose (Days 1-14) of prednisolone via oral gavage (1 mg/kg/day) as a standard immunosuppressive treatment and intravenous (IV) imlifidase (10 mg/kg/dose, Day 1) followed by IV AAVrh74.CMV.eGFP ($1.33x10^{14}$ vg/kg/dose, Day 3) in both anti-AAVrh74 antibody-negative and -positive animals. Part 2 assessed once-daily prednisolone (Days 1-62 or Days 1-96) and single (Day 1) or repeated (Days 1 and 36) imlifidase or saline control and/or AAVrh74.CMV.eGFP (Day 3 or Days 3 and 38). Animals underwent an observation period of at least 59 days. We assessed biodistribution, expression of eGFP, immunological response (anti-AAVrh74 total antibodies using an enzyme-linked immunosorbent assay and T-cell response to AAVrh74 peptides using an enzyme-linked immunosorbent spot), histopathology, and pharmacokinetics/pharmacodynamics of imlifidase. In brief, treatment with imlifidase prior to AAVrh74-eGFP in animals with pre-existing anti-AAVrh74 antibodies (titer range: 1:800-1:1600) led to a decreased anti-AAVrh74 antibody response. The decrease in anti-AAVrh74 antibodies observed in animals that received imlifidase prior to gene therapy resulted in efficient transduction (as measured by droplet digital polymerase chain reaction) and expression (as measured by immunofluorescent quantification) of AAVrh74.CMV.eGFP relative to animals with the same antibody titers that did not receive imlifidase. These results suggest that imlifidase can permit AAV transduction in seropositive animals. No adverse clinical events or mortality occurred subsequent to dosing with gene therapy, and no adverse immunotoxicological or histopathological findings related to imlifidase pre-treatment were found, including in the reproductive organs. In this proof-of-concept study, imlifidase pre-treatment lowered anti-AAVrh74 total antibody titers, allowing for safe administration of AAV-based gene therapy in seropositive animals. These findings may help enable treatment in patients currently excluded due to pre-existing antibodies against AAVrh74. This research was funded by Sarepta Therapeutics.

76 Bilateral Ixo-vec NHP Tolerability and Efficacy Following a Staggered Dosing Interval between Eyes - Gene Therapy nAMD

Kris Poulsen, Kelly Michiko Hanna, Diana Cepeda, Julio Delano Nieves, Ngoc D. Nguyen, Kristina Oresic Bender, Ruslan N. Grishanin, Brigit E. Riley

Adverum Biotechnologies, Redwood City, CA

Introduction: Ixo-vec is an AAV.7m8 capsid-based intravitreal (IVT) gene therapy designed to produce robust aflibercept levels and is being developed as a gene-based therapy for neovascular age-related macular degeneration (nAMD). Single IVT administration of Ixo-vec results in durable and efficacious levels of aflibercept as demonstrated in the long-term clinical study, OPTIC. The annual incidence of nAMD occurrence in the second eye is between 4-19%. Thus, an interval of months to years may occur between first and second eye treatment. Due to AAV immunogenicity there is a concern of adaptive immunity and neutralizing antibodies developing after the first dose, creating a tolerability and efficacy concern for second eye treatment. The objective of these nonclinical studies was to evaluate the ocular tolerability,

intraocular aflibercept levels, and immune response in non-human primates (NHPs) administered IVT Ixo-vec to contralateral eyes, with a staggered dosing interval between IVT injections. To understand the inflammation profile -onset, duration, and magnitude - no prophylactic regimen was used. Additionally, for comparison, the ocular humoral immune response was examined in a study of unilateral IVT Ixo-vec administration. **Methods:** Two staggered dosing bilateral studies and one unilateral dosing study were conducted in NHPs prescreened for neutralizing antibodies (Nabs). In the bilateral studies, Ixo-vec was administered IVT at 6E11 vector genomes (vg) per eye or 2E12 vg/eye with a 2-month interval between eye injections. As comparator control arms, Ixo-vec 6E11 vg/eye or vehicle was administered to NHPs bilaterally on Day zero. No prophylactic regimen was used. Ocular tolerability was assessed by ophthalmic examinations, OCT and tonometry. Levels of aflibercept in vitreous (VH) and aqueous humors (AH), as well as Nabs in serum and VH samples were assessed. Terminal ocular tissues were evaluated by histopathology. In the unilateral study 2E12, 6E12 or 2E13 vg/right eye were dosed and serum and bilateral humoral response was assessed. **Results:** Ixo-vec was well tolerated. After bilateral dosing, inflammatory findings in both eyes were limited to mostly mild to moderate self-resolving intraocular inflammation (IOI), with no evidence of exacerbated IOI in second treated eyes compared to first or equivalently dosed unilateral injected eyes. Microscopic findings were limited to mononuclear cell infiltrates of minimal severity. Aflibercept levels in second eyes trended lower compared to first eyes yet were within the predicted therapeutic range found across multiple NHP studies testing a wide range of doses including current clinical trial doses 3E10 vg/eye and 1E11 vg/eye (Human equivalent dose 6E10 vg/eye and 2E11 vg/eye). Animals developed Nabs in serum post Ixo-vec administration to first eyes. Nabs were also detected in the first eye following first dose. In the contralateral eye, Nabs were not detected prior to dosing of that eye. This observation was also made in the unilateral study. **Conclusion:** Staggered bilateral administration of Ixo-vec in NHPs did not result in exacerbated IOI in the second-treated eye and is anticipated to provide therapeutic aflibercept levels. Despite detection of Nabs in serum and injected eyes, Nabs were not detected in un-injected eyes suggesting that eyes prior to injection were largely isolated from the systemic humoral response. Clinical translation of the findings around systemic/ocular humoral response will need to be evaluated in the clinical disease setting of nAMD where there is potentially a reduced blood:retinal barrier. Altogether these nonclinical data set the expectation for tolerability and therapeutic aflibercept levels in clinical evaluation.

77 Monitoring Fetal and Infant Somatic Cell Genome Editing in Rhesus Monkeys with Total-Body PET

Alice F. Tarantal[1], Michele Martinez[1], Charles Lee[2], Lionel Sanz[1], Henriette O'Geen[3], Dennis J. Hartigan-O'Connor[4], David J. Segal[5]

[1]Pediatrics, Cell Biology and Human Anatomy, and California National Primate Research Center, University of California, Davis, Davis, CA,[2]Cell Biology and Human Anatomy and California National Primate Research Center, University of California, Davis, Davis, CA,[3]Genome Center, University of California, Davis, Davis, CA,[4]Medical Microbiology and Immunology, and California National Primate Research Center, University of California, Davis, Davis, CA,[5]Biochemistry and Molecular Medicine, and Genome Center, University of California, Davis, Davis, CA

Key issues for translational somatic cell genome editing are to understand the extent of editing in the body at a given time, the specificity of editing for the desired genomic target, if edited cells persist, the impact of editing on the immune system, and the potential for adverse events. Addressing these and related questions substantially benefits from a noninvasive approach that can identify edited cells *in vivo*. Positron emission tomography (PET) can provide three-dimensional quantitative images deep inside the body of radiotracers at subnanomolar concentrations. New, transformative total-body PET can image the entire body simultaneously. The goal of these studies was to use total-body PET to identify gene editing *in vivo* in fetal and infant rhesus monkeys. Time-mated dams were identified as pregnant by ultrasound then screened (seronegative for AAV9 and *Sa*Cas9) and selected for the study. Fetuses (N=12) were administered the imaging vector (AAV9/*Sa*Cas9/HSV-sr39TK) *in utero* using an intrahepatic (IH) ultrasound-guided approach in the late first or early second trimester (10e12 vector genomes [vg]/fetus). After administration of [18]F-FHBG intravenously to the dams (3 mCi/kg), imaging of fetuses *in utero* was performed in the second and third trimesters and consistently showed editing in the fetal liver, which was sustained across gestation. Findings were confirmed at the tissue level near term with 8-12% editing in the liver, and with no evidence of adverse effects. The AAV9 imaging vector was also administered in a separate study to infants at ~3 months of age (N=16, 10e13 vg/kg; IV or IH under ultrasound guidance). All infants remained healthy and robust during the study period (up to 3 months post-vector administration). Hematology and clinical chemistry panels were all within normal limits and no adverse events were detected. Infants were administered [18]F-FHBG IV (0.3 mCi/kg) for PET imaging at two weeks post-administration then monthly during the study period. Similar to fetal studies, extensive evaluation of the liver at tissue collection showed high levels of transduction and an editing outcome of ~7-12% in the liver. These studies have shown for the first time that total-body PET can noninvasively provide insights on gene-edited cells *in vivo* and with high sensitivity and reproducibility.

78 AAV Serotype Tropism and Editing in Young Rhesus Monkeys

Alice F. Tarantal[1], Michele Martinez[2], Lionel Sanz[2], Charles Lee[3], Henriette O'Geen[4], Aravind Asokan[5], Charles A. Gersbach[6], David J. Segal[7], Dennis J. Hartigan-O'Connor[8]

[1]University of California, Davis, Davis, CA,[2]Pediatrics, Cell Biology and Human Anatomy, and California National Primate Research Center, University of California, Davis, Davis, CA,[3]Cell Biology and Human Anatomy, and California National Primate Research Center, University of California, Davis, Davis, CA,[4]Genome Center, University of California, Davis, Davis, CA,[5]Surgery, Duke University, Durham, NC,[6]Biomedical Engineering, Duke University, Durham, NC,[7]Biochemistry and Molecular Medicine, and Genome Center, University of California, Davis, Davis, CA,[8]Medical Microbiology and Immunology, and California National Primate Research Center, University of California, Davis, Davis, CA

Recombinant AAV vectors are at the forefront of current gene therapy clinical trials. For example, AAV5, AAV6, AAV8, and AAVrh10 have shown promise for liver-directed gene transfer in Hemophilia A and B clinical trials. In musculoskeletal/cardiovascular-directed gene therapies, AAV8, AAV9, and AAVrh74 have attained efficient gene transfer, and AAV9 has proven useful for expression in brain. Despite the abundant and occasionally discordant data describing AAV serotype tropism in animal models and humans, significant uncertainties remain with regard to the selection of an optimal serotype for targeting specific human tissues; thus, there is a need for a side-by-side comparative analysis of multiple AAV serotypes at a comparable dose. A multiplexed (barcode-based) approach was used that enabled comparative and comprehensive evaluation of AAV serotypes following intravenous (IV) administration in rhesus monkeys. The editing cassette included a ubiquitously expressed, mini-chicken beta actin (CBA) promoter driving *Sa*Cas9 with a unique barcode and an adjacent U6 promoter driving a guide RNA (gRNA) This study compared seven AAV serotypes using systemic (IV) administration and young rhesus monkeys (N=40). The AAV serotypes tested (3B, 5, 6, 8, 9, rh10, rh74) delivered *S. aureus* (*Sa)*Cas9 with gene editing measured by assay of indels or integration of the barcoded AAV at the *PCSK9* (proprotein convertase subtilisin/kexin type 9) target site. The barcoding strategy provided a means to administer AAV vectors either individually or in single combined administrations of multiple serotypes (e.g., AAV9+AAVrh74; range 1x10e13-8x10e13 genome copies [gc]/kg). Infants were screened to confirm they were seronegative prior to vector administration, then monitored for 4 weeks post-administration (e.g., hematology, clinical chemistries, immune responses). Initial studies (N=6) tested vector safety and dose using a luciferase reporter (no editing). Overall, findings indicated: (i) all serotypes provided good levels of transduction for a wide range of tissues but limited selectivity was shown for target tissues based on vector tropism; (ii) RNA expression was noted in most tissues but transduction did not correlate with expression; (iii) systemic (IV) delivery resulted in low levels of editing (≤5%); (iv) adaptive immune responses to all AAV serotypes and/or *Sa*Cas9 were observed in all groups; and (v) all animals remained healthy and robust during the study period although transient liver toxicity was observed particularly with the highest dose studied (combined serotypes; total 8x10e13 gc/kg). These studies confirmed that editing was driven by the level of RNA expression, and that transduction is an imperfect predictor of editing. Studies also showed that AAV9 was preferential for many tissues when administered IV (e.g., AAV9>AAVrh10>AAVrh74 ≥AAV8>AAV6>AAV5~AAV3B). As a result of these and related studies where higher levels of editing was observed, we are addressing comparative tests of Cas9 expression cassettes for optimal editing.

79 The Machine Learning-Guided Fit4Function Platform Quantitatively Profiles the Biodistribution of Peptide-Modified AAV Capsids after a Single Round of Screening in Macaque

Fatma Elzahraa Eid[1], Albert Chen[1], Ken Chan[1], Qin Huang[1], Qingxia Zheng[1], Isabelle Tobey[1], Simon Pacouret[1], Pamela Brauer[1], Casey Keyes[1], Megan Powell[1], Jencilin Johnston[1], Binhui Zhao[1], Alice Tarantal[2], Yujia A. Chan[1], Benjamin Deverman[1]

[1]Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, MA,[2]Departments of Pediatrics and Cell Biology and Human Anatomy, School of Medicine, University of California, Davis, CA

Broadening gene therapy applications requires manufacturable vectors that efficiently transduce target cells in humans and preclinical models. Conventional selections of adeno-associated virus (AAV) capsid libraries are inefficient at searching the vast sequence space for the small fraction of vectors with desirable biodistribution profiles maintained across species. We developed a machine learning (ML)-guided Fit4Function platform that evenly samples the manufacturable sequence space of AAV capsids to generate reproducible screening data for training accurate sequence-to-function models.[1] From a single screen in macaque of a Fit4Function library with 100K peptide-modified AAV9 capsid variants, we identified hundreds of capsids with reproducible enhanced biodistribution to the brain, kidney, lung, muscle, heart and liver. With the high-quality data, we built and validated models that can accurately predict biodistribution to different organs (Fig 1A). In addition, we harnessed Fit4Function to assess combinations of functions that can predict a given trait of interest. We found that human cell and mouse models of liver-targeting function, used in combination, could accurately predict cross-species in vivo biodistribution to the macaque liver. Interestingly, human hepatocyte transduction models were more predictive of macaque liver enrichment compared to the mouse liver biodistribution model (Fig 1B). We accurately predicted and validated capsids with enhanced liver-transduction capabilities across species (Fig 1C). This demonstrated that Fit4Function can assess combinations of functional assays that are predictive of a cross-species function of interest, thus informing pipeline design for gene therapy vector development and directing efforts into screens with more predictive power.

[1]Eid, FE et al. "Systematic multi-trait AAV capsid engineering for efficient gene delivery." *bioRxiv* 2022.12.22.521680.

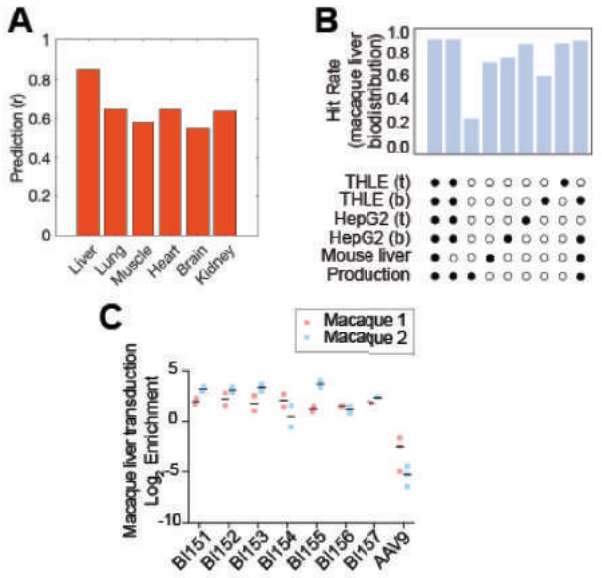


Figure 1. Applying the Fit4Function platform across human cells, mice and macaque to identify multi-trait AAV capsids with cross-species tropisms. (A) The performance of models predicting biodistribution to different macaque organs was measured as the correlation between measured and predicted scores. **(B)** A 100K variant Fit4Function library was injected intravenously into a cynomolgus macaque. Biodistribution was assessed four hours later. The fraction of the indicated variants enriched in the macaque liver (>4-fold more than AAV9) are shown for each combination of predicted traits. Binding or transduction are indicated by 'b' or 't'. **(C)** Fit4Function capsids predicted and validated through individual testing in mouse liver transduction and human cell screens were evaluated in rhesus macaques as part of a pooled library. The macaque liver transduction efficiencies 4 weeks post-injection are shown for the variants, each represented by two amino acid replicates in the library ($n = 2$).

80 AAV-Barcoding for High-Throughput Screening of Vector Transduction Efficiency in Cynomolgus Macaques Compared to C57BL/6 Mice

Frederick J. Ashby[1], Samuel Anyaso-Samuel[2], Paul D. Gamlin[3], Nadia Kabbej[1], Natalia Andraka[4], Ronald Mandel[5], Alberto Riva[6], Datta Somanth[2], Coy Heldermon[7]

[1]College of Medicine, University of Florida, Gainesville, FL,[2]Biostatistics, University of Florida, Gainesville, FL,[3]University of Alabama at Birmingham, Birmingham, AL,[4]University of Florida, Gainesville, FL,[5]Department of Neuroscience, University of Florida, Gainesville, FL,[6]Bioinformatics Core Facility, University of Florida, Gainesville, FL,[7]Department of Hematology and Oncology, University of Florida, Gainesville, FL

Neural degenerative disorders remain a prime target for AAV-based interventions, yet there remains clinical equipoise regarding minutia such as injection methodology and vector capsid characteristics. Moreover, disparities in vector tropism when delivered directly to the brain parenchyma or through the cerebrospinal fluid (CSF) are not well characterized. The clinical translational pipeline for AAV therapy also remains arduous, and many engineered AAV capsids that show enhanced transduction efficiency in mice do not replicate these characteristics in NHP models. Therefore, it is also important to know if there is a correlation of vector transduction dynamics between NPH and mouse models. Here, we set out to characterize vector biodistribution and transgene expression in non-human primate (NHP) and murine models using multiple capsids simultaneously with AAV barcode techniques previously described. Macaques (*M. fascicularis*) and C57/BL6 mice were injected with an AAV barcode mix using either intracisternal magna (ICM) or intraparenchymal (IC6) methods, and multiple analyses were done to reduce unnecessary animal use (*Mol Ther,* 30 115&439, 2022). Here, we demonstrate two such analyses: the characterization of IC6 versus ICM delivery of vector, addressing injection methodology differences, and the disparities between mouse and NHP models -- addressing interspecies differences. After performing rank-order analysis on both biodistribution and expression data organized by anatomical region, the CNS demonstrated a strong correlation ($R>0.70$) in vector rank ordering ($p<0.05$) between species despite visible magnitude differences for individual vectors. A moderate correlation ($R>0.50$) was also noted in non-CNS peripheral organs ($p<0.05$). This was surprising, as there are many cases in the literature where vectors that succeed in mice fail in NHP models, yet at least on a generalized level, there may still be strong correlation between mouse and primate AAV capsid transduction efficiency, at least relative to one another by rankings. Within each animal model, there was strong rank-order correlation ($R>0.70$) of vector capsid types between both IC6 and ICM methods ($p<0.05$), which was expected. Overall, our analysis suggests that rank-orderings of AAV capsids, at least based on the capsids tested in this study, correlate between C57/BL6 murine and *M. fascicularis* primate models. This is significant because it supports the use of mice as a screening tool for effective AAV capsids, since murine models can be powered much more cost-effectively than primates.

Nucleic Acid Therapeutics

81 Transferrin Receptor-Targeted RNA Aptamer Enhanced Blood-Brain Barrier Penetration in Brain Metastases Occurring from Triple-Negative Breast Cancer

Minsun Song[1], Haitang Li[2], Jessica Alluin[1], Trishabelle Manzano[1], Cynthia Rojero[1], Nicolette Pollock[1], Kevin Holm[1], Nagy A. Habib[3], John J. Rossi[4]

[1]RNA Therapeutic Center, City of Hope, Duarte, CA,[2]City of Hope, Duarte, CA,[3]Imperial College of London, London, United Kingdom,[4]Beckman Research Institute of City of Hope, Monrovia, CA

Triple-negative breast cancer (TNBC) is a highly malignant subtype of breast cancer. High invasiveness and heterogeneity, as well as a lack of drug targets, are the main factors leading to poor prognosis. It is estimated that 46% among patients with TNBC will develop brain metastases (BM). BM formation will not only affect the patients' physical function, independence, personality, quality of life, and self-

awareness. Still, it will also significantly increase the mortality rate compared with metastasis to other organs, which can be as high as 80% within one year. The lack of blood-brain barrier (BBB) penetrating ability has hindered the delivery of many therapeutic agents to BM. Herein, transferrin receptor (TfR) aptamer triggered transferrin receptor expressing brain capillary endothelial cells in BBB is subtly developed. TfR aptamer conjugated a small activating RNA (saRNA) targeting the CCAAT enhancer binding protein alpha (CEBPA) gene promotes transcription from target loci, with potential antineoplastic and anti-inflammatory activity. The TfR aptamer conjugated with CEBPa saRNA (TfR-CEBPA) was modified with albumin affinity tag to improve serum stability and validated their efficiency in TNBC-BM humanized mice model. This TfR aptamer with small RNA displays significantly improved brain exposure compared with nano-particle delivery system, as well as the ability to inhibit the tumor growth in mice brain from TNBC. Collectively, results from this study demonstrate that TfR aptamer internalization to delivery across the blood brain barrier into BM, supporting the potential of TfR as a target for drug delivery and antineoplastic activity with CEPBA saRNA in TNBC-BM.

82 The FORCE™ Platform Delivers Oligonucleotides to the Brain in a DM1 Mouse Model and in NHPs

Stefano Zanotti, Susana Correia, Jin Cui, Jenn Johnson, John Harrell, Lydia Schlaefke, Ryan Russo, Ann Chang, Christina Shen, Pei-Ni Tsai, Tyler Picariello, Timothy Weeden, Kim Tang, Oxana Beskrovnaya

Dyne Therapeutics, Waltham, MA

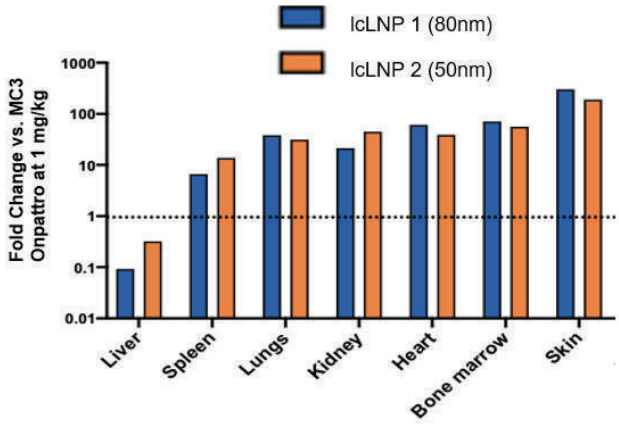
The FORCE platform was designed to overcome the challenges of oligonucleotide delivery to muscle for the treatment of neuromuscular diseases such as myotonic dystrophy type 1 (DM1). This is a severe neuromuscular disease with prominent manifestations in muscle as well as central nervous system (CNS). DM1 is caused by expanded CUG repeats in the dystrophia myotonica protein kinase (*DMPK*) RNA which sequester muscleblind-like splicing regulators into nuclear aggregates, thereby leading to a spliceopathy that drives clinical progression of the disease. The FORCE platform was optimized to enhance oligonucleotide delivery to muscle and consists of an antigen-binding fragment (Fab) that binds with high affinity to the human transferrin receptor 1 (TfR1) and is conjugated to an oligonucleotide. FORCE conjugates designed to address DM1 contain an antisense oligonucleotide (ASO) that targets nuclear *DMPK* RNA for degradation. Previous work in multiple preclinical models established that FORCE conjugates corrected manifestations of myotonic dystrophy in cardiac and skeletal muscle and demonstrated pharmacological properties that translate from mice to cynomolgus monkeys. It is also important for potential DM1 therapeutics to address CNS manifestations by targeting the mutant *DMPK* RNA in the brain. To determine whether the FORCE platform enables ASO delivery to the brain, hTfR1/DMSXL mice that express human TfR1 (hTfR1) and a mutant human *DMPK* RNA with >1,000 CUG repeats were used as a model of DM1. hTfR1/DMSXL mice were administered intravenously (IV) with either a FORCE conjugate or equimolar doses of unconjugated ASO or a negative control Fab conjugate. The FORCE conjugate, but not unconjugated ASO or the negative control Fab conjugate, delivered ASO to the brain cortex and cerebellum, and the effect was accompanied by suppression of mutant human *DMPK* transcripts and a maximal ~65% reduction of *DMPK* nuclear foci area in brain parenchymal cells. These observations demonstrate that the FORCE platform can deliver an ASO across the blood-brain barrier via TfR1 to drive a robust pharmacological effect in brain parenchymal cells. To establish the translatability of ASO delivery to the brain of higher species, wild-type cynomolgus monkeys were administered an IV infusion of FORCE conjugate or administered with an equimolar dose of unconjugated ASO either by IV or intrathecal (IT) routes. We show that IV dosing of FORCE conjugate delivered up to ~25 to 45-fold higher concentration of ASO compared to IV administration of the unconjugated ASO to cortex and deep brain regions as well as cerebellum. Moreover, ASO detection by *in situ* hybridization in brain sections demonstrated that dosing with the FORCE conjugate leads to widespread delivery of the ASO including the cortex and deep brain regions. In contrast, unconjugated ASO administered IV was not detected, and ASO injected IT remained confined within the most superficial layers of the cerebrum and cerebellar cortex. In conclusion, the FORCE platform delivers ASOs to the brain in preclinical models and has the potential to impact CNS manifestations of DM1.

83 Long-Circulating Lipid Nanoparticles for Agnostic Nucleic Acid Delivery to the Bone Marrow and Beyond

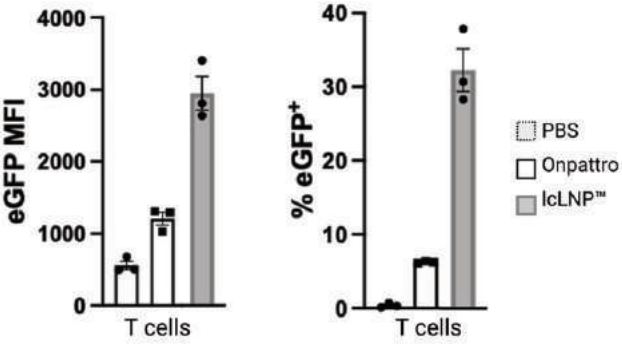
Kevin An[1], Daniel Kurek[1], Pieter R. Cullis[1,2], Dominik Witzigmann[1], Jayesh A. Kulkarni[1]

[1]NanoVation Therapeutics, Vancouver, BC, Canada,[2]University of British Columbia, Vancouver, BC, Canada

Introduction: Advancements in nucleic acid therapeutics have allowed for broader potential treatment of diseases at the genetic level. However, nucleic acids are prone to degradation by serum endonucleases and clearance through the immune system. Lipid nanoparticles (LNP) have enabled increased potency of these therapeutics by protection through encapsulation and improving their intracellular delivery. However, intravenous administration of current LNP therapeutics is subject to liver accumulation and limited extrahepatic biodistribution due to rapid clearance. Here, we illustrate a novel long-circulating LNP (lcLNP) system capable of extrahepatic delivery to the bone marrow, skin tissue, and solid tumors due to a substantially increased circulation half-life. Methods: LNP formulations consist of ionizable lipid, DSPC, cholesterol, PEG-DMG at differing molar ratios. We use *in vitro* and *in vivo* luminescence and fluorescence quantification assays to assess knockdown or expression in various cell types and isolated tissue samples post-LNP transfection of siRNA, pDNA, and mRNA. We additionally use fluorescence-based lipid dye LNP systems, radiolabelling, and flow cytometry to assess *in vivo* biodistribution and circulation half-life. Results: We have found that our lcLNPs circulate *in vivo* in murine models for greater than 24 hours post-intravenous administration and observe sustained expression up to 5 days. Additionally, our lcLNP systems notably show substantially higher protein expression levels (up to 100X) at later time points in extrahepatic tissues such as the bone marrow, spleen, heart, kidney, and lungs and demonstrate the capability of transfecting skin tissue (Figure 1).



We additionally demonstrate enhanced knockdown of protein expression in abdominal skin tissue and transfection of solid tumours, as well as *in vivo* targeting of T cells within the bone marrow (Figure 2) indicating the disease applicability of our LNP formulations.



Conclusions/Implications: Our lcLNP systems address a key barrier to one of the current issues impeding extrahepatic delivery of genetic payloads and this work demonstrates proof-of-concept experiments that could lead to potential treatment of unaddressed genetic diseases due to current biodistribution barriers.

84 RNA Base Editing for the Treatment of Alpha-1 Antitrypsin Deficiency

Prashant Monian, Chikdu Shivalila, Genliang Lu, Keith Bowman, Marissa Bylsma, Michael Byrne, Megan Cannon, Jigar Desai, Alyse Faraone, Frank Favaloro, Anamitra Ghosh, Jack Godfrey, Nidia Hernandez, Naoki Iwamoto, Tomomi Kawamoto, Jayakanthan Kumarasamy, Pachamuthu Kandasamy, Anthony Lamattina, Muriel Lemaitre, Amber Lindsey, Fangjun Liu, Richard Looby, Khoa Luu, Jake Metterville, Ik-Hyeon Paik, Qianli Pan, Tom Pu, Erin Purcell-Estabrook, Jeanette Rheinhardt, Mamoru Shimizu, Kuldeep Singh, Stephany Standley, Carina Thomas, Snehlata Tripathi, Hailin Yang, Ryan Yordanoff, Yuan Yin, Hui Yu, Padma Narayanan, Paloma H. Giangrande, Chandra Vargeese

Wave Life Sciences, Cambridge, MA

A point mutation in the *SERPINA1* gene (G-to-A mutation, PiZ allele) is the most common cause for Alpha-1 antitrypsin deficiency (AATD). The resulting E342K amino acid change leads to misfolding and aggregation of mutant Z-AAT protein in hepatocytes and a decrease in functional wild-type AAT (M-AAT) in circulation. Thus, this single mutation leads to both toxic gain-of-function and loss-of-function phenotypes, leading to progressive liver injury, lung injury, or both and culminates in end-stage liver and pulmonary disease. Current standard of care, which addresses only the lung manifestation, aims to restore serum M-AAT levels to an anticipated therapeutic threshold (11 μM) by weekly intravenous protein augmentation therapy with plasma-purified AAT. While there are multiple approaches in development to treat AATD, they either address only a subset of patient needs (e.g., silencing approaches to reduce liver aggregates) or do not restore M-AAT (e.g., small-molecule approaches). We aim to decrease Z-AAT and restore M-AAT protein by correcting the PiZ mRNA with AIMers—chemically modified oligonucleotides that direct A-to-I base editing in RNA. Our AIMers incorporate phosphoryl-guanidine (PN) chemistry on a stereopure backbone and recruit endogenous adenosine deaminase acting on RNA (ADAR) enzymes. This approach is expected to preserve physiological regulation of M-AAT while protecting the lungs and decreasing Z-AAT protein aggregation in liver. To facilitate delivery to hepatocytes, we conjugated AIMers to *N*-Acetylgalactosamine (GalNAc). In the NSG-PiZ mouse model that expresses the human PiZ allele, GalNAc-AIMers direct significant PiZ editing in hepatocytes and durably increase serum AAT protein levels. With loading dose followed by bi-weekly dosing, serum AAT levels are maintained at concentrations >11 μM and reach a peak concentration of ~20-30 μM. Secreted AAT protein has the expected wild-type amino acid sequence and inhibits neutrophil elastase. Over time, treated mice show a decrease in liver inflammation and hepatocyte turnover, and reduction in the size of PAS-D positive globules. Lastly, we show that GalNAc-AIMers support dose-dependent PiZ mRNA base editing *in vitro* in primary and iPSC-derived human hepatocytes deficient for M-AAT (MZ heterozygous and ZZ homozygous lines). These findings highlight the potential of GalNAc-AIMers as a therapeutic approach to address both liver and lung manifestations of AATD.

85 Phosphoryl Guanidine-Containing Oligonucleotides Support Exon Skipping in Skeletal Muscle in Mice and Boys with DMD

Pachamuthu Kandasamy[1], Graham McClorey[2], Laurent Servais[3], Craig Campbell[4], Xiao Shelley Hu[1], Andrew Hart[1], Joseph A. Haegele[1], Kuldeep Singh[1], Jeanette Rheinhardt[1], Anamitra Ghosh[1], Mamoru Shimizu[1], Nayantara Kothari[1], Naoki Iwamoto[1], Michael Byrne[1], Fangjun Liu[1], Chikdu Shivalila[1], Carlo Rinaldi[2], Hailin Yang[1], Danlin Xu[1], Stephen Lake[1], Michael Panzara[1], Anne-Marie Li-Kwai-Cheung[1], Matthew J. [1]Wave Life Sciences, Cambridge, MA,[2]University of Oxford, Oxford, United Kingdom,[3]Oxford Children's Hospital, Oxford, United Kingdom,[4]University of Western Ontario Children's Hospital, London, ON, Canada,[5]Department of Paediatrics, University of Oxford, Oxford, United Kingdom

Introduction: DMD is the most common genetic muscular dystrophy caused by mutations in the gene encoding dystrophin. Despite numerous FDA approvals, DMD remains a relentless disease, where lack of dystrophin protein results in severe, progressive muscle atrophy and premature death. WVE-N531 is an investigational stereopure antisense oligonucleotide being developed as a potential therapy for patients with DMD amenable to exon 53 skipping. WVE-N531 was designed based on stereopure oligonucleotides that exhibited improved pharmacology compared with phosphorothioate (PS)-modified oligonucleotides in mouse models for DMD. **Methods:** In preclinical experiments, *mdx23* or *mdx/utr*$^{-/-}$ double knockout (dKO) mice were treated with oligonucleotides by intravenous or subcutaneous injection, respectively. Oligonucleotide muscle concentrations (hybridization ELISA), exon skipping (RT-qPCR/TaqMan), and dystrophin (capillary western immunoassay) were quantified as indicated. Three ambulatory boys participated in an intra-patient dose-escalation clinical trial (NCT04906460). The boys received single-escalating doses of 1, 3, 6 and 10 mg/kg; in the multidose portion of the study, the same boys received three doses of 10 mg/kg every other week, and a muscle biopsy occurred 2 weeks after the third and final dose. Exon skipping (RT-PCR), dystrophin protein (western blot), and oligonucleotide in tissue (hybridization ELISA) were quantified as indicated. Oligonucleotide in muscle was visualized (RNAscope, *in situ* hybridization). **Results:** In preclinical studies, stereopure oligonucleotides containing PN chemistry increased muscle exposure, exon skipping and dystrophin restoration in dystrophic muscle compared with stereopure oligonucleotides with PS chemistry alone. The PN-containing molecule prevented premature death and improved median survival from 49 days to at least 280 days in dKO mice. In treated mice, restoration in dystrophin expression was delayed in time compared with exon skipping. The levels of dystrophin achieved in diaphragm and heart and rescue of respiratory function of severely affected dKO mice were encouraging, as expression in these tissues may be needed to improve survival. After the 6-week multidose portion of the clinical study, WVE-N531 reached a mean concentration of 42 µg/g in muscle tissue, with RNAscope providing evidence that WVE-N531 reached the nucleus. Mean exon skipping was 53% (range, 48-62%). Mean dystrophin production was 0.27% (BLQ) of normal. Adverse events were all mild, except for a COVID-19 infection of moderate intensity. There were no serious adverse events, no concerning trends in laboratory data, and no oligonucleotide class-related safety events. **Conclusion:** Preliminary clinical data provide evidence that WVE-N531, which is the first exon-skipping oligonucleotide containing PN chemistry to be tested in the clinic, is leading to substantial exon skipping after three biweekly doses. These data suggest PN chemistry may be impacting pharmacology at the level of human muscle tissue. Although measured dystrophin in patients was low, it is expected that dystrophin production would lag RNA splicing. Extended dosing and follow up are needed to confirm increased production of dystrophin in patients over time.

86 A Novel Small Molecule-Aptamer Pair for Regulating Gene Expression *In Vitro* and *In Vivo*

Yohei Yokobayashi[1], Keisuke Fukunaga[1], V. Dhamodharan[1], Nao Miyahira[1], Yoko Nomura[1], Yasuaki Oosumi[2], Kosuke Takayama[2], Akira Kanai[2]

[1]Okinawa Institute of Science and Technology Graduate University, Onna, Japan,[2]Applied Research & Operations, Astellas Pharma Inc., Tsukuba, Japan

Background: Chemical regulation of gene expression by a small molecule via an RNA molecular recognition element (aptamer) enables dynamic and precise tuning of therapeutic gene expression from viral vectors and in genetically engineered cells. Such "riboswitches" offer advantages such as small genetic footprint and lack of immunogenic protein components over the conventional gene switches based on transcription factors. However, the variety of the available small molecules and their cognate aptamers that have been reported to function in mammalian cells and animals are limited. Existing systems (e.g., theophylline, tetracycline, guanine) require >0.1 mM of the trigger molecule to regulate gene expression, limiting their potential biomedical applications. Although RNA aptamers that bind small molecules are not rare, most of them fail to either function in mammalian cells or exhibit a suitable structural change necessary for riboswitch development. **Results:** We set out to generate and screen new aptamers against a panel of pharmaceutically relevant small molecules for mammalian riboswitch applications by SELEX. This effort resulted in a 45-nt RNA aptamer AC17-4 that binds the small molecule ASP2905 with a dissociation constant of 48 nM at 37°C. We observed that, when incorporated into a self-cleaving ribozyme scaffold, the engineered aptazyme is inhibited by aptamer-ligand binding. By inserting the aptazyme in the 3' untranslated region (UTR) of an EGFP transcript, more than 10-fold induction of gene expression was observed in the presence of 5 µM ASP2905 in HEK293 cells transfected with a plasmid vector. The riboswitch was then inserted to an AAV8 vector to regulate human erythropoietin (hEPO) expression in mice. Oral administration of an ASP2905 analog resulted in up to 7.2-fold upregulation of hEPO secretion in serum compared to the control mice. The AC17-4 aptamer was also used to regulate exon skipping following the design strategy developed by another group. The switches showed excellent dynamic ranges (>200-fold induction) with very low basal expression levels in vitro (HEK293 cells). MTT assay showed no detectable toxicity to HEK293 cells up to 10 µM ASP2905. **Conclusions:** The novel aptamer-ligand pair AC17-4/ASP2905 functions at low-micromolar concentrations in mammalian

cell culture systems. In addition to riboswitches, our aptamer-ligand platform may be used to chemically regulate various RNA functions in mammalian cells.

87 tRNA Picovectors Represent a New Therapeutic Approach for the Rescue of Premature Termination Codons

Joseph J. Porter, Wooree Ko, Emily Sorensen, John D. Lueck

Pharmacology and Physiology, University of Rochester, Rochester, NY

Background: Mutations which when transcribed convert a sense codon into one of the three stop codons result in a premature termination codon (PTC) in the protein-coding gene sequence. Around 10% of all genetic lesions resulting in human disease are caused by the introduction of a PTC. Disease states caused by PTCs are difficult to address therapeutically because little or no protein target is expressed, both due to direct premature termination of translation and due to the loss of PTC-containing mRNA transcripts through the eukaryotic nonsense mediated decay (NMD) surveillance system. As such, approaches for the therapeutic rescue of PTCs must replace the gene itself or target the aberrant DNA, mRNA, or process of translation. Nonsense suppressor tRNAs or Anticodon Engineered tRNAs (ACE-tRNAs), where the anticodon has been altered to suppress the stop codon causing the PTC, have emerged as a therapeutic avenue to the treatment of disease-causing PTCs. As the translational fidelity of the processes involved in charging the tRNA with its cognate amino acid are retained following the alteration of the anticodon, the PTC is quantitatively reverted to the original amino acid that the protein contained at the site of the PTC. While ACE-tRNAs possess a number of attractive therapeutic properties, they are a fundamentally a gene therapy approach, and as such are subject to the delivery hurdle that all gene therapies face. A major advantage of ACE-tRNAs, however, is the small ~125 bp size of the ACE-tRNA gene including promoter and transcriptional terminator. Encoding ACE-tRNAs as so called 'tRNA picovectors' should impart favorable characteristics to the gene therapy vector including increased cell transfection efficiency, improved intracellular vector trafficking, lower levels of gene silencing, and higher molar equivalents of the cargo sequence per vector delivered. **Methods**: ACE-tRNA picovectors comprising both circular as well as covalently closed linear topologies of 200-400 bp were produced using *in vitro* production methods. *In vivo* recombination based vector production methodologies were also employed for the production of circular ACE-tRNA vectors 850 bp in size. Previously we developed several stable PTC reporter constructs including an mNeonGreen PTC reporter for determining ACE-tRNA delivery efficiency and a NanoLuciferase based PTC reporter for high throughput measurement of PTC suppression efficiency in HBE (human bronchial epithelial) cell lines. Here, we have employed these reporters to determine both the transfection efficiency and PTC rescue efficiency of our ACE-tRNA picovectors. **Results and Conclusions**: We have demonstrated ACE-tRNA function from what are, to the best of our knowledge, the smallest expression vectors used to date. As expected, these ACE-tRNA picovectors display higher transfection efficiency and higher PTC rescue than plasmid DNA in HBE cells. **Acknowledgements**: Funding for this work was provided by a Cystic Fibrosis Foundation Postdoctoral Fellowship to JJP (PORTER20F0) and Cystic Fibrosis Foundation and NIH grants to JDL (LUECK20GO, and NHLBI 1 R01 HL153988-01A1 respectively).

CAR Engineering and Production Advances for Targeting Hematologic and Solid Tumor Malignancies

88 CD5 CAR T-cells Promote Selection of Fratricide-Resistant Circulating T-cells Thus Avoiding Global T-cell Aplasia

Royce Ma[1], Mae Woods[1], Phillip Burkhardt[2], Noah Crooks[2], Dayenne Van Leeuwen[2], Malcolm K. Brenner[1], Maksim Mamonkin[1]

CAR T-cells specific to T-lineage antigens risk ablating normal T-cells resulting in dangerous immunosuppression. Targeting the pan-T cell antigen CD5, broadly expressed in both T-cell lymphoma (TCL) and acute lymphoblastic leukemia (T-ALL) but also by nearly all peripheral T-cells, increases the risk of T-cell aplasia. We have previously reported CD5 CAR T-cells escape self-elimination without additional engineering by undergoing CAR-driven degradation of CD5 protein thus enabling clinical manufacturing of CD5 CAR T-cells for patients with T-cell malignancies. In an ongoing Phase I clinical trial (NCT03081910), CD5 CAR T-cells produce complete tumor elimination in patients with TCL and T-ALL but, unexpectedly, do not eradicate circulating T-cells. The mechanism of this resistance of normal T-cells to CD5-directed cytotoxicity, and whether tumor cells can employ the same strategy to evade elimination, remains unknown. To model clinical findings, we cocultured CD5 CAR T-cells with normal autologous or malignant (T-ALL and TCL) cells. Exposure of normal and malignant T-cells to CD5 CART resulted in a gradual loss of surface CD5. Experiments with engineered dual-tagged CD5 and time-lapse microscopy showed loss of CD5 on target cells was driven by internalization and complete degradation of CD5 mediated by CAR engagement *in trans*. CD5 was re-expressed on target cells within 12-24h of removing CD5 CAR T-cells indicating trans-downmodulation was temporary. Importantly, loss of CD5 temporarily shielded target cells from CD5 CAR T-cell mediated killing but was insufficient to provide long-term protection *in vitro* due to gradual re-expression of CD5 on target cells, thus continuously re-exposing them to cytotoxic CAR T-cells. Despite both normal and malignant T-cells having similar kinetics of CD5 trans-downmodulation upon coculture with CD5 CAR T-cells, healthy peripheral blood T-cells were more resistant to CD5-directed cytotoxicity as a subset of normal T-cells survived a 36-hour coculture with autologous CD5 CAR T-cells while tumor cells were eliminated. Single-cell RNA-sequencing analysis revealed the resistant T-cells were enriched for CD8+ subsets with an effector T-cell program (upregulated cytotoxic effector molecules: granzymes A, B, M, K, perforin, NKG7, KLRB1; downregulated naïve/memory genes: SELL, LEF1, TCF7), consistent with prior reports demonstrating increased resistance of differentiated T-cells to self-directed killing.

To evaluate the contribution of these mechanisms to the resistance of normal circulating T-cells in patients post CD5 CAR T-cell infusions, we analyzed the phenotypic and subset composition of non-transgenic T-cells in peripheral blood. Expansion of CD5 CAR T-cells correlated with a rapid loss of CD5 on circulating T-cells and an enrichment for effector/memory CD8+ populations, mirroring *in vitro* findings. Expectedly, in patients with persisting CD5 CAR T-cells, the CAR-induced trans-downmodulation of CD5 was insufficient for long-term protection, leading to the selection of a non-classical T-cell population lacking CD5 gene expression and enriched for CD8+ alpha-beta and CD4-/CD8- double negative gamma-delta T-cells. These subsets were rapidly replaced with conventional CD5+ T-cells following contraction of CD5 CAR T-cells. Taken together, these results indicate CD5 CAR induces temporary internalization and degradation of CD5 antigen on target cells, but this mechanism provides only short-term protection for normal and malignant T-cells from cytotoxicity. Long-term resistance of normal T-cells in patients having received CD5 CAR T-cell therapy was associated with the emergence of CD5-negative T-cell subsets.

89 CAR Signaling Drives Distinct Immunological Synapse Dynamics That Influence the T Cell Behavior in Killing Cancer

Shearer Center for Human Immunobiology, Texas Children's Hospital, Houston, TX

CAR T cells that signal through CD28 and 41BB are highly effective against lymphoreticular malignancies, despite exhibiting distinct activity patterns in the clinic. We hypothesized that the dynamics of individual CAR T cells at the CAR immunological synapse (CARIS) level, can explain, at least in part, their behavior, *in vivo*. Studying the potency of CAR T cell products targeting HER2 and CD19, we discovered that CD28 polarizes T cells to highly lethal less expansive CD8 effectors. In contrast, 41BB stimulates a Th2 polarizing secretome that supports robust expansion of modestly cytotoxic CD4/CD8 balanced effectors, and persistence of less differentiated central memory T cells. We monitored the single cell behavior of CAR T cells in high throughput, the proteomic composition of the CARIS lipid raft compartment, the mechanical properties and the killing mechanisms of the CARIS, against time. We discovered that CD28 CAR T cells rely on short-lived highly lethal interactions with tumor cells, characterized by brisk shuttling of CARs and their downstream molecules in and out of the CARIS lipid rafts, which leads to rapid MTOC polarization and cytolytic degranulation in a manner that allows for a mastery of serial killing. In contrast, 41BB CAR T cells engage in synapses characterized by slower accumulation of CAR molecules and their associated interactome, and pertinently increased LFA-1 recruitment and retention at mechanically tonic CARIS, in a lengthier, and rather collaborative Fas ligand-mediated killing process. We show here that CAR T cell signaling domains mediate CARIS dynamics that can explain their distinct killing behavior. By understanding and potentially modulating these dynamics, the CAR T cell functionality and toxicity can be rationally optimized.

90 Potent *In Vivo* Transduction by iGPS Particles Generates CAR T Cells with Durable Anti-Tumor Activity

Shannon Grande Contrastano, Emily T. Beura, Denise Wong, Gabrielle Ndakwah, Howard J. Latimer, Jenifer Obrigewitch, Jose Sanabria, Alexander J. Najibi, Daniel Wambua, Jeff Wood, Jessica Murray, Maggie Lau, Josue Figueroa, Alyson Warr, Connor S. Dobson, Molly R. Perkins, Kevin Friedman

Adoptive autologous cell therapies have proven to be effective treatments for hematological malignancies. Access to such treatments is severely constrained by the length and complexity of ex vivo manufacturing. Allogeneic approaches are aimed at overcoming scalability and time to treatment but remain limited by inferior clinical responses. A chimeric antigen receptor (CAR) T cell therapy that improves patient access and reduces manufacturing complexity without sacrificing clinical benefit of autologous cell therapies is needed. CAR gene delivery to T cells in vivo is a potential solution that also eliminates the need for conditioning chemotherapy required for cell engraftment. Here we describe an in vivo gene placement system (iGPS™), an advanced lentiviral vector (LVV) particle harboring envelope modifications to improve in vivo gene transfer efficiency and tropism molecules to facilitate T cell-specific gene delivery. When an anti-BCMA CAR transgene was expressed by iGPS particles, low intravenous (i.v.) dose levels caused potent and durable multiple myeloma regression in preclinical models. In vitro culture of normal human peripheral blood mononuclear cells (PBMC) with iGPS particles without T cell-activating antibodies demonstrated concentration-dependent T cell transduction. Even at a low multiplicity of infection of 1, an average of 14% T cell transduction (VCN=1.2) was achieved. Transduction efficiency in vivo was assessed in humanized mouse models after a single i.v. dose of 2e7 TU iGPS particles. An average of 1.9% transduced blood T cells was observed with iGPS particles. Matched doses of "standard" VSVg-pseudotyped LVV particles with and without T cell tropism molecules resulted in 0.27% and 0% transduced T cells, respectively. These data indicate iGPS envelope modifications drive efficient in vivo transduction and preferential outgrowth of T cells. We evaluated anti-tumor activity of anti-BCMA CAR T cells generated in vivo by i.v. treatment with iGPS particles. Complete regression of established multiple myeloma tumors was possible at the lowest dose level tested (1e7 TU). A single dose of 2.5e7 TU iGPS particles resulted in complete tumor control comparable to mice

adoptively transferred with anti-BCMA CAR T cells generated ex vivo using established methods. To evaluate functional persistence of iGPS particle-generated CAR T cells, animals were rechallenged with multiple myeloma tumor cells ~2 weeks after primary tumor clearance. All animals treated with iGPS particles were completely protected against secondary tumor challenge, whereas animals treated with ex vivo-generated CAR T cells showed tumor progression. Off-target transduction was evaluated after infusion of iGPS particles at a therapeutic dose level of 2.5e7 TU in humanized mice. One week following i.v. iGPS administration, a comprehensive set of tissues including heart, brain, ovaries, intestinal tract lung and liver were analyzed for transduction. Across animals, the average T cell transduction was 3.9% and 14% in the blood and spleen, respectively. Strikingly, transduction of other tissues was limited to phagocytes like Kupffer cells, which are expected to nonspecifically take up iGPS particles. No transduction was detected in vital organs or in progenitor cells. iGPS particles can deliver CAR molecules to T cells in vivo with high efficiency and tissue specificity at therapeutic dose levels. Anti-BCMA CAR T cells generated with iGPS particles exhibit anti-tumor potency and functional persistence. These data demonstrate the potential for iGPS particles to be a highly effective, safer, off-the-shelf therapy for patients with multiple myeloma.

91 Engineering Optimal CAR T Cells to Overcome Pancreatic Tumors with Secreted Antagonistic Peptides

Heather K. Lin, Dejah A. Blake, Abhijay Mudigonda, Alysa N. Evans, Ruby Freeman, Tanisha Sinha, Elyse Christensen, Fan Fei, Tenzin Passang Fnu, Sruthi Ravindranathan, Tongrui Liu, Lily Yang, Edmund K. Waller, Sarwish Rafiq

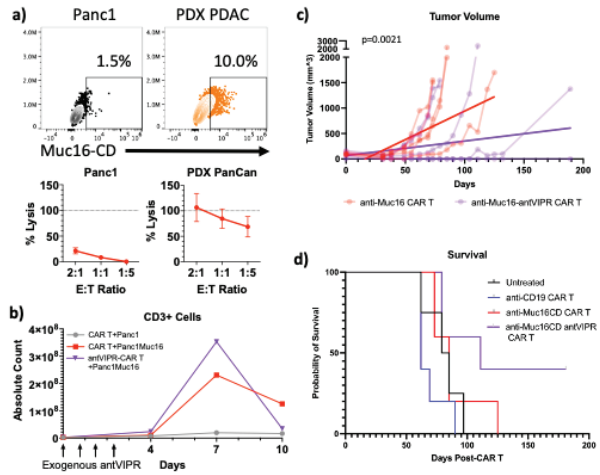
Chimeric antigen receptor (CAR) T cell therapies have shown remarkable clinical efficacy in hematological cancers but still face significant obstacles in the treatment of solid tumors such as pancreatic ductal adenocarcinoma (PDAC). Two major hurdles in developing effective CAR T therapies for PDAC are the identification of ideal tumor-associated antigens (TAA) to target and overcoming a complex tumor microenvironment (TME). We hypothesize that the optimal CAR T cell to treat PDAC recognizes an ideal TAA and protects itself from immune suppression from the TME. Here, we propose the ectodomain of Muc16 (Muc16CD) as a viable TAA expressed in PDAC tumors (Fig 1a) and antagonizing vasoactive intestinal peptide (VIP), an immunosuppressive neuropeptide, to overcome the PDAC TME. First, assayed patient-derived xenograft (PDX) PDAC cell lines were assayed for Muc16CD and VIP expression to establish the clinical relevance of these targets. Interestingly, despite modest Muc16CD expression on PDX lines, Muc16CD-directed 2nd generation CAR T cells had cytotoxic function *in vitro* (Fig 1a) and reduced tumor burden in mice engrafted with orthotopic PDX PDAC tumors. Next, we investigated whether VIP is immunosuppressive for CAR T cell function. VIP limits the proliferative capacity of CAR T cells, which can be reversed by treatment with novel, potent VIPR antagonist peptides. Therefore, anti-Muc16CD CARs were engineered to express antVIPR and provide continuous and localized delivery of antVIPR peptides within the TME. AntVIPR expression by CAR T cells impacts phenotype as these cells have improved cell viability and express less VIP and VIPRs at baseline. Functionally, antVIPR CAR T cells have a proliferative advantage after antigen-stimulation (Fig 1b) and enhanced activation compared to parental CAR T cells. Next, human Panc1 tumors were engrafted into SCID/Beige mice and treated with antVIPR CAR T cells. In this xenograft model of pancreatic cancer, antVIPR CAR T cells reduce tumor burden (Fig 1c) and improve overall survival in mice bearing human VIP-expressing PDAC tumors (Fig 1d). At 118 days, mice were found to have more circulating hCD3+ cells in the antVIPR CAR T-treated mice than the 2nd generation CAR T-treated mice. Collectively, this data demonstrates that the combination of targeting Muc16CD and VIP with a novel CAR T cell can improve anti-tumor efficacy against PDAC. Mouse-specific CAR constructs have been validated to employ in a syngeneic model of pancreatic cancer to determine the mechanisms by which locally secreted VIPR antagonists can modulate the PDAC TME. The long-term goal of translating antVIPR-secreting CAR T cells for the treatment of PDAC.



92 Harnessing CD39 for the Treatment of Colorectal Cancer and Liver Metastases by Engineered T Cells

Alessia Potenza[1], Balestrieri Chiara[1], Luca Albarello[1], Federica Pedica[1], Martina Spiga[2], Francesco Manfredi[3], Beatrice Claudia C. Cianciotti[4], Claudia De Lalla[1], Lorena Stasi[1], Elena Tassi[1], Silvia Bonfiglio[1], Giulia Scotti[1], Miriam Redegalli[1], Donatella Biancolini[1], Danilo Abbati[1], Fabio Simeoni[1], Dejan Lazarevic[1], Ugo Elmore[1], Guido Fiorentini[1], Giulia Di Lullo[1], Giulia Casorati[5], Claudio Doglioni[1], Giovanni Tonon[1], Paolo Dellabona[5], Riccardo Rosati[1], Luca Aldrighetti[1], Eliana Ruggiero[6], Chiara Bonini[7]

[1]IRCCS San Raffaele Scientific Institute, Milan, Italy,[2]San Raffaele Scientific Institute, Milan, Italy,[3]Vita-salute San Raffaele University, Milan, Italy,[4]San Raffaele Scientific Institute, Milano, Italy,[5]Fondazione San Raffaele Del Monte Tabor, Milan, Italy,[6]Ospedale San Raffaele, Milano, Italy,[7]Università Vita Salute San Raffaele, Milan, Italy

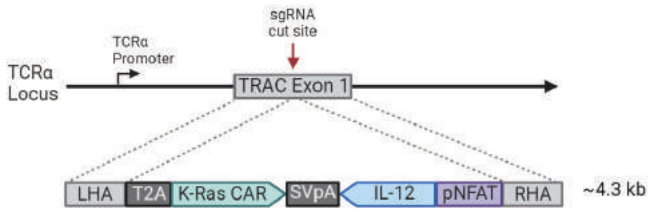
Colorectal cancer (CRC) is the 2nd cause of cancer-related death. Despite standard therapies, more than 50% of patients experience relapse, eventually with metastatic disease. Colorectal tumors are densely infiltrated by immune cells that have a role in surveillance and modulation of tumor progression, correlating with improved overall survival. However, exhaustion mechanisms acting within the tumour microenvironment impede their functional capacity against tumor cells. We paired high-dimensional flow cytometry, RNA sequencing, immunohistochemistry and immunofluorescence to describe the T cell functional landscape in tumor and peritumoral tissues from primary colorectal cancers and liver metastases. By CRISPR/Cas9 genome engineering technique, we redirected the specificity of T cells towards a tumor-specific antigen while disrupting inhibitory molecules, to counteract the immune-suppressive tumor microenviroment. Analysis of the healthy, peritumoral and neoplastic tissues of treatment-naïve primary CRCs and of the peritumoral and tumoral tissues of CRC patients undergoing surgery for liver metastasis, revealed extensive transcriptional and spatial remodeling across tumors, being metabolic pathways among the major drivers of this variance. Regarding the immune infiltrate, we found that T cells are mainly localized at the front edge and that tumor-infiltrating T cells co-express multiple inhibitory receptors. Unsupervised analysis of flow cytometry data performed by an advanced pipeline of data handling by dimensionality reduction and clustering algorithms allowed the definition of a peculiar inhibitory receptors signature in TILs enriched both in primary CRCs and liver metastases. Among the highly co-expressed inhibitory receptors, CD39 was found to represent the major driver of exhaustion in both primary and metastatic colorectal tumors. CD39 is a diphosphohydrolase converting ATP into AMP that is emerging as exhaustion marker for tumor-specific T cells, thus highlighting its relevance as molecular target for T cells engineering. By CRISPR/Cas9 genome editing tools, we simultaneously redirected T cell specificity by disrupting the alpha and beta genes of the endogenous T cell receptor with >90% efficiency for both genes, and disrupted CD39 with 100% efficiency, generating triple-knockout engineered lymphocytes. By lentiviral transduction, we redirected the specificity of our engineered T cell product employing a novel T-cell receptor targeting the HER-2 antigen. Triple-edited, HER2-redirected T cells were challenged against HER2+ patient-derived organoids (PDOs) *in vitro* and *in vivo*. Results showed that CD39-disrupted, HER2-redirected T cells have a functional advantage in eliminating CRC PDOs, compared to CD39-competent, HER2-redirected T cells. Thus, CD39 axis is relevant for further exploitation in adoptive T-cell therapy to treat primary and metastatic colorectal cancer.

93 Enhancement of K-Ras Neo-Antigen Targeting CAR-T Cells via Homogenous Knock in of Inducible IL-12

Alex Benton[1], Anze Smole[1,2], Mathilde Poussin[1], Daniel J. Powell[1]

[1]Center for Cellular Immunotherapies, University of Pennsylvania, Philadelphia, PA,[2]Genetic Toxicology and Cancer Biology, National Institute of Biology, Ljubljana, Slovenia

While CAR-T cell cancer immunotherapy has been successful in treating hematological malignancies, there have been significant difficulties in adapting these therapies for the treatment of solid tumors. Challenges include (i) heterogeneity of tumor associated antigens, (ii) insufficient CAR-T cell expansion and cytotoxicity, and (iii) a low therapeutic index, where responding patients experience severe toxicity. We hypothesized that these challenges could simultaneously be addressed with a single CAR-T cell product using our unique genetic engineering approach. To achieve high tumor specificity we developed CAR-T cells targeting K-Ras neo-antigens presented as mutant peptides in MHC molecules on cancer cell surfaces (NeoCARs). We demonstrated *in vivo* efficacy of our NeoCARs against highly conserved G12V mutant peptides in an HLA-A11 dependent context. However, cancer cells typically express 10-100 target neo-antigens each. Low target antigen abundance can result in weakened CAR-T cell activity and failure to achieve a clinical response. In our pre-clinical lung cancer model this resulted in only 43% complete response and survival for the top performing NeoCAR (n=7). We hypothesized that both additional immunostimulatory factors and enhancement of the safety profile are needed expand the therapeutic index for NeoCARs in the treatment of solid tumors. We elected to "armor" our NeoCARs with IL-12 due to its pleiotropic immunostimulatory effects. For an enhanced safety profile and simplified manufacturing of a homogenous product, we developed genetic systems referred to as Uni-Vect. These systems combine antigen induced expression via a nuclear factor of activated T cells (NFAT) response element, with constitutive CAR expression, in a single lentiviral vector. To eliminate aberrant TCR signaling as a source of inducible IL-12 expression, we adapted Uni-Vect for a genome editing approach with homology directed repair (HDR) as a means of template integration. This approach enabled single step generation of TCR disrupted, inducibly armored NeoCARs.



We demonstrate that Uni-Vect enabled homogenous delivery of the constitutive and NFAT inducible modules. Neo-CARs expressing

inducible IL-12 showed an 1-2 log increase in IFN- γ secretion, resulting in upregulation of HLA-A on target cells, and enhanced killing of tumor spheroids *in vitro* ($p<0.00001$). In an *in vivo* model of ovarian cancer we found that inducible IL-12 was necessary for complete clearance of solid tumors, but led to lethal toxicity in all mice receiving TCR positive CAR-T cells (n=5). Only the complete system of CAR, inducible IL-12, and knock in resulted in complete response without lethal toxicity in all mice receiving the treatment (n=5). This coalesced and modular system has broad applicability for the enhancement of next generation of CAR-T cells targeting solid tumors.

94 AMELI-01: A Phase I Trial of UCART123v1.2, an Anti-CD123 Allogeneic CAR-T Cell Product, in Adult Patients with Relapsed or Refractory (R/R) CD123+ Acute Myeloid Leukemia (AML)

David A. Sallman[1], Daniel J. DeAngelo[2], Naveen Pemmaraju[3], Shira Dinner[4], Saar Gill[5], Rebecca L. Olin[6], Eunice S. Wang[7], Eileen Stark[8], Ana Korngold[8], Carolyn Figliola[8], Kathryn J. Newhall[8], Daniel J. Lee[8], Mark G. Frattini[8], Gail J. Roboz[9]

[1]Moffitt Cancer Center, Tampa, FL,[2]DFCI, Boston, MA,[3]MDACC, Houston, TX,[4]Northwestern Univ, Chicago, IL,[5]Univ of Pennsylvania, Philadelphia, PA,[6]UCSF, San Francisco, CA,[7]Roswell Park Comprehensive Cancer Center, Buffalo, NY,[8]Cellectis, Inc, New York, NY,[9]Weill Cornell Medicine, New York, NY

UCART123v1.2 (UCART123) is a genetically modified allogeneic T cell product manufactured from healthy donor cells. Donor derived T cells are transduced using a lentiviral vector to express the anti-CD123 chimeric antigen receptor and are further modified using Cellectis' TALEN® technology to disrupt the T cell receptor alpha constant (TRAC) and CD52 genes to minimize risk of GvHD and allow use of anti-CD52-directed therapy as part of lymphodepletion (LD). AMELI-01 (NCT04106076) is a phase 1 trial evaluating the safety, tolerability, expansion, and persistence of UCART123 given at escalating dose levels after LD with either fludarabine and cyclophosphamide (FC) or FC with alemtuzumab (FCA) in patients (pts) with R/R AML. Key eligibility criteria include pts 18-65 yrs, adequate organ function, ECOG PS ≤ 1, and blasts positive for CD123 by flow cytometry. Pts must have received ≥2 cycles of chemotherapy, ≥ 1 cycle of a high/intermediate dose cytarabine containing regimen, ≥ 2 cycles of an HMA combination regimen, or prior allogeneic HSCT. After LD with FC or FCA, pts received UCART123 at one of the following dose levels in cells/kg: $2.5x10^5$ (DL1); $6.25x10^5$ (DL2); $1.5x10^6$ (DL2i); or $3.03x10^6$ (DL3). The primary endpoint is the safety, tolerability, and MTD/RP2D of UCART123. Additional endpoints include investigator assessed anti-leukemic activity per 2017 ELN criteria, and expansion, trafficking, and persistence of UCART123. As of Oct 10, 2022, 17 pts received UCART123; 8 pts received UCART123 after FC (DL1 [n=2]; DL2 [n=3]; DL2i [n=2]; DL3 [n=1]), and 9 pts received UCART123 after FCA (DL2 [n=8]; DL2i [n=1]). Median baseline BM and PB % blasts were 37% (0-88%) and 19% (0-79%). 5 pts experienced DLTs: 3 pts in FC arm (G4 CRS [1 pt in DL2i and 1 pt in DL3] and G3 ICANS [1 pt in DL2i]); and 2 pts in FCA arm (G5 CRS [1 pt in DL2 and 1 pt in DL2i). Cytokine release syndrome (CRS) occurred in all pts, of which 4 pts experienced ≥ G3 CRS which were classified as DLTs as noted above. Responses were assessed beginning on D28. Evidence of UCART123 activity was observed in 4/16 pts with best overall responses as follows: FC arm (DL2: 1 SD; DL2i: 1 MLFS); FCA arm (DL2: 1 SD and 1 MRD-negative CR). The pt in the DL2 FCA arm with SD achieved greater than 90% BM blast reduction (60% to 5%) at D28. The pt with CR, who failed 5 prior lines of therapy including HSCT and had baseline G4 cytopenias, had CRi at D28 with full count recovery at D56 and remains in an MRD-negative CR beyond the 12 month visit. Adequate LD was not achieved with FC, as host lymphocyte recovery was observed in 7/8 pts prior to D28, and only 3/8 pts had UCART123 expansion. UCART123 expansion was significantly higher with FCA LD (mean UCART123 $AUC_{0\text{-}28days}$ 34.9 ±28.4 days x copies/μg of DNA) vs. FC LD (mean $AUC_{0\text{-}28days}$ 10.2 ± 15.7 days x copies/μg of DNA; p= 0.04). An increase in inflammatory markers, notably serum ferritin, and cytokines with FCA correlated with both UCART123 expansion and CRS. Adding alemtuzumab to FC was associated with improved LD and significantly higher UCART123 cell expansion, which correlated with improved activity, including one pt in the DL2 FCA arm who achieved an ongoing durable MRD-negative CR. Overall, these data support the safety and activity of UCART123 after FCA LD in pts with CD123+ R/R AML. Based on observed UCART123 expansion patterns and cytokine profiles, the study was amended to include a UCART123 2-dose regimen with FCA LD, and enrollment is ongoing into this arm.

Genome Editing Therapies & Safety I

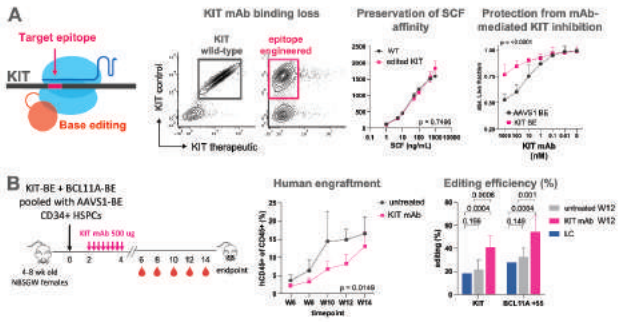
95 Epitope Edited Hematopoietic Stem Cells Allow Immune-Based *In Vivo* Selection of Genome-Engineered Cells

Gabriele Casirati[1], Andrea Cosentino[1], Adele Mucci[2], Mohammed S. Mahmoud[3], Marta Freschi[3], Jing Zeng[4], Christian Brendel[5], Daniel E. Bauer[6], Pietro Genovese[7]

[1]Pediatric Oncology, Dana Farber Cancer Institute, Boston, MA,[2]Boston Children's Hospital, Boston, MA,[3]Dana Farber Cancer Institute, Boston, MA,[4]Pediatric Oncology, Harvard Children's Hospital, Boston, MA,[5]Boston Children's Hospital/Dana-Farber Cancer Institute, Boston, MA,[6]Boston Children's Hospital/Harvard Medical School, Boston, MA,[7]Pediatric Oncology, Dana-Farber Cancer Institute, Boston, MA

Hematopoietic stem/progenitor cell (HSPC) transplantation (HSCT) offers curative options for patients affected by inheritable diseases for which substitution endogenous hematopoiesis with genetically corrected or healthy donor-derived cells can halt the pathogenic process. Nonetheless, the short- and long-term toxicities of genotoxic conditioning regimens remain a substantial barrier to a wider application of HSCT and gene therapy, in particular for patients with multiple comorbidities. Whereas the use of monoclonal, toxin-conjugated antibodies (mAb) or chimeric antigen receptor (CAR) T cells targeting HSPCs has been proposed as an alternative to chemo/radiotherapy, the mechanism of action and pharmacokinetics of these agents hamper their safe clinical use due to the risk of on-target killing of transplanted HSPCs, short time-window for transplantation,

insufficient clearance of the BM niche and no method to enrich transplanted cells over time. Here, we show that precise editing of the targeted epitope in HSPCs can endow hematopoietic lineages with selective resistance to mAbs or CAR-T, without affecting protein function or regulation. This strategy allows improved myeloablation - which can continue after HSCT - and progressive enrichment of gene-modified HSPCs. By means of epitope mapping libraries, we have identified amino-acid changes in the extracellular domain of KIT (CD117) that abrogate the binding of therapeutic mAbs without affecting surface expression, ligand-mediated activation, downstream signaling and proliferative response (FIG.A). We designed an adenine base editing (BE) strategy to introduce these mutations with high efficiency (up to 80%) in CD34+ HSPCs, with preservation of stem cell phenotype and long-term repopulating and multilineage differentiation capacity in both primary and secondary recipient mice. KITBE CD34+ cells were not affected by the dimerization-blocking effect of the KIT mAb, while expansion of control cells was inhibited in a dose-dependent fashion (FIG.A). To improve HSPC therapies for hemoglobinopathies, such as sickle cell disease, we multiplex base edited the KIT epitope and two BCL11A erythroid enhancer motifs. We obtained high editing efficiencies comparable to single editing on all three target sites and the erythroid progeny of triple-edited cells showed efficient upregulation of HbF. Mice xeno-transplanted with multiplex-edited CD34+ cells showed a 2-fold co-enrichment of both KIT and BCL11A editing in peripheral blood after 2 weeks of Ab administration (experiment in progress), confirming the possibility of selecting gene-modified cells in vivo up to therapeutic thresholds (FIG.B). We envision a new paradigm for non-genotoxic conditioning based on the transplantation of epitope-engineered HSPCs endowed with selective resistance to immunotherapeutic myeloablative agents to achieve safe engraftment and progressive selection of gene-corrected HSPC with substantial advantages over alternatives in terms of safety and tolerability.



96 Development of Prime Editing Strategies for the Treatment of β-hemoglobinopathies

Anne Chalumeau[1], Panagiotis Antoniou[1], Priyanka Loganathan[1], Giulia Hardouin[1], Cécile Masson[1], Carine Giovannangeli[2], Mégane Brusson[1], Annarita Miccio[1]

[1]Imagine Institute, Paris, France,[2]MNHN, Paris, France

β-hemoglobinopathies are genetic disorders caused by mutations that reduce adult β-globin production (β-thalassemia) or generate the sickle β^S-globin chain (Sickle Cell Disease, SCD). Genetic correction of autologous hematopoietic stem cells (HSCs) is a therapeutic option for patients lacking a compatible donor. The clinical severity of β-hemoglobinopathies is alleviated by the co-inheritance of genetic mutations termed hereditary persistence of fetal hemoglobin (HPFH), maintaining the fetal hemoglobin (HbF) expression in adult life. γ-globin compensates β-chain deficiency in β-thalassemia and exerts an anti-sickling effect in SCD. HPFH mutations in the promoters of the γ-globin genes (*HBG*) either generate binding sites (BSs) for transcriptional activators (i.e., KLF1, TAL1 or GATA1) or disrupt repressor BSs (i.e., LRF or BCL11A). Prime editing is a novel genome editing tool able to "rewrite" genomic sequences and consists of a prime editor (PE), a prime editing guide RNA (pegRNA) containing the desired edits (DEs) and a nicking guide RNA (ngRNA) that improve editing efficiency (PE3 system). Inhibition of the mismatch repair pathway using a dominant negative form of MLH1 (MLH1dn) favors the incorporation of DEs into the genome (PE5 system). Here, we aim at developing efficient prime editing strategies for β-hemoglobinopathies. In particular, we simultaneously generate multiple HPFH and HPFH-like modifications in the *HBG* promoters to further boost HbF expression. In humans, the co-occurrence of multiple HPFH mutations is associated with higher HbF levels compared to individual mutations. First, we designed multiple pegRNAs and ngRNAs to either (i) insert the KLF1 (-198 T>C) and TAL1 (-175 T>C) BSs, and disrupt the LRF BS in the -200 region or (ii) create the GATA1 (-113 A>G) and the KLF1 (-123; -124 T>C) BSs and disrupt the BCL11A motif in the -115 region of the *HBG* promoters. Plasmid transfection experiments in K562 cells allowed us to select the best performing pegRNAs and ngRNAs that efficiently bind the *HBG* promoters based on the cleavage efficiency induced by the Cas9 nuclease. We then inserted the tevopreQ[1] motif into the pegRNA to increase its stability (enhanced pegRNA, epegRNA) and, as a consequence, the editing efficiency. epegRNAs were tested using the PE3 and PE5 systems into K562 cells. The use of epegRNA and MLH1dn (PE5) improved prime editing efficiency. In the -200 region, we observed insertion either of the KLF1 BS alone or of both KLF1 and TAL1 BSs (up to 13% of promoters harboring both BSs) with a low frequency of InDels. In the -115 region, we observed different profiles using alternative epegRNAs, with ~18% of the promoters carrying only the GATA1 BS and up to 12% harboring both the GATA1 and KLF1 BSs. Interestingly, we also observed impure edits containing not only the BSs but also additional mutations that can be due to imperfect repair of the target region. Finally, we optimized the delivery of the prime editing system in HSCs. We inserted two copies of the *HBB* 3'UTR and a poly-A tail at the 3'-end of the PE mRNA to increase its stability. Furthermore, we tested a variety of parameters including the ratio PE/pegRNA and PE enhancers. Optimization of the different parameters led to increased prime editing efficiency in SCD HSCs upon RNA transfection (~25%). Overall, these results showed that our strategy can simultaneously insert multiple HPFH mutations in the *HBG* promoters. Additional optimizations of the system could improve the purity of the prime editing products and further increase the prime editing efficiency in HSCs with the goal of providing sufficient proof of efficacy for the treatment of β-hemoglobinopathies.

97 CHANGE-seq-BE Enables Sensitive and Unbiased Genome-Wide Profiling of Adenine Base Editors *In Vitro*

Cicera R. Lazzarotto[1,2], Yichao Li[1], Varun Katta[1], Elizabeth Urbina Obregon[1], Jonathan Yen[1], Mitchell J. Weiss[1], Shengdar Q. Tsai[1]

[1]St. Jude Children's Research Hospital, Memphis, TN,[2]Beam Therapeutics, Cambridge, MA

Base editors can correct pathogenic single-nucleotide variants without introducing DNA double-stranded breaks and have tremendous potential to become a new class of safe and effective genomic medicines. However, current methods for understanding the safety and genome-wide activity of base editors have limitations. Some have limited sensitivity as they do not enrich for base editor modified genomic DNA and others are experimentally biased by computational pre-selection of candidate off-target sites. To develop a method for direct, sensitive, unbiased, genome-wide discovery of base editor off-target sites we adapted CHANGE-seq, a scalable biochemical method for defining Cas9 nuclease genome-wide activity, to base editors (**CHANGE-seq-BE**). We used Tn5 tagmentation and exonuclease selection to generate libraries of highly purified genomic DNA circles. CHANGE-seq-BE enables the selective sequencing of adenine base editor modified genomic DNA by enzymatically processing circularized genomic DNA that is nicked and deaminated by base editors into full DNA DSBs for adapter ligation and sequencing. To systematically evaluate the genome-wide off-target activity of ABE8e *in vitro*, we performed CHANGE-seq-BE with sgRNAs targeted to seven therapeutic relevant target sites (*PCSK9*, *HBG1/HBG2* -198, *CD7*, *CIITA*, *PDCD1*, *B2M* and *CBLB*). We found CHANGE-seq-BE read counts were strongly correlated between independent CHANGE-seq-BE technical replicates (R^2>0.9). To validate the sensitivity of CHANGE-seq-BE for identifying sites of *bona fide* cellular off-target base editing, we selected 105 off-target sites from five sgRNA target sites, for analysis by multiplex targeted sequencing in ABE8e base edited cells. Of the 105 CHANGE-seq-BE detected sites we examined, we confirmed 26 (24.7%) by targeted sequencing, with activity ranging from 0.67-88.8%, demonstrating that our method can sensitively detect ABE off-target activity. Next, to determine whether CHANGE-seq-BE could identify base editor-specific off-target activity not detected by nuclease-specific methods, we compared sites identified by CHANGE-seq-BE and by CIRCLE-seq. For a sgRNA targeted to the *HBB gene,* we found that CHANGE-seq-BE identified all known off-target sites as well as an additional ~53% previously unknown *bona fide* off-targets than our initial screen with CIRCLE-seq (Newby et. al, 2021). Furthermore, percentile ranks of validated off-target sites were higher in CHANGE-seq-BE compared to CIRCLE-seq. Taken together, our results demonstrate that direct base-editor specific off-target discovery methods outperform indirect nuclease off-target discovery to comprehensively identify ABE genome-wide off-target activity. In summary, CHANGE-seq-BE enables the rapid characterization of ABE genome-wide activity at a scale not previously achievable by other methods and represents a simple, rapid, sensitive and unbiased method to routinely define genome-wide base editing activity for research and therapeutic applications.

98 Uncovering Upsides and Pitfalls of Base and Prime Editing in Hematopoietic Stem Cells

[1]SR-TIGET, Milan, Italy,[2]Vita-Salute San Raffaele University, Milan, Italy,[3]These Authors share first authorship, Milan, Italy,[4]These Authors share second authorship, Milan, Italy,[5]Pediatric Immunohematology Unit and BMT Program, IRCCS San Raffele Hospital, Milan, Italy,[6]University Center for Statistics in the Biomedical Sciences, Vita-Salute San Raffaele University, Milan, Italy,[7]National Research Council, Institute for Biomedical Technologies, Segrate, Italy

Emerging base and prime editing (BE/PE) may provide safer and more precise genetic engineering than nuclease-based approaches bypassing the dependence on DNA double strand breaks (DSBs). However, comprehensive characterization of efficiency, tolerability and genotoxicity of these platforms is lacking and relevant to instruct safe clinical application. Here, we comparatively assessed state-of-the-art cytidine and adenine BE, such as BE4max and ABE8.20-m respectively, and PE versus Cas9 in human hematopoietic stem/progenitor cells (HSPCs) upon mRNA delivery. When targeting a common locus using the same sgRNA, ABE8.20-m outperformed BE4max and Cas9 reaching up to 90% of alleles modification. Cas9-edited HSPCs displayed the lowest engraftment capacity, despite all treatments maintained multilineage reconstitution and no output skewing, as assessed by clonal tracking analyses. Cas9 editing, however, showed moderate shrinkage of clonal complexity in xenotransplanted mice. However, BE4max edited cells tended to decrease over time in the graft pointing to some detrimental response to the treatment in the long-term engrafting HSPC subset. Transcriptional analyses uncovered that BE4max trigger p53 pathway activation, albeit to lower extent as compared to Cas9 treatment, likely due to the conversion of nickase-induced DNA single-SB to DSB. Indeed, sequencing of the target locus revealed that DNA DSBs were less frequent but not abrogated by BE, particularly for the cytidine BE due to suboptimal inhibition of base excision repair. Concordantly, large deletions and translocations were detected upon BE4max treatment despite to lower frequency than upon Cas9 editing. Moreover, ultrahigh coverage whole exome sequencing on long-term xenografts uncovered a genome-wide effect of BE4max on the mutational landscape of hematopoietic clonotypes. Conversely, we did not observe detectable impact of ABE8.20-m in the same analysis. Additionally, both BEs, but not Cas9, upregulated interferon-stimulated genes, suggesting sensing of exogenous long mRNAs. mRNA engineering abolished interferon response without aggravating p53 activation and allowed >80% editing for all platforms in long-term xenografts. In addition, tailored BE4max expression resulted in more efficient BER inhibition leading to reduced proportion of DSBs and improved precision at the target site. We then applied the same mRNA engineering strategy to PE and reached >50% editing in HSPCs. Around 10% of PE alleles carried imprecise editing outcomes, including indels and long-range deletions, despite less frequently than upon Cas9 treatment. Transcriptional analyses showed upregulation of p53- and apoptosis-related genes upon PE. While some p53 targets

were shared by PE and Cas9 treatments, others were specific of PE and likely due to cellular sensing of the reverse transcriptase. Despite these adverse effects reduced the hematopoietic graft size compared to mock electroporated controls, >50% PE efficiency was maintained upon serial transplantation. Overall, our study validated the potential for precise and effective editing of adenine BE among emerging nickase-based platforms, building confidence on its current entry into the clinical arena.

99 Sniper2L, a High-Fidelity Cas9 Variant with High Activity

Jungjoon Lee[1], Young-hoon Kim[1], Nahye Kim[2], Ikena Okafor[3], Sungchul Choi[2], Seonwoo Min[4], Joonsun Lee[1], Seung-Min Bae[1], Keunwoo Choi[1], Janice Choi[3], Vinayak Harihar[3], Youngho Kim[1], Jin-Soo Kim[5], Benjamin P. Kleinstiver[6], Taekjip Ha[3], Hyongbum Kim[2]

[1]Toolgen, Seoul, Korea, Republic of,[2]Yonsei University College of Medicine, Seoul, Korea, Republic of,[3]Johns Hopkins University, Baltimore, MD,[4]LG AI Research, Seoul, Korea, Republic of,[5]Center for Genome Engineering, Institute for Basic Science, Seoul, Korea, Republic of,[6]Massachusetts General Hospital, Boston, MA

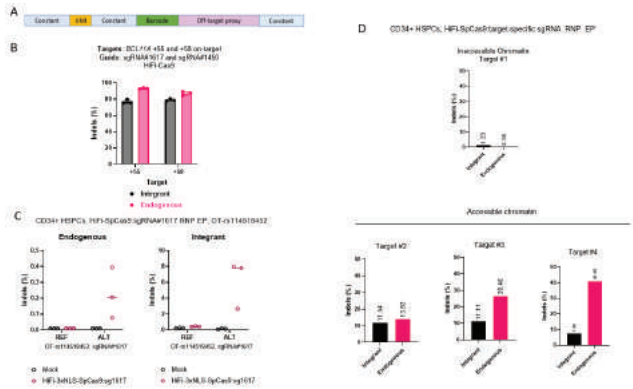
Although several high-fidelity SpCas9 variants that have reduced activities at mismatched target sequences have been reported, it has been observed that this increased specificity is associated with reduced on-target activity, limiting the applications of the high-fidelity variants when efficient genome editing is required. Here, we developed an improved version of Sniper-Cas9, Sniper2L, which represents an exception to this trade-off trend as it showed higher specificity with retained high activity. We evaluated Sniper2L activities at a large number of target sequences, and developed DeepSniper, a deep-learning model that can predict the activity of Sniper2L. We also confirmed that Sniper2L can induce highly efficient and specific editing at a large number of target sequences when it is delivered as a ribonucleoprotein complex. Mechanically, the high specificity of Sniper2L originates from its superior ability to avoid unwinding a target DNA containing even a single mismatch. We envision that Sniper2L will be useful when efficient and specific genome editing is required.

100 Genetic Variant Off-Target Editing Assessment by Lentiviral Proxy Assay

My Anh Amy Nguyen[1], Linda Lin[1], Jing Zeng[1], Jiecong Lin[1], Archana Verma[1], Nola Neri[1], Scot A. Wolfe[2], Daniel E. Bauer[3]

[1]Hematology/Oncology, Boston Children's Hospital, Boston, MA,[2]UMass Chan Medical School, Worcester, MA,[3]Boston Children's Hospital/Harvard Medical School, Boston, MA

Genetic variation invariably produces allele-specific off-target potential of genome editors. A major challenge for investigating genetic variant-associated off-target editing is that primary cells of relevant genotype are rarely available for experimental validation. Here we describe a proxy assay to transduce HSPCs by a lentiviral (LV) vector carrying a set of user-specified off-target (OT) sequences including alternative-allele specific OTs (Fig A). The LV proxy OT library is integrated to the genome of HSPCs, which may then be subject to a clinically relevant ribonucleoprotein (RNP) electroporation genome editing protocol. After in vitro cell culture for 7-10 days (allowing for decay of episomal lentiviral genomes), genomic DNA is isolated and the proxy off-target sequences are amplified using common primers recognizing flanking sequences and with adapter stubs for amplicon sequencing. First we tested the ability of the assay to identify editing of two on-target BCL11A enhancer protospacers, sg1617 and sg1450, recognizing the +58 and +55 enhancers. We found that the integrant proxies showed similar editing frequency as the endogenous loci across an RNP dose-response range (Fig B). We also found ~1% background indels detected in unedited cells, which could be due to oligo synthesis errors. When we filtered UMIs linked to barcodes and proxy sequences perfectly matching the intended design, background were reduced to less than 0.1%. Next, we tested the ability of the assay to recover off-target edits. We had previously identified an alternative allele specific off-target site for sg1617, associated with the rs114518452 SNP alternative allele C. We had found that editing CD34+ HSPCs heterozygous for the alternative allele with HiFi-Cas9:sg1617 RNP produced 0.2% allele-specific off-target edits. We introduced a lentiviral proxy off-target protospacer in the context of the alternative allele and identified 6% allele-specific edits at the proxy (Fig C). We hypothesized that the heightened sensitivity of editing at the integrant could be due to the endogenous site residing in inaccessible chromatin in CD34+ HSPCs while the integrant proxy would often be in open chromatin due to the nature of lentiviral integration. We tested another inaccessible chromatin candidate OT site with OT matching sgRNA and again found greater sensitivity of the integrant proxy to endogenous target (1.23% indels at integrant proxy as compared to 0.18% indels at the endogenous site). In contrast, we tested 3 sites known to be in accessible chromatin in HSPCs and found at least as great editing at the endogenous sequence as compared to the integrant proxy (13.8%, 26.5%, 41.1% at endogenous vs 11.6%, 11.1% and 7.4% indels at integrant, respectively, Fig D). Finally, we cloned a pool of 80 OT sites, transduced and edited cells, and amplified the pool, showing we could detect all sites in a single amplified pooled proxy library while maintaining sensitivity to detect indels with at least 0.1% frequency. In conclusion, we have developed a sensitive, reliable, and scalable assay that can detect editing potential of pooled synthetic candidate OT sites in clinically relevant primary cells. This allows for validation of genetic variant associated off-target potential in a relevant cellular, editor delivery, and chromatin context while overcoming the limitation of requiring donors of specified genotype.



101 Prime Editing of Human CD34+ Long-Term Hematopoietic Stem Cells Precisely Corrects the Causative Mutation of p47phox Chronic Granulomatous Disease and Restores NADPH Oxidase Activity in Myeloid Progeny

Jennifer L. Gori[1], Jack M. Heath[1], Justin G. Tedeschi[1], Allen Ng[1], Julia M. Kushakji[1], David P. Waterman[1], Jacob Stewart-Ornstein[1], Maria D. Collier[1], Alan Wilhelm[1], Andrew T. Taylor[1], Aditi Chalishazar[1], Marine Z. C. Hatit[1], Hetal Patel[1], Suk See De Ravin[2], Harry L. Malech[3], Andrew V. Anzalone[1], Jeremy Duffield[1]

[1]Prime Medicine, Inc., Cambridge, MA,[2]National Institutes of Health, NIAID, Bethesda, MD,[3]NIH/NIAID Laboratory of Clinical Immunology and Microbiology, Bethesda, MD

Chronic granulomatous disease (CGD) is an inherited primary immunodeficiency characterized by low or absent nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activity in phagocytic myeloid cells. Upon sensing pathogens, the NADPH oxidase protein complex produces reactive oxygen species (ROS), that kill the pathogen thus controlling infection. Patients with CGD lack this innate immune response by myeloid cells, which leads to increased susceptibility to, and occurrence of opportunistic infections, chronic inflammatory or autoimmune conditions, impaired quality of life, and decreased life expectancy. The only standard of care disease-modifying approach for CGD is an allogeneic hematopoietic stem cell transplant (allo-HSCT) from a matched donor. However, many patients lack access to matched donors and the risk of complications limits the utility of this approach. p47phox CGD, the most common autosomal recessive form of the disease, is caused by mutations in the *NCF1* gene, which encodes the p47phox protein, a subunit of the NADPH oxidase complex. Approximately 80% of patients with p47phox CGD are homozygous, and most of the remainder heterozygous, for a 2 nucleotide GT deletion (ΔGT) in exon 2 of *NCF1*. This mutation is correctable by Prime Editing (PE). Transplantation of autologous CD34+ cells from p47phox CGD patients in which the ΔGT mutation has been corrected by PE may provide a potential new curative approach. To evaluate this, Prime Editors were developed to precisely correct ΔGT in *NCF1*. Human CD34+ cells were electroporated with PE components and transplanted into NBSGW immunodeficient mice. Sixteen weeks after CD34+ cell transplantation, >84% of long-term hematopoietic stem cells (LT-HSC) that repopulated the bone marrow had at least one *NCF1* allele corrected. No significant differences were observed between 'electroporation only' mock treated control and electroporated Prime Edited human CD34+ cells with respect to long-term CD34+ cell engraftment, human CD45+ blood cell chimerism, hematopoietic multilineage blood cell reconstitution, or LT-HSC cell potency (statistical analyses by ANOVA). Off-target editing events were not detected using a robust, genome-wide suite of assays. In CGD patient CD34+ cells electroporated with PE components, 80% of cells carried at least one corrected allele. These data show that Prime Editing precisely corrects the ΔGT mutation at *NCF1* in p47phox CGD patient CD34+ cells and restores NADPH oxidase activity and myeloid cell function in progeny of these PE corrected cells, thus representing a potential curative approach for p47phox CGD patients.

AAV Engineering for CNS Targeting

102 Structure-Activity Relationships Guided Engineering of AAV Capsids with Optimized Skeletal Muscle, Cardiac Muscle, and CNS Tropism

Kevin Olivieri[1], Jie Tan[1], Lin-Ya Huang[1], Jackson Lee[1], Stephanie Malyszka[1], Sri Siripurapu[1], Allegra Fieldsend[2], Cynthia Pryce[1], Matt Edwards[1], Bryan Mastis[1], Roberto Calcedo[1], Laura K. Richman[3], Sherry Cao[1], Charles F. Albright[1]

[1]Affinia Therapeutics, Waltham, MA,[2]Affinia Therapeutics, Inc., Waltham, MA,[3]Affinia Theraputics, Damascus, MD

Experimental medicines using adeno-associated virus (AAV) to deliver molecular material for muscle and CNS diseases, such as Duchenne muscular dystrophy, genetic cardiomyopathies, and Huntington's disease, hold great promise. For muscle diseases, however, the current medicines use naturally occurring AAV serotypes that require high doses when given intravenously (often >1e14 vg/kg). Reducing these high doses can reduce adverse events, such as liver toxicity, and reduce the high cost of goods sold. For CNS diseases, capsids have limited tropism, particularly for deep brain regions. To overcome these limitations, we have rationally designed a series of new capsids with increased muscle or CNS tropism and reduced liver tropism. Our previous work identified a point mutation (G266A, aka Mut1) that significantly detargeted liver in mice and non-human primates (NHP). When AAV9-Mut1 was combined with a myotropic peptide containing an RGD motif, designated Deco1, the resulting capsid had modestly improved skeletal muscle tropism and reduced liver and heart tropism in NHPs relative to AAV9.To further improve muscle tropism, we tested a combinatorial library of RGD-containing 7-mer peptides inserted at position 588 in AAV9 in NHPs. This screen led to multiple myopeptides with improved muscle tropism compared to Deco1, including myopeptides with >8-fold increased mRNA expression relative to AAV9. In addition, these studies identified myopeptides that specifically increased tropism to either cardiac or skeletal muscle relative to AAV9. Statistical modeling allowed us to determine the structure-activity relationship (SAR) for muscle tropism. Clonal studies in NHPs confirm the results from the library studies showing that the novel capsids had significantly improved skeletal and cardiac muscle tropism (mRNA expression, fraction myocytes expressing cargo) compared to AAV9. Based on the observation that the liver detargeting mutation G266A is in a capsid region that binds to AAVR (VR1), we explored whether additional mutations in the VR1 region would modulate liver tropism while enabling increased muscle tropism. As a result, we identified hundreds of variants using a combinatorial library with liver tropism between AAV9 and AAV9-Mut1 (range of 100-fold mRNA expression) and determined the SAR for liver and muscle tropism. To overcome the limited tropism of CNS capsids, particularly in deep brain regions, we identified a capsid with a median >250-fold increased mRNA expression across different brain regions relative to AAV9 when delivered intravenously using a combinatorial library in NHPs. This capsid lead to widespread CNS expression, including in deep brain regions, compared to AAV9. The structure-activity relationship for CNS tropism was also determined.

In conclusion, we used rational design of combinatorial libraries based on structural modeling and mechanistic hypotheses combined with statistical modeling to deduce SAR relationships for muscle, CNS, and liver tropism. These efforts led to muscle capsids with >8-fold increased mRNA expression in muscle and CNS capsids with >250-fold increased mRNA expression in the brain plus more uniform tissue expression relative to AAV9. Further, these novel capsids have acceptable manufacturing yields and levels of pre-existing immunity to support development to potential medicines.

103 The Use of Transcription-Dependent Directed Evolution (TRADE) to Identify a Novel AAV Capsid That Transduces Motor Neurons with High Efficiency

Christina Chatzi[1], Dhwanil Dalwadi[1], Samuel J. Huang[2], Hiroyuki Nakai[1,2]

[1]Capsigen Inc., Vancouver, WA,[2]Department of Molecular and Medical Genetics, Oregon Health & Science University School of Medicine, Portland, OR

Motor neuron diseases (MNDs) are characterized by degeneration of upper and/or lower motor neurons, causing muscle weakness which can lead to paralysis, respiratory failure, and even death. Recombinant adeno-associated virus (AAV) vector-mediated gene therapy is one of the most promising approaches to ameliorate genetic forms of neuromuscular diseases. Although AAV9 has been used clinically for the treatment of MND, the wild-type AAV9 still requires the use of high vector doses (>10E14 vg/kg) to deliver a therapeutic effect. In addition, AAV9 transduces a wide range of cell types effectively, leading to substantial vector spillover to non-target cells in the body. Such a high dosage requirement results in a number of critical issues including off-target toxicities, a limited therapeutic window, and high cost of manufacturing. Thus, the development of an engineered AAV capsid that is efficient in transducing motor neurons is highly desired to effectively treat motor neuron diseases. Here we report that AAV-CGN2, a novel AAV capsid identified by the TRAnscription-dependent Directed Evolution (TRADE) platform, exhibits an enhanced motor neuron tropism following intravenous (i.v.) vector administration in both rodents and non-human primates (NHPs). Cynomolgus macaques and C57BL/6 mice were treated with a single i.v. injection of an AAV-CGN2-CAG-GFP vector. Animals were euthanized 3 weeks after injection and tissues were harvested for downstream histological and biodistribution analyses. To evaluate the efficiency and specificity of motor neuron transduction with the CGN2 variant, we characterized the phenotype of the GFP-positive transduced cells with triple immunolabeling utilizing selective pan-neuronal (NeuN, neuronal nuclei) and motor neuron markers (SMI-32 and choline acetyltransferase, ChAT). Based on previous histological descriptions Betz cells in the NHP primary motor cortex were identified by a set of criteria: their soma size (>600 μm), localization (5b sublayer), proximal dendritic morphology and SMI-32 immunoreactivity. The CGN2 variant demonstrated a significant bias for transducing SMI-32 immunopositive upper motor neurons with minimal glia transduction in both species. In the NHP ventral horn, the ChAT immunostaining revealed that a large number of motor neurons expressed GFP homogeneously all along the ventral horn from the cervical to the lumbar segments. The GFP signal was also present in the axons of the sciatic nerve indicating a transport of the GFP protein along the peripheral axonal pathway. The GFP-positive motor neurons were scored in the cervical and lumbar enlargements that innervate upper and lower limbs, respectively. Motor neuron quantification revealed that >80% of the lower motor neurons expressed GFP in the cervical and lumbar spinal cord segments of the vector-injected NHPs. Notably, no obvious GFP signal was detected in ChAT-negative cells, supporting the motor neuron tropism of the CGN2 variant. Spinal motor neuron transduction was also evident in mice but to a lesser extent compared to NHPs, suggesting possible cross-species differences. Our data demonstrate that TRADE technology can be successfully employed for identification of enhanced AAV variants and that AAV-CGN2 is a powerful vector for the potential treatment of a wide number of motor neuron diseases.

104 AAV-Mediated CNS-Wide Gene Delivery via a De Novo Engineered Capsid-Human Receptor Interaction

Ken Y. Chan[1], Qin Huang[1], Jencilin Johnston[1], Andrew J. Barry[1], Qingxia Zheng[1], Albert T. Chen[1], Thomas Beddow[2], Casey Keyes[1], Simon Pacouret[1], Pamela P. Brauer[1], Shan Lou[3], Gabrielle Clouse[1], Jason Wu[1], Nuria R. R. Navarrete[1], Fatma Elzahraa Eid[1], Yujia A. Chan[1], Benjamin E. Deverman[1]

[1]Broad Institute of MIT and Harvard, Cambridge, MA,[2]Broad Institute of MIT and Harvard, Boston, MA,[3]Broad Institute of MIT and Harvard, Belmont, MA

Numerous monogenic central nervous system (CNS) diseases can potentially be treated with AAV-mediated gene therapy. The search for AAV capsids that efficiently cross the blood-brain barrier (BBB) to transduce cells throughout the CNS has predominantly relied on in vivo screens. These can identify rare hits that perform well in the animal model tested. However, it is often challenging to determine whether these capsids will exhibit the same tropism in humans without first elucidating their mechanism of action. Here, we avoided this potential pitfall by directly engineering a suite of capsids that cross the BBB using a known mechanism of action. We screened peptide-modified AAV9 capsid libraries in vitro for their ability to bind to a protein receptor that is highly expressed in human brain vasculature. We identified novel capsids that efficiently transduce CHO cells expressing the human receptor and human brain endothelial cells in vitro. Transduction of human brain endothelial cells by the top performing capsid BI-huBBB1 was inhibited in the presence of a monoclonal antibody against the human receptor. Remarkably, BI-huBBB1 efficiently crossed the BBB in knock-in mice expressing the targeted human receptor, but not in control C57BL/6J mice. In the human receptor knock-in mice, the capsid transduced a large fraction of neurons and glia throughout the brain and spinal cord. These human CNS receptor-targeting AAV capsids are promising vectors for CNS gene therapy applications.

105 Directed Evolution of an AAV9 Library Identifies a Capsid Variant with Enhanced Brain Tropism and Liver De-Targeting in Non-Human Primates and Mice Following Systemic Administration

Tyler Moyer, Kristin Graham, Jiachen Liu, Xiaoqin Ren, Joseph Clement, Alexis Bloedel, Anupriya Kulkarni, Kailyn Looby, Hamza Khalid, Bruce Amy, Chiso Egbuchulam, Dan Laks, Matthew Child, Rupinderjit Kaur, Ambreen Sayed-Zahid, Michael Grannan, Charlotte Chung, Tatiana Knox, Brett Hoffman, Alex Kutchin, Amy Johnson, Andrew Cameron, Kyle Grant, Johnny Yao, Nilesh Pande, Jeff Thompson, Garrett Heffner, Todd A. Carter, Mathieu E. Nonnenmacher

Voyager Therapeutics, Cambridge, MA

A significant limitation of Adeno-Associated Virus (AAV)-mediated gene therapy in the central nervous system (CNS) is the ability of gene transfer vectors to efficiently cross the blood-brain barrier (BBB) upon systemic administration. Recent efforts in directed evolution across the field have yielded AAV variants with marked improvement in translocation across the BBB. However, these variants often only display the increased CNS tropism in the animal species in which the evolution scheme was performed. In an effort to identify capsids with broad species tropism, we applied our RNA-driven TRACER™ capsid evolution platform to evolve Variable Region IV (VR-IV) of AAV9 in two rounds of biopanning in NHPs and mice before synthesizing a library of 1500 top candidates for a third, more focused round of screening in both species. A family of capsids with a distinct consensus motif emerged as the top BBB-penetrant capsids in both mice and NHPs. One member of this capsid family, VCAP-102, was tested individually in African green monkeys (*Chlorocebus sabaeus*) by intravenous dosing of a self-complementary transgene. Across diverse brain regions, VCAP-102 displayed anywhere from 20-fold to 90-fold increased transgene expression relative to wt AAV9. Regions of particularly high tropism compared to AAV9 include the frontal cortex, motor cortex, and cerebellar cortex, putamen, and caudate. In these regions, VCAP-102 transduced anywhere 30 to 50% of cells, targeting both neurons and astrocytes. Notably, VCAP-102 demonstrated reduced expression in both the dorsal root ganglia and liver relative to wt AAV9. Iterative evolution of the VCAP-102 capsid has resulted in a next generation of capsids with upwards of 6- to 7-fold improved BBB-penetrance relative to VCAP-102 in the cynomolgus macaque while maintaining or improving the tropism of VCAP-102 in mice. Taken together, our data presents a novel, CNS-tropic capsid with significantly enhanced BBB-crossing potential, suggesting the likelihood for clinical development.

106 Developing Blood-Brain Barrier-Crossing AAV9 Variants with Reduced Sensitivity to Neutralizing Antibodies

Simon Pacouret, Ken Y. Chan, Fatma Elzahraa Eid, William Donahoe, Pamela Brauer, Binhui Zhao, Qin Huang, Jencilin Johnson, Qingxia Zheng, Albert Chen, Andrew J. Barry, Casey Keyes, Yujia A. Chan, Benjamin E. Deverman

Pre-existing neutralizing antibodies (NAbs) against adeno-associated virus (AAV) capsids are an obstacle to the success of AAV gene therapies as they limit the range of patients who can receive these treatments. Upon vector administration, NAbs that bind the AAV capsid surface can prevent target tissue transduction and also activate the complement system. We hypothesized that NAbs could be detargeted from the AAV9 capsid via the mutagenesis of carefully chosen surface-exposed residues, without disrupting its blood-brain barrier (BBB)-crossing phenotype. We generated a combinatorial AAV9 capsid library, 'Chameleon', comprising substitutions across 14 distributed, surface-exposed variable residues. We first show that the Chameleon library yields a highly diverse set of capsid variants with a Hamming distance of 1-10 from AAV9, many of which retain their parental production fitness, in vitro and in vivo transduction and thermal stability phenotypes, as well as their compatibility with BBB-penetrating peptides pre-selected in AAV9. The Chameleon library was then subjected to a high-throughput in vitro screen that distinguished capsid variants based on NAb binding. We are currently investigating the production fitness, in vivo transduction and antibody neutralization phenotypes of 12 variants with reduced NAb binding based on our library screen. By combining Chameleon-derived capsid modifications with additional capsid diversification strategies, we seek to develop novel AAV variants with highly reduced NAb binding and desirable in vivo tropisms.

107 Machine-Learning Guided Design of Cell-Specific AAVs in Human Central Nervous System (CNS)

Danqing Zhu[1], Galina Popova[2], Akosua Busia[3], David Brookes[4], Julio Rivera[3], Jennifer Listgarten[3], Tomasz J. Nowakowski[2], David V. Schaffer[3]

[1]HKUST, Hong Kong, China,[2]UCSF, San Francisco, CA,[3]UC Berkeley, Berkeley, CA,[4]Dyno Therapeutics, Watertown, MA

Introduction:The CNS comprises a multitude of cell types with diverse functionality and specialization. Dysregulation of neuronal or glial populations has been implicated in multiple disorders, including Alzheimer's, Parkinson's, Huntington's disease, etc. AAVs hold tremendous promise as gene delivery vectors to treat such conditions given their reasonable starting efficiency and safety profile. However, such strategies remain challenging due to difficulties in efficient and targeted delivery to specific brain cell populations. Directed evolution can achieve improvements in AAV performance without pre-existing knowledge of virus-cell interactions. Here we apply directed evolution technologies guided by machine-learning (ML) design for developing efficient AAV vectors that target specific CNS cell populations in human

brain tissues, which can serve as basic tools to investigate neuro-glial interactions as well as therapeutic delivery vehicles to treat a range of neurological disorders. Methods/Results:To optimize our library design, we first developed and applied a ML-based framework to design an AAV5-capsid library, focusing on a 7-amino acid insertion region at the 3-fold symmetry axis that was identified as a retargeting site for cell-specific entry. Using the trained predictive model, we designed ~2,238 individual libraries that lie on an optimal curve that trades off predicted enrichment with maximal sequence diversity (**Fig 1A**). To judge the utility of our *in-silico* design approach, we synthesized two of the libraries and showed that our ML-library achieves 5-fold higher packaging fitness than the state-of-the-art library, with approximately 10-fold more successful variants after primary brain infection. From this, we demonstrated that 1) individual ML-predicted AAV sequences exhibited experimental packaging fitness positively correlated to their predictions (**Fig 1B**); 2) synthetic ML-libraries present higher packaging fitness while retaining their high diversity of variants (**Fig 1C**). We then transfected our ML-designed library into packaging cell lines and purified capsid libraries were then administered to human brain slices. Functional selective pressure was imposed by harvesting glial- and neuronal-only cells using MACS 72 hours after infection. Using PCR-based recovery of variants with deep sequencing, we identified converged variants that successfully transduce human glial or neuronal cells specifically (**Fig 1D**). Conclusions:In summary, our approach offers a roadmap for designing an AAV library that broadly improves packaging functionality while retaining high diversity. Our computational method can generate as many libraries as desired by leveraging one predictive model. This approach can be harnessed to optimize libraries for downstream selection for properties of therapeutic relevance, including production, infectivity, specificity, and others. In particular, using our ML-guided library design, we generated novel variants targeting specific CNS cell populations, which will enable future investigation of molecular mechanisms underlying neural disorders and provide potential therapeutics for disease treatment. We also anticipate that such ML-guided design of AAV vectors will have broad utility for the development and selection of novel variants targeting different cells and tissues for applications in the near future.

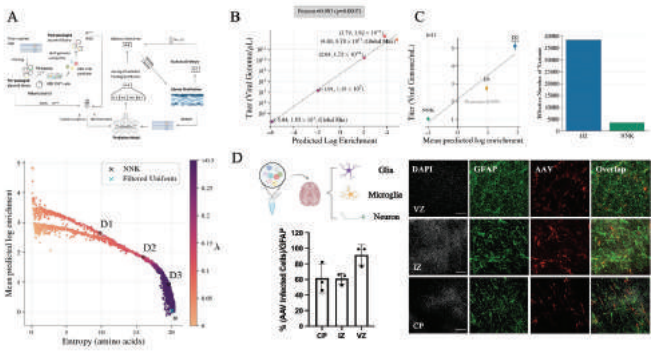

Figure 1: (A) Experimental workflow for generating data for building a ML-based library design using supervised regression model. The predictive model was then systematically inverted to design libraries that trace out an optimal trade-off curve between diversity and packaging fitness. (B) Experimental titers versus predicted log enrichment scores for five synthetic variants. (C) Comparison of ML-designed libraries D2 and D3 to the NNK library. (D) Cell-specific AAVs validation selected from the post-brain infection pool. [1]Caltech, Pasadena, CA,[2]Duke University Medical Center, Durham, NC,[3]Allen Institute for Brain Science, Seattle, WA,[4]University of Zürich, Zürich, Switzerland,[5]University College London, London, United Kingdom,[6]University of California, Davis, Davis, CA,[7]University of California San Diego, La Jolla, CA,[8]CUniversity of California, Davis, Davis, CA

Delivering genes to and across the brain vasculature efficiently and specifically across species remains a critical challenge for addressing neurological diseases. We have evolved adeno-associated virus (AAV9) capsids into vectors that transduce brain endothelial cells specifically and efficiently following systemic administration in wild-type mice with diverse genetic backgrounds and rats. These AAVs also exhibit superior transduction of the CNS across non-human primates (marmosets and rhesus macaques), and *ex vivo* human brain slices although the endothelial tropism is not conserved across species. The capsid modifications translate from AAV9 to other serotypes such as AAV1 and AAV-DJ, enabling serotype switching for sequential AAV administration in mice. We demonstrate that the endothelial specific mouse capsids can be used to genetically engineer the blood-brain barrier by transforming the mouse brain vasculature into a functional biofactory. Vasculature-secreted Hevin (a synaptogenic protein) rescued synaptic deficits in a mouse model.

AAV Vectors - Product Development Manufacturing: Analytics & Stability Studies

109 *In Vivo* and *In Vitro* Assessment of Residual DNA Impurity-Derived Transcriptions

Hsin-I Jen, Wei Zhang, Xiaohui Lu

Analytical Development, Ultragenyx, Woburn, MA

Gene therapy products, such as rAAV, are typically produced by DNA plasmid transfected to mammalian cell lines. Host cell DNA and plasmid DNA can be inadvertently packaged inside the rAAV capsids during production. It is important to characterize these residual DNA impurities in gene therapy products due to the theoretical risk of immunogenicity, infectivity, and oncogenicity. Previous studies

showed the level of residual DNA impurity is around 1-2% of the expected rAAV genome. However, it remains unclear whether these DNAs undergo transcription and translation. To address this question, RNA was isolated from transduced cells or mouse liver various days after rAAV transduction, followed by reverse transcription for cDNA synthesis and library preparation. qPCR, ddPCR, and RNA-seq were used to quantify the level of the gene of interest and the impurity genes (Cap8, KanR, Rep2, Ad5 Fiber). Results showed a low but detectable level of Cap8, Rep2, and KanR transcripts. The result from these studies enables targeted risk assessment and better understanding of the potential adverse effects associated with AAV gene therapy. It also points to the importance of improving vector design to reduce the level of DNA impurities.

110 AAV Vector DNA Carrying Two Concatenated miRNA Stem-Loops is Highly Homogenous and Stable in GLP-Grade AAV Product

Chenxia He[1,2], Ildar Gainetdinov[3], Jeffrey Levine[4], Matthieu P. Guibert[4], Azadeh Bazarchi[4], Amanda Zhang[4], April R. Giles[4], Andrew C. Mercer[4], Olivier F. Danos[4], Richard Porter[1,5], John Little[1,2]

[1]Corlieve Therapeutics, AG, a wholly owned subsidiary of uniQure N.V., Basel, Switzerland,[2]UniQure biopharma B.V., Amsterdam, Netherlands,[3]Consultant, Worcester, MA,[4]REGENXBIO, Rockville, MD,[5]UniQure biopharma B.V., Basel, Switzerland

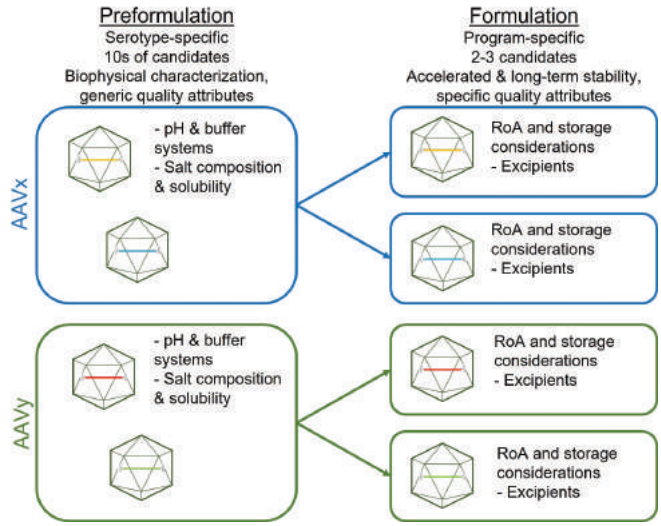
MicroRNAs (miRNAs) delivered by recombinant AAV vector (rAAV) are valuable tools in treating gain-of-function diseases by lowering expression of the related genes. However, miRNA stem-loop structure carried in an expression cassette can cause DNA heterogeneity and instability during rAAV production, generating truncated non-functional vectors. AMT-260, our clinical candidate for treating refractory temporal lobe epilepsy, is a single-stranded DNA AAV9 vector carrying two miRNA sequences targeting *GRIK2*, embedded separately in two stem-loop scaffolds. To investigate the genomic integrity of AMT-260, the rAAV was subjected to PacBio single-molecular real-time (SMRT) sequencing. The optimized bioinformatic pipeline increased alignment accuracy, eliminated artefactual sequencing errors and exhibited a highly homogenous rAAV population, with 93% particles containing full-length single-stranded DNA identical to the reference sequence. The results of our meticulous sequencing analysis indicate that high genomic fidelity of rAAV products carrying stem-loop secondary structures can be achieved with a combination of good vector design and using a well-developed manufacturing platform.

111 A Rapid, Serotype Specific Approach to AAV Formulation Development

Robert Damitz, Catherine Dial, Wayne Yount

Kriya Therapeutics, Inc., Research Triangle Park, NC

Adeno-associated virus (AAV) is the most widely used vector for gene therapy. Many AAV serotypes, including wild-type and engineered serotypes, are utilized for different tissue tropism and other properties. AAV serotypes are differentiated by protein structure and may each behave differently in aqueous systems. The design space for formulation scientists is vast, and a "generic" formulation is not sufficient to stabilize all AAV serotypes. Compounding challenges include the high cost of goods and variability associated with AAV production as well as the complexity of AAV products which requires evaluation of many quality attributes and large sample-analysis volumes. As such, traditional design of experiment-based formulation approaches are not feasible for AAV, especially at early stages of development. To manage these challenges, a stepwise approach to AAV formulation was developed.



Pre-formulation is performed on each serotype which consists of screening many candidate formulation systems for recovery and stability using generic methods and biophysical characterization techniques requiring small sample volumes. Buffer systems and pH ranges which produce stable formulations as well as ionic strength ranges and salt compositions which yield stable dispersions at high target concentrations are identified. Relative thermal stability parameters of known degradation pathways are compared to identify buffer systems which may yield the most stable formulations over accelerated and long-term stability. Formulation development is then performed for each individual program using information from pre-formulation as well as program-specific design considerations, like routes of administration or patient populations. Stabilizing excipients are evaluated to achieve desired product stability at storage conditions to meet program needs. Larger volumes of fewer candidate formulations are prepared during formulation development. Program-specific quality attributes are evaluated at accelerated stability conditions to select a final formulation. Using the approach described above, we were able to achieve isotonic formulations of AAV1 at up to 2e13 vg/mL with excellent freeze-thaw and accelerated stability at pH 6.9. We also achieved isotonic formulations of AAV2 at up to 1e13 vg/mL at pH 7.5. These accelerated stability results were in agreement with the predictive thermal stability results measured during pre-formulation. Long-term stability is ongoing. Also notable, AAV2 formulated in commonly-used phosphate buffers was highly unstable.

112 Formulate for Success: Early Investment in Drug Product Development Enables Platform Stabilization of Multiple AAV Serotypes, Refrigerated Supply Chain, and Accelerated Dosing Timelines

Kelly Walsh, Tyler Peters, Lori Karpes, Michael Mercaldi, Tim Kelly

Oxford Biomedica Solutions, Bedford, MA

AAV preparations have a long-held reputation as difficult to produce, store, distribute, and administer in a clinical setting. As this sector has seen recent growth, a renewed focus on well-developed drug products has become even more critical as regulatory expectations for gene therapies increase. To this end, we have integrated a comprehensive understanding of Drug Product development into our proprietary Process and Manufacturing Platform and applied it to a range of serotypes to demonstrate wide applicability. Our early investment and focus on drug product development allowed us to understand AAV degradation pathways and employ stabilization tactics to design a highly stabilized AAV drug product formulation. Our serotype-independent formulation enables long term storage and shipping at refrigerated temperatures; robustness to freeze-thaw stresses and chemical degradation; prevention of subvisible particulate formation; and aggregation free high-titer products. Our platform formulation has demonstrated long term liquid phase stability in standard titer solutions; high titer stability (>1E14 vg/mL) for at least 1 year at 2-8°C, 3 months at 25°C; and demonstration of liquid stability and aggregation-free solutions at extremely high titers (>1E15 vg/mL). Our proprietary drug product platform offers significant advances for AAV clinical presentations including ease of shipping and storage requirements, reduced vial pooling requirements, and accelerated drug product development timelines for a wide variety of serotypes. Compatibility in our platform formulation has been demonstrated with a wide variety of AAV serotypes in clinical use, including AAV1, AAV2, AAV5, AAV6, AAV8, AAV9, AAVrh10, and AAVrh74. Our streamlined formulation platform evaluation enables rapid identification of serotype compatibility. As an innovation-driven company, OXB Solutions continues to improve its drug product platform to keep our partners ahead of the game.

113 Systematic Comparison of rAAV Vectors Manufactured by Large-Scale Suspension Cultures of Sf9 and HEK293 Cells

Shengjiang Shawn Liu[1], Haifeng Chen[1], Jinzhong Li[1], Sameera Peraramelli[1], Ningguang Luo[1], Alan Chen[1], Minghua Dai[1], Fang Liu[2], Yanbao Yu[3], Ryan D. Leib[2], Derrick Huynh[1], Shuyi Liu[1]

[1]Avirmax Biopharma Inc., Hayward, CA,[2]Stanford University Mass Spectrometry, Stanford University, Stanford, CA,[3]Department of Chemistry and Biochemistry, University of Delaware, Newark, DE

HEK293 and Sf9 cell cultures are broadly used in rAAV production. To study characteristics of rAAV packaged in HEK293 & Sf9 cells, we created self-complementary AAV2.N54-Aflibercept constructs suitable for the production in both systems. Suspension cultures of rBV-Sf9 cells at 2-50 L (Sf9-rAAV) and HEK293 cells (HEK-rAAV) of 2-200 L scales were utilized separately to produce harvest bulks for rAAV purification. The rAAV drug substances (DS) with high purity were systematically characterized including next generation sequencing (NGS), LC-MS/MS analysis, *in vitro* biological activity and *in vivo* efficacy. The integrity of vector genome (vg) was accessed by alkaline agarose gel electrophoresis. Both Sf9-rAAV and HEK-rAAV showed a main vg band plus some minor species in the gel image. SF9-rAAV vg ran slightly lower than vg of HEK-rAAV, likely due to loss of some nucleotides at ITR ends. The culture scale did not affect vg integrity. The rAAV vg contents were assessed by Illumina and PacBio NGS platforms. Interestingly, the resulting vg contents varied between these methods. Specifically, the vg content of Sf9-rAAV was determined at 98.24% and 90.02% by Illumina and PacBio method, respectively, 8% difference between the two methods. The PacBio method was detected at 90.02% and 84.7% for Sf9-rAAV and HEK-rAAV separately, indicating Sf9-rAAV had 5% more vg content than HEK-rAAV. The packed host DNA (HCD) content was measured at 0.03% for Sf9-rAAV and 0.32% for HEK-rAAV by the PacBio method, indicating HEK-rAAV has ~10x more HCD than Sf9-rAAV. The vector DNA chimeric events with HCD were estimated at 2.7% and 10.6% for Sf9-rAAV and HEK-rAAV, respectively. High resolution accurate mass (HR/AM) based proteomic approach was employed to assess the protein level variations. LC-MS/MS protein score plot showed more species at 1500-1800 m/z of the Sf9-rAAV compared to HEK-rAAV, indicating more post translation modifications (PTMs) in Sf9-rAAV. Overlapped and unique PTM sites of rAAVs between the two system are shown in Table 1. **Table 1. Some Commonly Found PTM sites in Sf9 and HEK293 Cell Systems** Furthermore, rAAV infectivity was assessed by the ratio of vg copies per $TCID_{50}$ (I). The vg/I ratios for Sf9-rAAV and HEK-rAAV were at 13-74 and 23-208, respectively. HEK293 and ARPE-19 cells were transduced with Sf9-rAAV and HEK-rAAV vectors in the expression assay. Sf9-rAAV showed 13.6 and 2.1 μg/mL of Aflibercept in HEK293 and ARPE19 cells respectively. HEK-rAAV on the other hand showed 7.3 and 1.2 μg/mL in HEK293 and ARPE19 cells respectively. Final comparison was conducted using the mouse laser choroidal neovascularization (LCNV) model via intravitreal (IVT) dosing with Sf9-rAAV and HEK-rAAV at 4×10^8 and 1.6×10^{10} vg/eye separately. The LCNV model revealed essentially similar anti-inflammation effect. Both rAAV products showed protection at 4×10^8 vg/eye nearly identical to that achieved by 40 μg/eye of commercial product. Complete protection was achieved at 1.6×10^{10} vg/eye. Overall, this work detected notable differences in physiochemical characteristics of rAAV vectors produced by the HEK293 and rBac-Sf9 cell culture systems. However, the *in vitro* and *in vivo* biological functions of the rAAV products from both systems were highly comparable.

Table 1. Summary of the Number of Protein Posttranslational Modification (PTM) sites in rAAV Manufactured in Sf9 and HEK293 Cell Systems (Only some of the commonly found modifications are shown here)

PTM type	Sf9-rAAV	Overlapped sites	HEK-rAAV
Acetylation	4	2	0
GG (ubiquitylation)	4	0	0
Gln>pyro-Glu	0	4	0
Methylation	11	7	3
Oxidation	1	5	0
Phosphorylation	17	3	1
Propionamide	18	14	2

114 Deamidation Analysis for Supporting AAV Gene Therapy Development

Yu Zhou, Yueju Wang

Analytical Development & Operation, Novartis Pharmaceuticals, San Diego, CA

In recent years, recombinant adeno-associated viral (AAV) vectors with nonpathogenic nature and ability to provide long-term gene expression have taken center stage as gene delivery vehicles for gene therapy. Adeno-associated viral capsid proteins (AAV VP) are the major components that determine the tissue specificity and immunogenicity, and play important roles in receptor binding, escape of the virus from the endosome, and transport of the viral DNA to the nucleus. The unique N-terminal region of VP1 is necessary for viral vector infectivity. It was reported that an amino acid mutation from asparagine (N) at 57 to aspartic acid (D) in AAV8 and AAV9 decreased transduction efficiency by more than 50%. Deamidation of asparagine residue is a common post-translational modification of proteins (PTM) and is mostly detected and quantified by liquid chromatography-tandem mass spectrometry (LC-MS/MS)-based peptide mapping. However, deamidation can be spontaneously introduced during sample preparation prior LC-MS/MS analysis. Traditional sample preparation for AAV VP peptide mapping results in exaggerating the original deamidation levels. It is important to accurately monitor and provide true values of asparagine deamidation for development of AAV gene therapy products. Using AAV serotype 9 (AAV9), we evaluated denaturation temperatures, digestion durations, and digestion temperatures for LC-MS/MS-based assessment of deamidation of capsid proteins. The results demonstrated that the optimal sample preparation method for AAV9 VP peptide mapping minimized asparagine deamidation artifacts significantly. We applied the optimized peptide mapping method and analyzed AAV9 N57 asparagine deamidation on drug substance (DS) stability samples. Increased deamidation in the DS incubated at 25°C for two weeks or one month, or at 2-8°C for 18 months was observed in comparison with the control samples. Although AAV serotype 9 was used for method optimization, due to the high similarity of N57 or N56 containing tryptic peptides from other AAV serotypes, this study provides a general guidance on how to control deamidation artifacts for all AAV serotypes on peptide mapping to support AAV gene therapy development.

115 A Comparative Analysis of Recombinant AAV9 Product Generated from Insect and Mammalian Bioproduction Processes

Phuong C. Nguyen, Courtney Barlament, Natasha Patel, Adib Shafipour, Anandita Seth

Neurogene Inc., New York, NY

Background: In the generation of clinical and commercial-grade gene therapy products, mammalian (HEK-AAV) and insect cell-based (Sf9-AAV) manufacturing continue to be the two predominant recombinant Adeno-Associated Virus (AAV) manufacturing platforms. Each offers its unique advantages and challenges depending on the AAV serotype, transgene design, and material requirement. Insect-based manufacturing is known to provide higher volumetric productivity, whereas transient transfection-based mammalian manufacturing can reduce project timelines associated when switching to a new transgene or a new capsid. In recent years, technical reports have suggested that HEK-AAV is of superior quality and potency than Sf9-AAV. The application of these reports is limited, as these studies utilized Sf9-AAV generated using unoptimized, poorly designed RepCap vectors. In addition, working with the Sf9-AAV platform requires a solid understanding of baculovirus virology, which was not demonstrated in these studies. Neurogene has developed both insect and mammalian cell-based processes as scalable GMP manufacturing platforms. Here, we have generated materials from both processes for a head-to-head analytical comparison. **Methods:** The two optimized, scalable platforms were used to generate AAV9 containing the same transgene of medical importance (GMI) for a direct comparison. Both platforms utilize suspension cell-based production, lysis, clarification, affinity, and Anion-Exchange chromatography (AEX) steps and have been scaled up in our facility from pilot scale to production scale with no impact to volumetric productivity. For this study, AAV9 was generated in single-use bioreactors (SUB). Material generated from these two processes was tested using industry standard analytical methods. **Results:** While the productivity at harvest was higher in Sf9-AAV system (~1e12 vg/mL compared to ~1e11 vg/mL in HEK-AAV9 system), the percent full was similar at harvest for both platforms; and upstream recoveries were comparable. Downstream process also resulted in similar percent full enrichment and removal of impurities in the final product. Finally, the formulated products from both these processes were tested to evaluate quality attributes. Data generated shows that the two processes resulted in products of similar quality based on post-translation modifications, packaging profiles, process related impurities, and *in vitro* potency of products measured by a biological activity assay. **Conclusion:** Using our optimized upstream process, the same downstream process and same GMI, we yield high quality products from both processes with consistently higher productivity from the insect cell-based process.

Genome Editing Therapies & Safety II

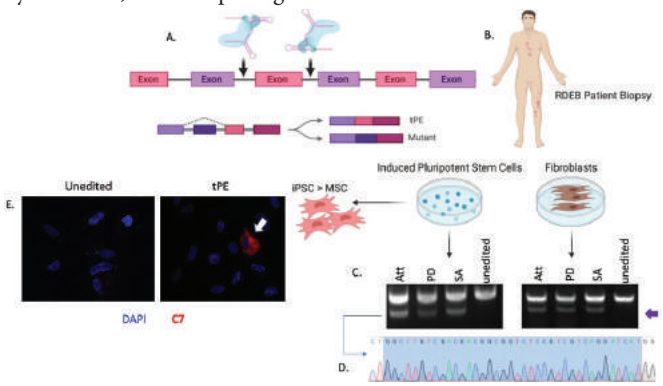
116 Pathogenic Exon Deletion Using Prime Editing for Correcting Primary Recessive Dystrophic Epidermolysis Patient Cells

Mark J. Osborn[1], Xin Daniel Gao[2], Benjamin S. Steinbeck[1], Amber N. McElroy[1], David R. Liu[2], Jakub Tolar[1]

[1]University of Minnesota, Minneapolis, MN,[2]Broad Institute of MIT and Harvard, Merkin Institute of Transformative Technologies in Healthcare, Harvard University, Chemistry and Chemical Biology, Harvard University, Howard Hughes Medical Institute, Cambridge, MA

Recessive dystrophic epidermolysis bullosa (RDEB) is a severe mucocutaneous disease caused by loss-of-function mutations to the collagen VIIa (*COL7A1*) gene that encodes the type VII collagen peptide (C7). Previously, we used programmable nucleases and DNA base editors (BE) to repair *COL7A1* mutations through homology-directed repair or precise base editing (BE), respectively. These efforts represent a personalized medicine approach; however, reagents with applicability to multiple patients are desirable. Entire *COL7A1* exons with RDEB causative mutations can be excised to create in frame

deletions leading to restored C7 production. Nucleases that generate double-stranded DNA breaks (DSBs) have been used to accomplish this; however, DSBs can be toxic to the cell and are repaired in a stochastic manner that can limit efficiency. BEs offer gene modification capabilities with low frequency of DSBs; however, they operate through a mechanism not well suited for targeted deletions. Prime editing (PE) is a platform comprised of a Cas9 nickase and an associated fused reverse transcriptase that primes off a user provided prime editor guide RNA (pegRNA). PE enables the ability to install any base substitution and insertions and deletions. Efficiencies of single pegRNA-based PE diminishes as the size of the edit increases. Toward expanding the ability to edit larger sequences, two pegRNAs have been employed flanking a target site that can serve to integrate, replace, or delete large sequences without significant occurrence of DSBs. As such, the use of two pegRNAs represents an ideal strategy for precisely excising entire pathogenic exons such as is observed in *COL7A1* (Fig 1A). We pursued three prime editing strategies with dual pegRNAs in patient-derived induced pluripotent stem cells (iPSC) and fibroblasts (Fig 1B) toward removing a target *COL7A1* exon containing an inactivating premature stop codon mutation: i.) PrimeDel, that generates deletions between paired sites that are nicked by Cas9; ii.) single anchor (SA) that places a fixed deletion at one of the Cas9 nicking sites, and iii.) twinPE (tPE) to replace the target exon with a 38 bp attachment site B (*attB*) from the Bxb1 serine integrase. We observed target exon deletion for each PE approach (purple arrow in Fig 1C). We Sanger sequenced the tPE product and observed *attB* site installation without significant DSBs (Fig 1C; 38 bp *attB* sequence shown shaded in blue, junction is not highlighted). Corrected fibroblasts represent an approach for autologous gene correction and iPSCs can be differentiated in vitro into derivative therapeutic populations for RDEB such as keratinocytes and mesenchymal stromal cells (MSC). TwinPE-editing iPSC-derived MSC demonstrated restoration of C7 production when analyzed by confocal microscopy (arrow/red staining in Fig 1E). The diverse constellation of *COL7A1* mutations makes individual patient specific reagents impractical. Our data shows that tPE is an approach for *COL7A1* correction where a small, well-characterized set of reagents could be employed across numerous RDEB patients to restore C7 expression by DSB-free, in frame pathogenic exon excision.



117 Genome Editing B Cells to Express Custom Heavy Chain Antibodies with Modified Antigen Specificity and Fc Function

Chun Huang, Geoffrey L. Rogers, Atishay Mathur, Chan-Hua Chang, Paula M. Cannon

Molecular Microbiology and Immunology, University of Southern California, Los Angeles, CA

We previously described a genome editing strategy to reprogram the immunoglobulin (Ig) locus of human B cells to express custom Heavy chain antibodies (HCAbs) that recognize specific antigens or other protein ligands. We achieved this by inserting custom antigen recognition domains into the constant region of the IgG1 Heavy chain. This resulted in custom HCAbs that retained essential features of natural antibody function, such as switching from expression of a membrane-anchored (BCR) to the secreted antibody isoform upon plasma cell differentiation. In our initial designs, the constant region of the HCAb was provided by endogenous IgG1 sequences (i.e. Hinge, CH2, and CH3 domains). However, for some applications, it will be desirable to also modify these regions, for example to increase antibody half-life, or enhance effector functions such as antibody-dependent cellular cytotoxicity (ADCC). To achieve these modifications, we expanded our editing strategy to target other sites in the constant region of IgG1, and for other antibody isotypes. In this way, we were able to produce HCAbs with customized Fc domains, such as the GASDALIE mutation in CH2 to enhance ADCC, or the LS mutation in CH3 to increase half-life. By combining these alternate editing strategies and modified Fc domains with different antigen recognition domains that recognize the HIV gp120 protein, we created a series of HCAbs that we could evaluate for optimal anti-HIV activity. Finally, we developed a strategy to accommodate additional domains at the C-terminus of the H chain, while still retaining the ability to produce a BCR isoform. Such a design lends itself to the secretion of engineered molecules such as eCD4-IgG1, whose potent anti-HIV activity is dependent on the presence of a C terminal CCR5 mimetic peptide. We evaluated each HCAb expressed from edited B cells and confirmed that they retained the expected gp120 binding and HIV neutralization activities. This included eCD4-IgG1 secreted from edited B cells, which showed a similar neutralizing activity as recombinant eCD4-IgG1 produced from transfected 293T cells. Ex vivo human tonsil organoids were used to demonstrate that HCAb-edited B cells responded to immunization by the specific HIV gp120 antigen. Finally, the inclusion of the GASDALIE modifications increased killing of HIV-infected target cells by NK cells. In this way, we are able to completely customize all aspects of HCAb design, producing edited human B cells expressing potent anti-HIV antibodies that respond to immunization and that could form the basis of a B cell therapy to suppress HIV replication in vivo.

118 A Targeted Non-Viral CRISPR-Based *In Vivo* Gene Editing Strategy for the Treatment of Sickle Cell Disease

Christophe Lechauve[1], Jacob M. Hope[1], Justin A. Pater[1], Sheryl Wang[1], Andrew Drabek[1], Akimmee Green[1], Patricia B. Berthelette[1], Hong Wang[1], Eyoung Shin[1], Aaron Griset[1], Zhaohua Richard Huang[1], Christian Mueller[2], Tongyao Liu[1], Christopher Borges[1]

[1]Sanofi, Waltham, MA,[2]Sanofi Genzyme, Framingham, MA

CRISPR/Cas9 has demonstrated tremendous promise to cure sickle cell disease (SCD) by preventing red blood cell sickling and vaso-occlusive events through the genetic modification of BCL11a. Despite the success of clinical studies, there remain limitations. This therapy requires hematopoietic stem cells (HSCs) to be harvested from the patients, genetically modified, and expanded *ex vivo*. While the HSCs are manufactured, patients require treatment with busulfan-based myeloablative conditioning regimens prior to infusion of the genetically engineered HSCs. We have developed a non-viral gene therapy strategy that leverages mRNA, CRISPR editing technology, and targeted lipid nanoparticles (LNPs). This strategy will enable CRISPR nuclease mRNA and an associated guide RNA (gRNA) to be encapsulated by an LNP as cargo. The LNP will then be intravenously injected into a patient, where a targeting moiety will enable specific transfection of HSCs *in vivo*. Once the mRNA cargo is released into the HSCs, the translated CRISPR effector will complex with the gRNA to genetically modify the target resulting in a concomitant increase in the expression of HbF. LNPs were engineered to effectively encapsulate nuclease mRNA and associated gRNA specific for our therapeutic genetic target or the hematopoietic cell-surface markers CD45 or B2M (used as surrogate surface markers to measure editing efficiency). LNPs were then conjugated with an array of antibodies that specifically target cell-surface proteins on HSCs and were screened for binding and transfection on primary human HSCs *ex vivo*. From this screen, one antibody was identified and characterized to optimally transfect HSCs (FabGMU101) (Figure 1). Moreover, we validated the specificity of our strategy by successfully mutating FabGMU101 to block the binding of the surface epitope demonstrating that the editing observed is specifically enabled by FabGMU101 (Figure 1). By incorporating our strategy to enable LNP binding and transfection of nuclease-mRNA, we demonstrate successful disruption of multiple loci in primary human HSCs *in vitro*. This success provides the foundation for a non-viral gene therapy for SCD that will be effective, economically viable, and safe.

Figure legend: HSC targeted-LNP for gene editing. Primary HSC were culture in vitro and treated with LNP encapsulating CRISPR mRNA and beta-2-microglobulin (B2M) guides. LNP are either coated with A) the selected FabGMU101 antibody (binding Ab), recognizing long-term hematopoietic stem cells (LT-HSC) or B) the mutated FabGMU101 (non-binding Abm). The gene editing effects were measured by flow cytometry targeting the cell surface marker B2M.

Be Biopharma, Cambridge, MA

The clinical success of engineered T cell therapies has proven the power of harnessing or re-directing intrinsic cellular functions for therapeutic benefit. Plasma cells (terminally differentiated B cells) offer the possibility to expand the tractable pharmacology of the cell therapy toolkit beyond cytotoxicity. Plasma cells' natural longevity (mean half-life of 17 years) and capacity for high levels of protein secretion (up to 10,000 Ig molecules/cell/sec) make them an attractive source for the sustained delivery of biologics, which require continuous infusion or frequent dosing to achieve a therapeutic benefit. However, until recently B cells were intractable to efficient genome engineering in part due to their resistance to lentiviral vector transduction. Herein, we describe a versatile CRISPR/Cas9-based B cell engineering platform, which allows for the generation of B Cell Medicines (BeCMs) that express and secrete therapeutically relevant proteins at high levels. Transgene knock-in is achieved via HDR-mediated DNA repair, and our platform supports AAV-mediated as well as non-viral delivery of DNA donor templates. Following multiple rounds of optimization of culture and engineering conditions, our platform achieves gene knockouts with greater than 90% efficiency as well as targeted HDR-mediated gene insertions at frequencies as high as 60% without selection. Moreover, the simultaneous editing of multiple genes and knock-in of multiple cargos in a single reaction can be achieved at rates of up to 70% and 25%, respectively. Systematic guide screening identified highly efficient, as well as novel insertion sites including B cell-specific loci that enhanced the amount of cellular protein secretion 5-fold compared to knock-in of the same expression cassette at the CCR5 safe-harbor locus. We also established a clinical guide selection pipeline that allows for the identification of off-target sites in primary human B cells using a combination of *in-silico*, cellular and biochemical off-target discovery techniques. To enable rapid testing of targeted transgene expression constructs, we developed a plasmid-

based screening pipeline in primary human B cells. Using our pipeline, we defined the regulatory elements necessary for optimal transgene expression in plasma cells and can identify the most appropriate coding sequences and signal peptides for the secretion of a given transgene in a matter of weeks. Optimized expression cassettes were then incorporated into AAV vectors and used to engineer primary human B cells with subsequent differentiation into long-lived plasma cells. The robustness of our BeCM platform was demonstrated by the expression of multiple therapeutic proteins such as lysosomal storage disease enzymes, serum proteases, and bispecific T cell engagers. The above-described B cell engineering platform supports the development of autologous as well as allogeneic B cell medicines and allows us to rapidly move from idea to prototype. Novel BeCMs capable of expressing one or more therapeutically relevant transgenes have the potential for broad and meaningful therapeutic utility in rare diseases, cancer, and beyond.

120 Restoration of Full-Length Dystrophin Using AAV-Delivered U7snRNA in Patient Cells with a *DMD* Pseudoexon: A Model for Bespoke Gene Therapies in an Orphaned Mutational Class

Joseph C. Beljan[1], Kevin M. Flanigan[1,2], Liubov V. Gushchina[1], Stefan Nicolau[1], Anthony A. Stephenson[1]

[1]Center for Gene Therapy, Nationwide Children's Hospital, Columbus, OH,[2]Department of Pediatrics, The Ohio State University, Columbus, OH

Duchenne muscular dystrophy (DMD) is an X-linked disease caused by a null allele of the *DMD* gene. Thousands of pathogenic *DMD* variants have been described, with deep intronic mutations in the *DMD* gene causing loss of dystrophin expression in 1-7% of all DMD patients. These mutations create cryptic splice sites that mimic canonical splice acceptor and donor sites, resulting in the creation of a pseudoexon, where an intronic fragment is spliced into the coding sequence of the mRNA transcript. Patients with deep intronic mutations possess all of the correct *DMD* coding exons, therefore skipping the pseudoexon should restore a full-length transcript. Objective: To induce expression of full-length dystrophin in cells carrying an intron 18 point mutation, using U7snRNAs targeting either the splice acceptor (SA), splice donor (SD), or exon splice enhancer (ESE) sequences of the resultant frame-shifting pseudoexon. Methods: The AAV-delivered U7snRNA vector repurposes an endogenous U7 small nuclear ribonucleoprotein to induce exon skipping at the pre-mRNA processing step of mRNA maturation. To test for pseudoexon skipping efficacy, human MyoD-transformed cells with a c.2292+1024 G>T mutation were treated with increasing doses of AAV1 containing a single U7snRNA antisense sequence targeting the SA, SD, or ESE. Results: We achieved successful skipping of the pseudoexon, restoring up to 93% of full-length dystrophin mRNA transcript, and 34% of dystrophin protein, as compared to wild-type cells, with the SD and ESE antisense sequences resulting in the most robust skipping response. Conclusions: Our preliminary data confirms the pseudoexon class of *DMD* mutations is amenable to U7snRNA treatment, and we plan to further validate this in other DMD patient cell lines. This approach addresses an orphaned class of *DMD* mutations, and demonstrates the potential of bespoke gene therapies to restore full-length dystrophin in individual patients.

121 Large-Scale GUIDE-seq-2 Profiling Reveals Effects of Human Genetic Variation on Cellular Off-Target Genome Editing Activity

Cicera R. Lazzarotto[1,2], Yichao Li[1], Varun Katta[1], Elizabeth Urbina Obregon[1], Rachael Wood[1], Azusa Matsubara[1], Yong Cheng[1], Shengdar Q. Tsai[1]

[1]St. Jude Children's Research Hospital, Memphis, TN,[2]Beam Therapeutics, Cambridge, MA

CRISPR-Cas genome editors hold enormous potential for the treatment of a wide spectrum of genetic diseases and some therapeutic approaches are in ongoing Phase III clinical trials. As gene therapy products that incorporate human genome editing become approved, thousands of patients may to be treated with these new future therapies. An important unanswered question is how individual genetic variation may impact the safety of these treatments. We and others have described examples of point mutations that affect genome editing activity. Here we describe the first, to our knowledge, large-scale experimental studies of the effects of genetic variation within four human populations (ASW, African Ancestry in Southwest USA; CEU, Utah residents with Northern and Western European ancestry; HCB, Han Chinese in Beijing; and MXL, Mexican Ancestry in Los Angeles) on the genome-wide off-target activity of editors. We reasoned that a high-throughput version of GUIDE-seq, a cell-based method for defining nuclease genome-wide activity, could enable the rapid measurement of change in genome editing activity due to genetic variation within on- and off-target sites. We designed and optimized GUIDE-seq-2, a sensitive, streamlined, automated and high-throughput Tn5-tagmentation enabled version of GUIDE-seq which is comparable to the original method and highly reproducible. To determine the impact of single genetic variation on Cas9 off-target activity, using GUIDE-seq-2 we performed a large-scale evaluation of genome-wide off-target activity for six sgRNAs in lymphoblastoid cell lines (LCLs) from ninety-four individuals across four populations characterized by the 1000 genomes project. We measured CRISPR-Cas9 off-target activity across the six target sites and 94 LCL donors using GUIDE-seq-2 aided by an automated liquid handling system. We detected a total of 963 unique off-target sites across the six target sites and 94 LCL donors that we evaluated. Interestingly, we found that 18.7% (180/963) of the off-targets detected, a relatively high proportion, harbored SNPs within at least one individual's genome. We then modeled the effects of genetic variation on GUIDE-seq-2 read counts (a direct measurement of cellular Cas9 activity) and found 15% (27/180) of genetic variants within off-target sites had significant effects on Cas9 activity ($P<0.05$). Variants with strong effects on off-target activity were found at expected protospacer adjacent motif (PAM)-proximal and also less likely PAM-distal regions of the off-target sites. In sum, we found approximately 2.8% (27/963) of all detected off-target sites were significantly affected by non-reference genetic variants, with an average of 32.4% (1.1%-93%) of individuals affected per off-target site. Taken together, our results show that genetic variation can strongly

impact cellular Cas9 genome-wide off-target activity and highlights the importance of considering how this may affect the safety and efficacy of broadly applicable genome editing therapies.

122 Modeling Gene Editing Outcomes in Microphysiological Human Tissue System Models of Duchenne Muscular Dystrophy

Madeleine J. Sitton, Alastair Khodabukus, Joel D. Bohning, Nenad Bursac, Charles A. Gersbach

Biomedical Engineering, Duke University, Durham, NC

Gene editing has shown potential to treat human diseases, however there remains an unmet need for physiologically relevant preclinical models that can accurately predict the safety and efficacy of gene editors in humans. To address this, we have engineered human skeletal muscle microphysiological tissue systems (myobundles) that model the dystrophic phenotype characteristic of Duchenne muscular dystrophy (DMD). In this study, we report successful editing of the DMD gene using two different myobundle models and three different gene editing strategies delivered via AAV. We show that gene correction leads to significantly improved muscle health and function, demonstrating the potential of myobundles as a preclinical model. We first determined whether myobundles could accurately model the effects of gene editors delivered via AAV. We completed an AAV serotype screen where hiPSC-derived *DMD*Δ48-50 myoblasts were transduced at the time of 3D tissue formation with a panel of AAV serotypes encoding GFP. Based on GFP+ cross-sectional area (CSA), AAV6 had the highest transduction efficiency at 40%, followed by AAV2 at 20%, and AAV8 and 9 had little to no transduction. We then evaluated the editing efficiency of deleting exon 51 by a CRISPR-based editing strategy delivered via two AAV vectors (g51). We observed productive edits in 15% of alleles, which restored the reading frame in 40% of dystrophin transcripts and rescued 12% of wild-type dystrophin protein levels. To further demonstrate the utility of this model, we created an additional myobundle line lacking *DMD* exon 44 and evaluated two exon skipping strategies: an adenine base editor and SpCas9 targeted to the exon 45 splice acceptor. Treatment with the adenine base editor and SpCas9 led to exon 45 skipping in 30% and 6% of transcripts and restoration of 17% and 5% of wild-type dystrophin protein levels, respectively. We also compared the function of myobundles treated with g51 vs. a non-targeting gRNA (gCtrl). Interestingly, we found that g51-treated myobundles had a small, but significant decrease in specific force (contractile force/CSA) compared to gCtrl-treated myobundles. However, g51-treated myobundles showed significantly less reduction of force generation compared to gCtrl after injury, suggesting partial amelioration of the dystrophic phenotype. Further histological analysis will characterize the effect of editing on myobundle health and function. Finally, we treated an immortalized patient myoblast line lacking *DMD* exons 48-50 with g51 and isolated edited cells to create a monoclonal line of uniformly corrected cells (*DMD*Δ48-51), which were then used to make myobundles. Histological analysis showed that *DMD*Δ48-51 had significantly increased myotube diameter and improved sarcomere structure, suggesting improved muscle structure and health, compared to uncorrected controls. *DMD*Δ48-51 myobundles generated a significantly greater specific force and were protected from injury compared to unedited myobundles. Together, these results suggest that restoration of dystrophin reverses the functional deficits seen in dystrophic human myobundles. Collectively, this foundational work shows that 3D microphysiological muscle tissue models can be used to perform safety, efficacy, and functional assays in a model that accurately captures human muscle physiology, directly addressing a need in the gene editing field that has been unmet by 2D cell culture and animal models. Additionally, improvements to the model, including the incorporation of immune cells and vasculature, may continue to increase its ability to accurately predict the safety and efficacy of gene therapies in patients.

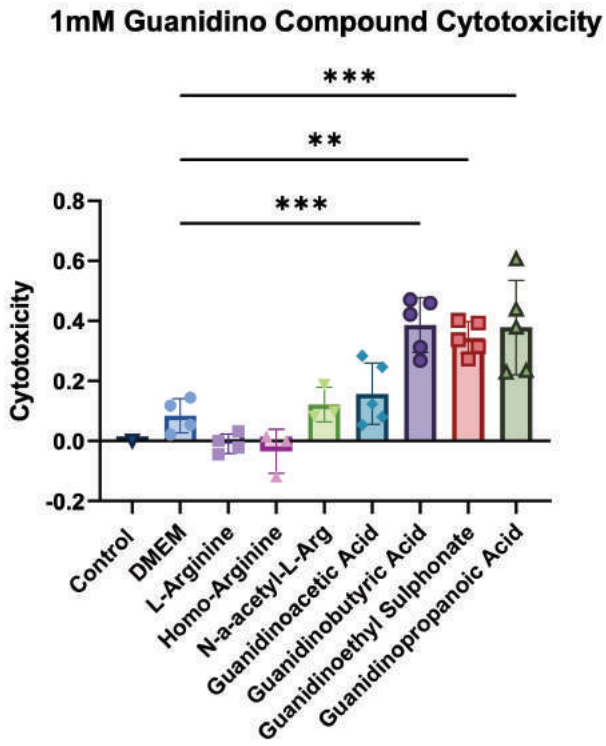
123 Oligodendrocyte Toxicity by Guanidino Compounds, Not Arginine, Fosters Dysmyelination in Arginase Deficiency and is Prevented by AAV-Based Gene Therapy

YuChen Zhang[1], Colleen Thuy Le[1], Xiaobo Liu[2], Gerald S. Lipshutz[2]

[1]University of California, Los Angeles, Los Angeles, CA,[2]Department of Surgery, University of California, Los Angeles, Los Angeles, CA

Introduction: Arginase deficiency is a distal urea cycle disorder (UCD) that has unique, characteristic symptoms that differ from other UCDs. These include spastic diplegia/tetraplegia, intellectual disability, & progressive irreversible neurological decline. Recent studies have demonstrated that central nervous system (CNS) dysmyelination is a prominent feature of the disorder & may in part be the cause of the unique neuromotor phenotype. While also classified now as a leukodystrophy, the underlying cause of oligodendrocyte dysfunction in arginase deficiency is unclear. We hypothesized that either hyperargininemia itself or substances related to arginine metabolism (i.e., guanidino compounds, which are generally related to transamidination by the promiscuous enzyme L-arginine-glycine amidinotransferase) may be the cause of the observed dysmyelination phenotype. In this study, we investigated the potential mechanisms of myelination dysregulation in arginase deficiency & have shown that dysmyelination can be prevented by AAV-based treatment. **Methods/Results**: Microarray analysis suggested alteration of oligodendrocyte function by postnatal day (P) 15 & histological markers in the brain supported this finding. Utilizing electron microscopy & murine model of arginase deficiency, we found a lack of myelination during beginnings of CNS model myelination in untreated Arginase 1 knockout mice. Myelinated axon density in subcortical white matter was significantly lower in untreated Arginase 1 knockout mice than Wild Type at P15. Myelinated axon density in the pyramidal tract was also significant lower in untreated Arginase 1 knockout mice when analyzed at P6, P10 & P15. To restore Arginase expression, we generated a serotype rh10 AAV expressing human codon-optimized Arginase 1 under a TBG promoter; 1e14 GC/kg was administered intravenously on P2. Analysis demonstrated that AAV treatment successfully restored myelinated axon density to a level comparable to wild type in both brain regions by 4-months. We isolated oligodendrocyte progenitor

cells (OPC) through antibody-based cell selection & exposed them to guanidino compounds. Guanidino compound treatment at concentrations of 1mM & 3mM resulted in significant cell death. In contrast, exposing OPCs to arginine at both concentrations did not induce changes in cell viability (Figure 1). We further hypothesized that guanidino compounds enter OPCs through the creatine transporter SLC6A8 due to similarity in structure between guanidino compounds & creatine. SLC6A8 overexpression in HEK293T cells demonstrated competition between creatine & several guanidino compounds as assessed by a creatine uptake assay. Supplementation of media with creatine resulted in greater survival of OPCs, suggesting a potential mechanism how elevated guanidino compounds could cause OPCs' death. **Conclusion**: In arginase deficiency, OPC survival is impacted by elevated guanidino compounds, but not by hyperargininemia, in a creatine-dependent manner & results in pronounced dysmyelination in the early neonatal period. This phenotype can be alleviated by AAV-based gene therapy controlling guanidino compound production. These findings demonstrate the potential impact that successful hepatic gene therapy may have on the developing brain in arginase deficiency due to the better understanding of the underlying disease pathology.



124 Enhanced Enzyme Uptake and Glycogen Clearance in Muscles and CNS of Pompe Mice Administered AAV9 Expressing Novel Engineered GAA

Waijiao Cai[1], Nick Marze[2], Erin Lopez[1], Lucy S. Marie[1], Ilya Tikh[2], Susan A. Benard[2], Vincent Chihyi Yu[2], Michael St. Andre[1], Jane M. [1]Rare Disease, Pfizer Inc., Cambridge, MA,[2]BioMedicine Design, Pfizer Inc., Cambridge, MA,[3]Cellular and High Content Imaging Tech-Center IMRU, Pfizer Inc., Cambridge, MA,[4]Drug Safety R&D, Pfizer Inc., Norwich, CT,[5]Drug Safety R&D, Pfizer Inc., Pearl River, NY,[6]Drug Safety R&D, Pfizer Inc., Cambridge, MA,[7]Drug Safety R&D, Pfizer Inc., Groton, CT,[8]BioMedicine Design, Pfizer Inc., Morrisville, NC

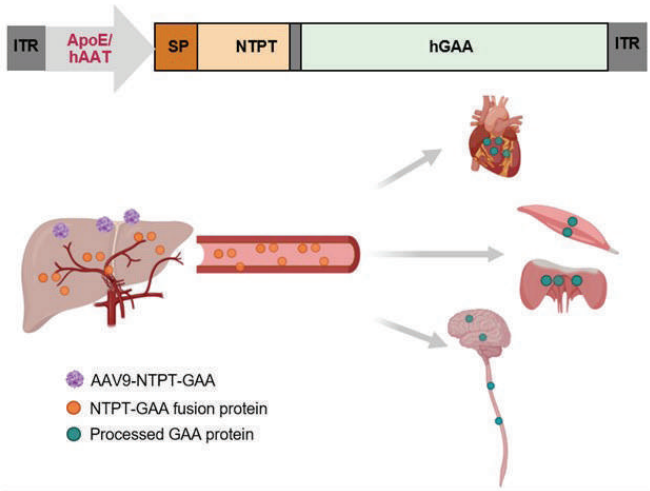
Pompe disease is a life-threatening glycogen storage disorder caused by deficiency of acid-alpha-glycosidase (GAA). The effectiveness of recombinant human acid-alpha-glucosidase (rhGAA) enzyme replacement therapy treatment is limited due to hepatic clearance and insufficient mannose-6-phosphate (M6P) glycans, the latter being required for uptake and lysosomal delivery by M6P receptor (M6PR). Here, we fused an N-terminal peptide tag (NTPT) derived from Insulin-like growth factor-II to hGAA. The chimeric protein NTPT-hGAA also binds to M6PR, albeit at a site that does not require M6P glycans. We first evaluated the NTPT-hGAA and hGAA in a cellular uptake assay by adding increasing amounts of enzyme to cells. Addition of NTPT-hGAA led to high uptake in rat myoblasts and patient fibroblasts; however, hGAA administration, even at the highest level did not result in increased cellular uptake. Systemic administration of AAV expressing NTPT-hGAA to $Gaa^{-/-}$ mice enhanced enzyme uptake, cleared glycogen, corrected autophagic defects in muscle and brain, and restored muscle function. The NTPT was further engineered to reduce undesired binding to Insulin-like growth factor-I receptor (IGF-IR) and insulin receptor (IR). A screen of NTPT variants identified a unique sequence (#44) that demonstrated reduced IGF-1R and IR binding. Signal peptides of NTPT-hGAA and NTPT44-hGAA variants were replaced by an alternate sequence (SP13) to optimize liver secretion. Intravenously administered AAV-SP13-NTPT-hGAA and AAV-SP13-NTPT44-hGAA efficiently reduced muscle, brain, and spinal cord glycogen content. Cynomolgus macaques administered AAV-SP13-NTPT-hGAA and AAV-SP13-NTPT44-hGAA demonstrated dose-dependent liver expression. Vector constructs were well tolerated at the administered dose levels. In an effort to lower the dose and reduce the immunogenicity risk we codon-modified the transgene sequence. These optimized second-generation constructs demonstrated higher NTPT-hGAA expression and activity in a human liver cell line. Systemic administration led to increased serum NTPT-GAA concentration and tissue enzyme uptake in wild type and $Gaa^{-/-}$ mice when compared to non-optimized constructs. Simulation models suggest 3 to 5-fold dose lowering with the new codon-optimized constructs in non-human primates. Taken together, these studies demonstrate an effective

strategy to deliver liver-expressed hGAA to muscle and central nervous system that is glycosylation independent yet minimizes the safety risks associated with off-target receptor engagement.

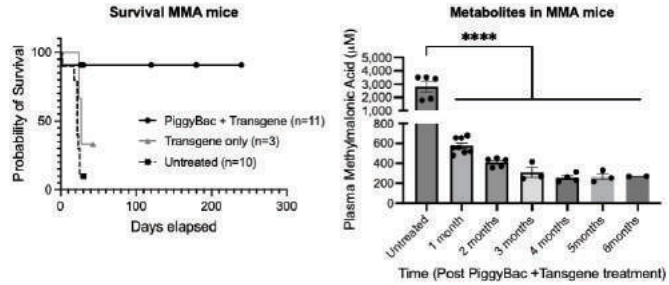


SP=signal peptide, NTPT=N terminal peptide tag, hGAA=human acid alpha-glucosidase

125 Rescue of a Lethal Murine Model of Methylmalonic Acidemia by AAV Mediated Delivery of PiggyBac Transposase and a Therapeutic Transgene

Randy J. Chandler, Charles P. Venditti
National Institutes of Health, Bethesda, MD

Introduction: Methylmalonic acidemia (MMA) is a severe autosomal recessive metabolic disorder caused most frequently by variants in the methylmalonyl-CoA mutase (MMUT) gene, which encodes for this mitochondrial localized enzyme. MMA results in both acute and chronic multisystemic medical complications that can be fatal. Severely effect patients can undergo liver transplantation to treat the underlying enzymatic defect and the success of this procedure suggests that liver direct gene delivery maybe a viable treatment option. Systemic AAV gene therapy has recently emerged as a promising new therapy for MMA but could be limited by the temporal loss of AAV episomes, a well-recognized limitation of therapy with non-integrating vectors. Here we explore the therapeutic efficacy of a dual AAV transposase gene delivery system to integrate a therapeutic transgene into the hepatocytes of mice using a recently generated mouse model of a lethal form of MMA caused by a MMUT p.R106C variant. Methods: Two AAV vectors were created and pseudoserotyped with an AAV8 capsid: one AAV expresses a therapeutic MMUT transgene under the control of a liver specific promoter, cloned between AAV2-ITRs and internally flanked by transposon-specific terminal repeats (TR), while the second is similarly designed to express a modified PiggyBac transposase but lacks transposon TRs. When both AAVs transduce the same cell, the PiggyBac transposase will mediate a cut-and-paste insertion of the *MMUT* transgene into the genome. Either the transgene only or transgene plus Piggybac vectors were delivered at birth by retroorbital injection, at doses of 5.4e13 vg/kg (transgene) and 4.3e13vgkg (PiggyBac), to MmutR106C/R106C mice and control littermates. Survival, growth, metabolite levels, and transgene expression were assayed.Results: *Mmut*$^{R106C/R106C}$ mice treated with PiggyBac+transgene had significantly ($p<0.01$) increased survival versus both untreated and transgene only treated mice. While rare untreated *Mmut*$^{R106C/R106C}$ mice that survived to weaning were approximately 40% the mass of normal wildtype mice, PiggyBac+transgene treated mice had normal growth, not significantly different than control littermates . Plasma levels of the disease-related biomarker, methylmalonic acid, in PiggyBac+transgene treated mice were significantly lower than in untreated mice at all time points measured out to 6 months posttreatment ($p<0.001$). Lastly, in situ hybridization to detect transgene expression in the livers harvested from PiggyBac+transgene treated mice revealed large numbers of hepatocytes expressing *MMUT* mRNA one month after treatment, with abundant positive staining hepatocytes, widely distributed throughout the liver.Conclusions: AAV mediated gene editing using a transposase to enable hepatic integration of a therapeutic transgene enables the permanent correction of the clinical manifestations of MMA in a disease model with a severe and lethal phenotype. The modular design of the vectors we have developed should enable the rapid assessment of other transposable elements for therapeutic benefits in the treatment of MMA, and by extension, other disorders of intermediary metabolism where early hepatic correction is beneficial, and stable transgene expression is required.



126 New Mouse Models of, and AAV9 Gene Therapeutics to Treat, Isolated Methylmalonic Acidemia, Cobalamin B (*cblB*) Type

Eun-Young Choi, Karenna Choi, Lina Li, Charles P. Venditti
MMB, OARS, NHGRI, NIH, Bethesda, MD

Introduction: Cobalamin B-type (*cblB*) methylmalonic acidemia (MMA) is an rare and severe autosomal recessive inborn error caused by pathogenic variants in the MMAB gene, which encodes the enzyme ATP:cob(I)alamin adenosyltransferase (ATR) and catalyzes the synthesis 5'- deoxyadenosylcobalamin (AdoCbl), the cofactor for methylmalonyl-CoA mutase (MMUT). MMUT and MMAB deficiencies are clinically similar, recalcitrant to medical management, and treated using elective liver (LT) and liver-kidney transplantation (LKT). There are no animal models or gene therapies that have been developed for MMAB deficiency, a Platform Vector Gene Therapy (PaVe-GT) indication. **Methods:** We assessed the correlations between patient mutations, clinical phenotypes and treatment with transplantation in a cohort of N=17 subjects with MMAB deficiency ascertained via a natural history study of MMA (NCT00078078). Two severe mutations, the orthologue of a missense mutation recurrently noted in those who received LT/LKT (p.Arg186Trp), and another that removed exons 3-7, were engineered into the Mmab locus. In addition, a germline

rescue transgene, designed to restore expression of MMAB in the skeletal muscle under the control of the murine muscle creatine kinase (MCK) promoter, was knocked into the ROSA26 locus ($Tg^{MCK\text{-}Mmab}$), and used to generate a hypomorphic model ($Mmab^{R180W/R180W}$; $Tg^{MCK\text{-}Mmab}$). AAV vectors to express *MMAB* under the control of the EF1L or EF1s promoters, in either the single strand (ss) or self-complementary (sc) genome configurations respectively, were pseudoserotyped with an AAV9 capsid, and assayed for in vivo efficacy. **Results:** $Mmab^{\Delta 3\text{-}7/\Delta 3\text{-}7}$ and $Mmab^{R180W/R180W}$ mice displayed lethality and massively increased plasma [MMA] levels (1150 +/- 177 uM, 360x WT), very much like patients with severe forms of *cblB* MMA. $Mmab^{R180W/R180W}$;$Tg^{MCK\text{-}Mmab}$ mice survived until weaning but manifested pronounced MMAemia (520+/- 79 uM, 200x WT), growth retardation, increased FGF21, and decreased ^{13}C propionate oxidation. In a proof of concept study, neonatal treatment of $Mmab^{\Delta 3\text{-}7/\Delta 3\text{-}7}$ mice (n=6) with the scAAV9 EF1s MMAB vector, systemically delivered at a dose of 1e11 GC/pup on DOL1, resulted in complete rescue from lethality, and full phenotypic correction persisting > 100 days (Figure 1). $Mmab^{R180W/R180W}$; $Tg^{MCK\text{-}Mmab}$ mice treated with either vectors as young adults (n=6), given at a dose of 1e13 GC/kg, produced equally robust responses by 2 weeks, with a 38x reduction (12.9 +/- 3.7 uM) of the circulating plasma [MMA], restoration of ^{13}C propionate oxidation to wild type levels, and transgene expression in the liver (Figure 2) and kidney (Figure 3) exceeding WT MMAB levels. **Conclusions:** In this work, we have developed a series of clinically relevant MMAB animal models and AAV9 vectors that mediate robust hepatorenal transgene expression after systemic delivery. These mouse models can be used for neonatal and adult proof of concept therapeutic studies, including dose finding and pharm-tox, and will be used to rapidly enable a new class of AAV9 gene therapeutics to treat patients with MMAB deficiency, a severe form of MMA.

127 Preclinical Proof-of-Concept: A Novel Hybrid Gene Therapy Approach to Treat Severe Early-Onset Ornithine Transcarbamylase Deficiency

Bernard Kok[1], David Ebeid[2], Nairika Mishgin[2], Ryan Loveless[2], Khal Hajj[2], Tuyen Nguyen[2], Christopher Deng[2], Peter Griffin[2], Mu Li[2], Michael Bennett[2], Pavan Battiprolu[2], Brent Warner[2], Blair Madison[2], Joshua Rychak[2]

[1]In Vivo Gene Therapy, Poseida Therapeutics, San Diego, CA,[2]Poseida Therapeutics, San Diego, CA

Ornithine Transcarbamylase deficiency (OTCD) is an X-linked urea cycle disorder that prevents the breakdown and excretion of ammonia; this allows ammonia to rise to toxic levels and affect the central nervous system leading to coma, seizures, brain damage, and death. For young, early-onset patients, the disease burden is severe and without treatment can be fatal. Liver transplant is the only current corrective option, as other interventions do not enable survival past childhood for most patients. Thus, there is an urgent unmet need for efficient therapies to rescue the disease burden by intervening early in life. Gene therapy approaches utilizing recombinant adeno-associated virus (rAAV) are likely to be ineffective when used early in life due to the expected dilution of the therapeutic transgene during cell division commensurate with liver growth. Currently, re-dosing of AAV is not feasible due to the strong inherent immunity against AAV capsids. We have developed a gene therapy platform utilizing the super piggyBac® DNA insertion system that enables integration of the therapeutic human OTC gene into the genome. Genomic integration of the OTC gene enables it to be maintained during cell division, potentially enabling durability of the therapeutic effect throughout life. The system entails two components: 1) a piggyBac transposon comprising the human OTC gene under a weak liver-specific promoter and formulated as a liver-tropic AAV(AAV-hOTC) and 2) an mRNA coding for the super piggyBac transposase (SPB) formulated as a liver-directed lipid nanoparticle (LNP-SPB). Severe OTCD was modelled in the hypomorphic OTC-deficient mice (spf^{ash}), using an AAV-delivered shRNA to knock down residual OTC activity. Mice were treated on day=1 of life by intravenous administration of the hOTC-AAV and LNP-SPB. As a negative control, some mice were administered the AAV-hOTC alone or AAV-hOTC with an LNP containing an mRNA for the catalytically deficient form of SPB that is unable to mediate genomic integration of the hOTC transgene. Mice were administered the shRNA construct forty days post-treatment, which rapidly induced hyperammonemia and death within 10 days. Treatment with the AAV-hOTC alone or AAV-hOTC combined with the catalytically deficient SPB LNP did not meaningful extend the survival of these mice even at high AAV dose (5E13 vg/kg), and immunohistochemical analysis of the liver showed only few and scattered (<3%) hepatocytes expressing the hOTC transgene. In contrast, mice treated with the AAV-hOTC and LNP-SPB exhibited full survival at AAV doses as low as 5E12 vg/kg, coupled with normalization of plasma ammonia and urinary orotic acid to wild type levels. Immunostaining demonstrated a substantial (>40%) proportion of hepatocytes expressing the hOTC gene, which persisted well into adulthood. Integration analysis showed low integrated copy numbers (1-3 hOTC per diploid genome) in

the liver, and the frequency of integrations was proportional to the dose of LNP-SPB. No clinically significant elevations in liver enzymes were observed in mice or non-human primates at any of the evaluated doses. Serum pro-inflammatory cytokines were transiently elevated and proportional to LNP-SPB dose. Both the AAV and LNP exhibited strong liver tropism, with no detection in brain or gonad. These data demonstrate the correction of severe OTCD, entailing complete survival and normalization of biomarkers of urea cycle function, following a single administration of our integrating gene therapy administered on day 1 of life and supports subsequent development toward evaluation in human patients.

128 Long-Term Safety and Efficacy of DTX301 in Adults with Late-Onset Ornithine Transcarbamylase (OTC) Deficiency: A Phase 1/2 Trial

Cary O. Harding[1], Tarekegn Geberhiwot[2], Maria Luz Couce[3], Nathalie Guffon[4], Leticia Ceberio Hualde[5], Aneal Khan[6], Laura Konczal[7], Wen-Hann Tan[8], Janet Thomas[9], Margo Breilyn[10], Kaushik Patra[11], J Lawrence Merritt[11], Eric Crombez[11]

Background: OTC deficiency is an X-linked urea cycle disorder resulting in life-long risk of episodic hyperammonemia that can lead to coma or death, even with ongoing treatment with ammonia scavenger medication and dietary protein restriction. DTX301 is an AAV8 vector containing the OTC transgene being investigated for treatment of OTC deficiency. We report the long-term follow up (LTFU) of 11 adults with late-onset OTC deficiency who received a single IV infusion of DTX301 in the Phase 1/2 trial (NCT02991144). **Methods:** The initial Phase 1/2 study lasted 52 weeks; all participants will be followed thereafter semi-annually for up to an additional 5 years. Complete responders discontinued all ammonia-scavenging drugs and protein-restricted diet. Responders had ≥50% reduction in medications and dietary protein restriction. Data cutoff was 09 Dec 2022. **Results:** Currently, no treatment-related serious AEs, dose-limiting toxicities, or infusion-related events have been reported. One patient experienced a hyperammonemic crisis, and two patients experienced mild ALT elevations during LTFU (all considered unrelated to DTX301). As of cutoff, 7/11 patients have shown a continued response to DTX301 from 2 to now over 5 years after dosing; 4 patients were complete responders, and 3 patients were responders (**Table**). Plasma glutamine levels showed considerable individual variability but were generally lower for complete responders and responders. Citrulline levels were in the normal range and generally stable for all groups. Overall mean plasma ammonia area under the curve $(AUC)_{0\text{-}24}$ showed improvement over time with variability. Values were more consistently in the normal range (< 1440 µmol*h/L) for complete responders and responders. **Conclusions:** DTX301 continues to suggest a manageable safety profile and encouraging evidence of durable efficacy with the longest treated complete responder exhibiting efficacy for over 5 years. Patients in this study will continue to be followed. The Phase 3 trial (NCT05345171) is currently recruiting.

129 Single AAV Vector Gene Therapy with a Mini-GDE Transgene Corrects Muscle Impairment in Mouse, Rat and Human Cellular Models of Glycogen Storage Disease Type III

Antoine Gardin[1], Jeremy Rouillon[1], Valle Montalvo-Romeral[1], Lucille Rossiaud[1,2], Patrice Vidal[1], Romain Launay[3], Mallaury Vie[1], Bérangère Bertin[1], Guillaume Dubreuil[1], Justine Nozi[1], Louisa Jauze[1], Romain Fragnoud[1], Nathalie Daniele[1], Laetitia Van Wittenberghe[1], Jeremy Esque[3], Isabelle Andre[3], Xavier Nissan[2], Lucile Hoch[2], Giuseppe Ronzitti[1]

[1]Genethon, Evry, France,[2]I-STEM, Evry, France,[3]Toulouse Biotechnology Institute, Toulouse, France

Glycogen storage disease type III (GSDIII) is a rare inborn error of metabolism affecting liver, skeletal muscle, and heart due to mutations of the *AGL* gene encoding for the glycogen debranching enzyme (GDE). The 4.6 kb GDE cDNA represents a technical challenge toward the development of a single *adeno-associated virus* (AAV) vector strategy, since an expression cassette containing the full-length GDE cDNA is largely oversized. Dual vectors or the use of bacterial orthologs of GDE were proposed to overcome this size limitation. However, the clinical translation of these approaches is complicated by possible immune responses and the higher doses required. Here we developed a single rAAV-based gene therapy strategy for GSDIII using a truncated GDE to correct skeletal muscles and heart impairment in $Agl^{-/-}$ mice and rats and to decrease glycogen content in skeletal myotubes differentiated from $AGL^{-/-}$ human pluripotent stem cells (iPSC). Using molecular modeling, the 3D structure of GDE and considering the positions of known *AGL* missense mutations, we identified the GDE N-terminal as the most promising region to reduce the size of the enzyme while retaining its activity. Particularly, the ΔNter2 mutant showed similar glycogen clearance *in vivo* to the full-length GDE. Moreover, this mutant size allowed encapsidation with strikingly improved rAAV vector yields and quality. Intravenous injection of ΔNter2-expressing rAAV vectors in adult $Agl^{-/-}$ mice and rats allowed complete glycogen clearance in muscles and heart and normalization of histology features

three months after injection. It also allowed complete reversal of the muscle strength impairment in *Agl*$^{-/-}$ mice. Finally, transduction of AGL$^{-/-}$ iPSC-derived muscle cells with ΔNter2-expressing rAAV vectors resulted in almost complete glycogen clearance with no overt toxicity compared to mock-transduced cells. In conclusion, our results show for the first time the ability of a functional truncated GDE transgene to correct the muscle and heart phenotype in multiple models of GSDIII, supporting its clinical translation in GSDIII patients

Gene Therapy Approaches for Muscle and Skeletal Diseases

130 AAVrh74.tMCK.hBAG3 Gene Therapy Improves Function and Decreases MYOT Aggregate Formation in TgT57I Mice

Burcak Ozes[1], Lingying Tong[1], Kyle Moss[1], Morgan Myers[1], Zayed Attia[1], Tatyana A. Vetter[1], Zarife Sahenk[1,2,3]

[1]Center for Gene Therapy, Nationwide Children's Hospital, Columbus, OH,[2]Department of Pediatrics and Neurology, Nationwide Children's Hospital and The Ohio State University, Columbus, OH,[3]Department of Pathology and Laboratory Medicine, Nationwide Children's Hospital, Columbus, OH

Myofibrillar myopathies (MFMs) are a group of protein aggregate diseases, defined histologically by abnormal protein aggregations and myofibrillar disintegration. Myotilinopathy, also called limb-girdle muscular dystrophy type 1A (LGMD1A), belongs to the distal MFM group and is characterized by initial weakness of proximal girdle muscles. Mutations in myotilin gene have been associated with myotilinopathy and the underlying pathology was suggested to be toxic gain-of-function leading to myotilin-positive protein aggregates as well as a loss-of-function that impairs the integrity of myofibrils. Degradation of non-native proteins can be facilitated by Ubiquitin-proteasome system, however when this pathway is overloaded under pathophysiological conditions, the protein quality control system leans on the autophagy-lysosome pathway (ALP) to mediate degradation of aggregates. BCL2-associated athanogene 3 (BAG3) protein facilitates aggresome formation and initiates this macroautophagic pathway. In this study, we assessed our strategy of reducing the aggregate burden in the muscle by overexpressing the BAG3 in a mouse model for LGMD1A, carrying a human myotilin gene with T57I mutation. Ten male TgT57I mice received 3x10^{12} vg total dose of AAVrh74.tMCK.BAG3, via tail vein injection, aged 4-8 weeks, and eight sex and aged-matched TgT57I mice served as untreated (UT) control. Mice were tested for rotarod, treadmill, grip strength and *in vivo* muscle contractility, which included maximum twitch and tetanic responses at the endpoint, around 8 months post gene delivery. The BAG3-treated cohort demonstrated increased rotarod duration by 43.2% (BAG3, 39.54 ± 1.33 sec; UT, 27.6 ± 1.77 sec; p=0.0001) and running distance on treadmill by 70.5% (BAG3, 156.03 ± 13.93 m; UT, 91.53 ± 13.35 m; p=0.0048), compared to UT cohort. Grip-strength values of treated cohort improved by 38.7% (BAG3, 0.102 ± 0.008 kg; UT, 0.074 ± 0.004 kg; p=0.006). The *in vivo* muscle contractility assay showed that muscle strength was increased significantly for maximum tetanic response (BAG3, 6.26 ± 0.44 mN*m; UT, 5.19 ± 0.23 mN*m; p=0.047), while the increase was not significant for maximum twitch response. Myotilin aggregate burden was quantified using immunofluorescence technique on 4 randomly selected representative images at 20x-magnification from quadriceps muscles of BAG3-treated (n=10) and UT (n=8) cohorts. The number of myotilin positive aggregates per unit area was decreased significantly in the treated group, compared to untreated counterparts (BAG3, 466.1 ± 31.3 /mm^2 vs. UT, 585.6 ± 47.9 /mm^2; p=0.0007). Aggregate size distribution analysis revealed a reduction of numbers in all aggregate sizes with treatment, demonstrating significance for aggregate sizes up to 10 μm in diameter. We also noted a decrease in mean aggregate fluorescence intensity with treatment, without reaching significance level. In conclusion, systemic BAG3 gene therapy in a mouse model for LGMD1A have significantly improved function and maximum tetanic response compared to UT cohort. Efficacy of AAVrh74.BAG3 was supported by significantly decreased aggregate number in the treated cohort as proof of principle that our strategy of reducing the aggregate burden in the muscle, by overexpressing BAG3, may be used in treatment for protein aggregate myopathies.

131 Toxicology, Pharmacokinetics and Biodistribution of a PATrOL™-Enabled Investigational Genetic Therapy for Myotonic Dystrophy, Type 1

William Riedl, Lyuqin Chen, Lindsey R. Spiker, Steven M. Murphy, Nathan Tavenor, Barry Badeau, Jeremy W. Gleaton, Dani Stoltzfus, Dietrich A. Stephan

NeuBase Therapeutics, Pittsburgh, PA

Patients with myotonic dystrophy, type 1 (DM1) suffer from cognitive deficits and muscle pathologies caused by a trinucleotide repeat expansion on one allele of the *DMPK* gene. This mutation, when transcribed, results in a toxic mRNA that sequesters splice proteins resulting in broad-based splice dysregulation and the generalized signs and symptoms of the disease. In order to address this disease, we utilized our peptide nucleic acid-based platform, PATrOL™, to develop both a novel PNA-based pharmacophore and a novel delivery technology that allows systemic routes of administration. Previously, we have described the ability of a DM1 lead candidate to correct the pathogenic lesion through knock-down of the human *DMPK* transcript and correction of downstream splicing defects in both fibroblasts and myoblast cultures derived from DM1 patients. We subsequently determined the EC50 to be 30nM, independent of the trinucleotide repeat expansion length. We have reported molecular and functional pharmacologic activity in the HSA^{LR} transgenic mouse model where treatment with our lead candidate rapidly reduced mutant transcript levels, corrected splicing defects, and rescued myotonia. This pharmacophore is delivered via our novel delivery technology. Previously we have demonstrated pharmacological activity of various pharmacophores in both brain and muscle after systemic routes of administration including both intravenous and subcutaneous routes. In addition, a radiolabeled biodistribution study with the delivery module after intravenously administration in nonhuman primates showed distribution to brain, muscle, and heart, and all major organs affected in DM1 patients. Additional three-month PK studies in NHP

have been completed and illustrate tissue-specific elimination rates that facilitate the design of multi-dose regimens for the Phase 1/2 trials. This data will be presented. Recently we have completed exploratory toxicology studies in rodents and non-human primates (NHPs) and have determined the single dose IV maximum tolerated doses (MTDs) based upon histology to be less than 29 mg/kg. The toxicology signal is seen in the kidney and is exemplified by tubular degeneration and followed presumably after the C_{max} with regeneration of tubules noted. Our lead candidate displayed no abnormal blood chemistries up to and including the MTD, and no test-article related immunogenicity in NHPs. A three-month pharmacokinetic (PK) study was completed in NHPs and based upon the EC50 value for patient-derived myotubes, we anticipate a human effective dose of <2.0 mg/kg. This data will be presented.

132 Management Of Patients Following Investigational Delandistrogene Moxeparvovec Gene Therapy For Duchenne Muscular Dystrophy: Delphi Panel Consensus Considerations Based on Clinical Trial Experience

Natalie Goedeker[1], Amal A. Aqul[2], Russell J. Butterfield[3], Anne M. Connolly[4], Ronald G. Crystal[5], Kan N. Hor[6], Katherine D. Mathews[7], Crystal M. Proud[8], Aravindhan Veerapandiyan[9], Paul B. Watkins[10], Kara E. Godwin[11], Elizabeth Smyth[11], Craig M. Zaidman[1], Jerry R. Mendell[4]

Background/Objectives: Delandistrogene moxeparvovec is an investigational rAAVrh74-based gene transfer therapy for the treatment of Duchenne muscular dystrophy (DMD) by expression of SRP-9001 dystrophin protein. An integrated analysis of 3 ongoing clinical trials for individuals with DMD (N=85) reported collective safety outcomes following the single intravenous infusion of delandistrogene moxeparvovec. Most treatment-related treatment-emergent adverse events (TEAEs) occurred within 90 days of treatment. A Delphi panel convened to formulate expert consensus recommendations for management of select TEAEs that require urgent medical intervention, including vomiting, acute liver injury (ALI), myocarditis, and immune-mediated myositis (IMM). **Methods:** A panel of 12 US-based neuromuscular, hepatology, cardiology, and gene therapy experts utilized a modified Delphi process to reach consensus guidance on TEAE management. Consensus was defined as a majority of experts either agreeing or disagreeing (5-point Likert scale). Surveys were developed based on systematic literature review, data on file, clinical trial experience, and expert panel responses. All experts completed two rounds of virtual surveys followed by a live meeting. **Results:** An as-needed antiemetic was recommended for vomiting. Initial mild elevations of liver laboratory tests should be assessed with repeated labs and close monitoring. If ALI is diagnosed, considerations for additional diagnostic testing, baseline corticosteroid dose adjustment, and hospitalization should be based on timing of onset and severity of symptoms. For patients with elevations in troponin I, considerations should be based on the severity of the elevation and presence of symptoms, and include corticosteroid optimization, repeated labs, electrocardiogram, echocardiogram, and cardiac MRI. Experts agreed that for suspected symptomatic IMM, emergent evaluation by physical exam, labs, and additional diagnostics would be required. In addition to hospitalization and optimization of corticosteroids, non-steroidal immunosuppressive therapy could be considered depending on the clinical scenario. **Conclusions**: The Delphi recommendations offer initial guidance that can be considered by clinicians for management of selected TEAEs following delandistrogene moxeparvovec therapy.

134 Lentivirus-Based Hematopoietic Stem/Progenitor Cell Therapy Provides Safe and Long-Term Treatment of Hypophosphatasia in Murine Models

Anjie Zhen[1], Shallu Tomer[1], Li Wang[1], Ng Hwee[1], Wally Wennerberg[1], Jeyashree Alagarsamy[1], Valerie Rezek[1], Heather Martin[1], Mayra Carrillo[1], Scott G. Kitchen[2], Irvin S.Y. Chen[3], Steven Lee[4], Yan Ming[4], Minh-Ha Do[5], Jeffrey S. Bartlett[4]

[1]UCLA, Los Angeles, CA,[2]David Geffen School of Medicine at UCLA, Los Angeles, CA,[3]UCLA School of Medicine, Los Angeles, CA,[4]Rampart Bioscience, Inc, Monrovia, CA,[5]Rampart Bioscience, Inc, San Diego, CA

Hypophosphatasia (HPP) is a multi-system metabolic disorder characterized by defective bone mineralization and skeletal abnormalities, as well as complications such as seizure, muscle weakness and respiratory failure. It is caused by loss of function mutations of the tissue-nonspecific isoenzyme of alkaline phosphatase (TNALP). HPP has a wide range of clinical manifestations and can affect patients of all ages with devastating outcomes at any stage of life. Severe forms of HPP in infants and young children is life-threatening. Currently, enzyme replacement therapy with asfotase alfa is the only treatment that enhances survival and improves bone mineralization. However, it does not cure the disease and patients must remain on the therapy for the rest of their lives as discontinuation of asfotase alfa leads to reappearance of bone hypomineralization. Here we report successful development of a hematopoietic stem/progenitor cell (HSPC) based lentiviral gene therapy to provide lifelong treatment for HPP. In humanized mice, we demonstrated that human HSPCs modified with lentivirus vectors (LVVs) expressing soluble forms of TNALP allow safe and successful engraftment of HSPCs and differentiation into multiple hematopoietic lineages. Using a murine model of severe HPP, we demonstrated that in TNALP-/- neonates transplanted with TNALP-expressing LVV-modified HSPCs, correction of plasma ALP level was fast and durable and significantly improved life span. X-ray and micro-CT analysis

showed significantly improved bone structure and mineralization in treated mice. Open field analysis and grip strength tests also demonstrated significantly improved musculoskeletal activities, to levels similar to wildtype mice. Importantly, we observed successful long-term engraftment of the LVV-modified HSPCs that supported differentiation into the expected hematopoietic lineages, resulting in continued correction of plasma ALP level and bone structure over the 11 month study duration, after a single transplantation. Our study provides critical insights into treating bone metabolic disorders with an HSPC-based gene therapy and demonstrates that this approach has the potential to offer a safe and permanent treatment for HPP.

135 AUF1 Gene Therapy for Duchenne Muscular Dystrophy Increases Durable Endogenous Utrophin Expression, Muscle Regeneration and Muscle Function Performance in Pre-Clinical Animal Studies

Dounia Abbadi[1], Riley McConnell[1], Steven Foltz[2], Subha Karumuthil-Melethil[2], Chunping Qiao[2], Joseph T. Bruder[2], Ye Liu[2], Olivier F. Danos[2], Robert J. Schneider[1]

[1]NYU Grossman School of Medicine, New York, NY,[2]REGENXBIO, Rockville, MD

Duchenne Muscular Dystrophy (DMD) is one of the most severe disorders of muscle degeneration, caused by mutations in the *DMD* gene encoding dystrophin. Dystrophin is central to the oligomeric dystrophin-associated protein complex (DAPC) that links skeletal and cardiac muscle cell actin to extracellular laminin, stabilizing the muscle cell membrane known as the sarcolemma. The absence of dystrophin leads to progressive muscle degeneration, chronic inflammation, and fibrosis. Because the dystrophin gene is too large to package in AAV vectors, gene therapies for DMD express subsets of dystrophin domains to generate truncated "microdystrophins" (μDys). While efficacy has been shown in animal and human clinical trials, issues remain, particularly an inability to rescue muscle stem cell (satellite cell) exhaustion and low regenerative capacity of DMD muscle and loss of slow-type, oxidative myofibers. Therefore, there remains an urgent need for approaches that address the full suite of pathophysiological features in DMD including loss of muscle strength, endurance regenerative capacity, myogenesis program dysfunction and restoration of the satellite cell niche population. AU-rich mRNA binding factor 1 (AUF1) is an RNA binding protein that binds repeated AU-rich elements (AREs) located in the 3' untranslated region of approximately 3% of mRNAs. AREs target mRNAs for either rapid degradation or stabilization, and/or increases ARE-mRNA translation, largely controlled by AUF1. We showed that many key regulators of muscle satellite cell activation and maintenance, myogenesis and oxidative metabolism are encoded by ARE-mRNAs regulated by AUF1, including PGC1α. Moreover, we previously reported that systemic AUF1 gene therapy strongly increases skeletal muscle expression of the dystrophin homolog utrophin, which can functionally substitute for dystrophin in the DAPC, by binding to and stabilizing its mRNA. Thus, AUF1 directly regulates skeletal muscle maintenance, regeneration, mitochondrial biogenesis, and myofiber integrity, providing strong rationale for AUF1 gene augmentation as a therapy for DMD. As proof of principle, one-month-old *mdx* DMD mice were administered i.v. AAV8.tMCK.AUF1. After 3 and 6 months of gene therapy, treated mice demonstrated significantly increased physical endurance and strength by all testing parameters compared to *mdx* controls. Remarkably, AUF1 gene therapy ameliorated the diaphragm and skeletal muscle dystrophic phenotype, reduced myofiber centro-nucleation, embryonic myosin heavy chain (eMHC) expression, and elevated serum creatine kinase. AUF1 increased utrophin, leading to an increase in DAPC protein expression and improvement of diaphragm and limb skeletal muscle integrity and morphology. Because AUF1 acts through a distinct mechanism from μDys, we tested a tandem AAV8.AUF1/AAV8.μDys approach. μDys combined with low level AUF1 demonstrated superior muscle function strength and endurance compared to AUF1 or micro-dystrophin alone (91% of WT grip strength, 70% of WT time to exhaustion) for age and sex matched mice. Furthermore, the μDys/AUF1 combination demonstrated superior muscle morphology, myofiber size, near normal satellite cell numbers, protection of muscle from atrophy following muscle injury and durable increased exercise endurance. Altogether, these results are compelling evidence that AUF1 mono- or μDys combination gene therapy may offer an alternate and superior approach in the treatment of DMD.

136 Intra-Articular Delivery of AAV Vectors Encoding Immune Checkpoint Protein as a Novel Treatment for Arthritis

Wenjun Li[1], Junjiang Sun[2], Susi Liu Feng[1], Chengwen Li[2]

[1]Gene Therapy Center, University of North Carolina at Chapel Hill, Chapel Hill, NC,[2]University of North Carolina at Chapel Hill, Chapel Hill, NC

Rheumatoid arthritis (RA) is a chronic inflammatory disease characterized by skewed and dysregulated immune responses that affect multiple organs, particularly the joints. Currently, there is no cure for RA, and patients are usually treated with one or more disease-modifying anti-rheumatic drugs (DMARDs) and/or biologics, such as cytokine inhibitors, to inhibit immune and inflammatory responses. However, less than 30% of patients have robust responses to these drugs, and achieve long-term remission. It is well known that immune cells, particularly T cells and macrophages, infiltrate the joints in inflammatory arthritis.Therefore, targeting immune cells may represent a more ideal strategy to improve arthritis treatment outcomes when compared to single cytokine. Immune checkpoints are known to regulate immune cells by balancing the co-stimulatory and co-inhibitory signals. In this study, we explored the therapeutic role of immune checkpoint protein PD-L1 in RA after intra-articular administration of adeno-associated virus (AAV) vector encoding human PD-L1. In a mouse model with the collagen induced arthritis (CIA). 5 x 10^9 vg AAV5/PD-L1 vectors encoding wild type PD-L1 with the transmembrane domain were injected into the knee joints of male DBA/1J mice at age of 7-8 weeks on the day 0 of priming immunization of collagen II or day 21 of booster post primary immunization. On day 49 post primary immunization, we found that mice treated with AAV5/PD-L1 vectors had experienced a 4-fold decrease in joint swelling and a 2.5-fold lower histopathological score compared to the control mice injected with AAV5/luc vectors. The infiltration of T cells and macrophages was remarkably lower in the joints of CIA mice that had received AAV5/PD-L1 vectors ($P<0.05$). Levels of pro-inflammatory cytokines, including IL-1, IL-6, IL-17 and TNFα, were

also 2-4 fold lower in the AAV5/PD-L1 treated joints than that in the control joints (P<0.05). Strong PD-L1 expression was detected in AAV transduced joints but no PD-L1 protein expression was detected in other tissues. High AAV genomes were detected in the AAV5/PD-L1 treated knees with ~ 1.3 viral copy numbers per diploid genome and in the liver at levels of about 0.008 viral copy numbers per diploid genome. Furthermore, the administration of AAV5/PD-L1 vectors into the joints of RA mice didn't impact the antibody titers to type II collagen and the cytokine levels in the serums. Similar to the results of AAV5/PD-L1 vector administration on day 0, decreased joint swelling and lower histopathological damage were observed in joints treated with AAV5/PD-L1 vectors on day 21. To further enhance the PD-L1 efficiency, three soluble PD-L1 variants with different transmembrane domain knockouts (shPD-L1, hPD-L1, secPD-L1) were constructed. After transfection into 293 cells, we found that shPD-L1 was able to induce much higher transgene expression in both the supernatant and the cell lysate than other two variants; total shPD-L1 protein expression in the HEK-293 cells was 7 fold higher than that of wildtype PD-L1. Next, we compared the efficiencies of wildtype PD-L1 and shPD-L1 to inhibit arthritis in CIA mice. After intra-articular injection of different doses of AAV vectors at day 0, the similar arthritis improvement was achieved with the minimum dose for AAV5/PD-L1 at a dose of 5×10^7vg and for AAV5/shPD-L1 at the dose of 5×10^6 vg, indicating that shPD-L1 has a more potent effect than wild type PD-L1. The results from this study demonstrate that AAV mediated PD-L1 gene delivery into the joints is able to prevent the development and block the progression of arthritis in CIA mice without impacting systemic immune responses, and provides a novel strategy to effectively treat chronic inflammatory joint diseases by interference with immune checkpoint pathways using local AAV gene therapy.

Understanding and Modeling Immune Responses to Gene Therapy and Vaccines

137 High-Dose AAV Toxicity in Mice: Serotype-Dependent Hepatocellular Damage and Complement Deposition and Activation

George Buchlis, James D. Montgomery, Sushobhana Bandyopadhyay, Cameron Ranken, Joanna K. Chorazeczewski, Jenny A. Greig, Juliette Hordeaux, James M. Wilson

University of Pennsylvania, Philadelphia, PA

Clinical success has been achieved with adeno-associated virus (AAV) gene therapies that result in secreted proteins or are confined to small regions of organs. However, for disease settings in which gene delivery and expression over a broad area of tissue are required (e.g., muscular dystrophy), the larger delivery burden has necessitated high systemically administered doses of AAV to achieve therapeutic levels of protein expression. Such high-dose AAV regimens have led to unanticipated toxicities in clinical trials, most often including thrombocytopenia, liver damage, and complement activation. To ameliorate these toxicities, a better preclinical animal model that is predictive of high-dose vector toxicity is needed. Here, we systemically administered high doses of AAV expressing enhanced green fluorescent protein (eGFP), while varying capsid serotypes, doses, and DNA content. In wild-type C57BL/6J mice receiving 3×10^{14} genome copies (GC)/kg of AAV9, we observed elevated levels of C3b (the cleavage product of complement factor C3 upon activation) in the plasma beginning at day 1 and peaking at day 3. This systemic elevation of C3b corresponded in time with histological findings of the terminal membrane attack complex of the complement cascade, C5b-9, in treated livers. Histopathological analysis of these livers at day 3 revealed single-cell hepatocellular necrosis, consistent with elevated serum transaminase levels peaking at day 3 post vector administration. These toxicities were more pronounced when mice received a supraphysiologic dose of AAV9.eGFP at 7×10^{14} GC/kg, where a mild thrombocytopenia arose at day 7. Importantly, dosing mice with AAV9.eGFP at 10^{14} or 5×10^{13} GC/kg avoided most of the toxicities observed at doses above 3×10^{14}GC/kg, establishing an apparent dose threshold. Interestingly, AAV8 and AAVrh74 vectors expressing eGFP administered at 3×10^{14} GC/kg in C57BL/6J mice elicited minimal to no toxicity. AAV8- and AAVrh74-treated mice did not display elevated liver transaminases and exhibited only infrequent mild hepatocellular necrosis on histopathological analysis. There was evidence of complement activation (C3b) and deposition (C5b-9) in the liver, but to a much lesser extent than what was observed in AAV9-dosed mice. Next, we interrogated which elements were responsible for the observed toxicity in high-dose AAV9.eGFP administration. We first generated empty AAV9 vectors with no packaged DNA to assess whether 3×10^{14} GC/kg equivalent particles administered systemically to C57BL/6J mice would elicit toxicity. Eliminating the packaged DNA prevented complement activation and deposition and led to a marked delay and reduction in transaminases and single-cell hepatocellular necrosis. This result confirmed that both the capsid serotype and the presence of packaged DNA contribute to the observed systemic toxicities in wild-type mice. We subsequently administered AAV9.eGFP at 3×10^{14} GC/kg in mice lacking C3 (C57BL/6J background strain), a key node in the proteolytic complement cascade. Like empty AAV9 in wild-type mice, a high dose of AAV9 in C3-knockout mice resulted in the loss of complement activation and deposition, and a delayed occurrence of transaminitis and single-cell necrosis. In summary, we observed high-dose AAV toxicity in mice in a serotype-specific manner, with DNA-containing AAV9 eliciting the largest array of toxicological findings. Observing these clinical toxicities in a mouse model will help inform future efforts in pre-clinical toxicity models of high dose AAV.

138 Effectiveness of Engineering AAV Vector Genomes to Evade TLR9 Signaling for Prevention of CD8$^+$ T Cell Responses in Muscle Gene Transfer is Vector Dose Dependent

Sandeep Kumar, Ning Li, Roland W. Herzog

Indiana University School of Medicine, Indianapolis, IN

Gene therapy using adeno-associated viral (AAV) vectors is being widely evaluated in clinical trials for the treatment of neuromuscular disorders. However, immune responses to vector and transgene product are a major concern. It has been established that recognition of pathogen associated molecular patterns by innate immune sensors drives the activation of CD8$^+$ T cells. For instance, Toll-like receptor

(TLR) 9 senses unmethylated CpG motifs in AAV genomes (one of the hallmarks of viral DNA), resulting in type I IFN mediated activation of anti-viral response. However, our recent studies show that similar to WT mice, TLR9$^{-/-}$ mice elicit transgene product specific CD8^{+} T cell response following intramuscular (IM) administration of AAV1 vector at a dose of 2x10^{11} vg/mouse. Interestingly, blockade of IL-1 signaling in TLR9$^{-/-}$ mice substantially reduced these CD8^{+} T cell responses (*24th ASGCT Annual Meeting abstract# 70*). In the present study we evaluated how engineering of AAV genetic pay load (either depletion of CpG motifs or incorporation of a TLR9 inhibitory sequence) effects transgene product specific CD8^{+} T cell response. We also tested the effect of combining IL-1 blockade with TLR9 inhibitory sequence in AAV cassette on these CD8^{+} T cell response. Further, we examined the role of RNA (TLR3-TRIF pathway) and cytoplasmic DNA (cGAS-STING pathway) sensing in mediating transgene product specific CD8^{+} T cell responses. In order to minimize or antagonize TLR9 activation, AAV vectors expressing ovalbumin (OVA) containing either depleted CpG motifs (AAV1-OVA-CpG^{-}) or TLR9-inhitbitory sequence (AAV1-OVA-TLR9i) were produced. Different groups of C57BL/6 WT mice (n=5) were injected with doses of either 2x10^{10} vg (low) or 2x10^{11} vg (high) of these vectors via IM route. For IL-1 blockade studies, C57BL/6 WT mice (n=5) received the high vector dose and were treated with a combined regimen of anti-IL-1α and anti-IL-1β (2x/wk for 5 wks). To study the role of RNA and cytoplasmic DNA sensing C57BL/6 WT mice or knockout of various innate sensors on C57BL/6 background (n=5) were injected with low- or high-dose of AAV1-OVA vector. All groups of mice were bled weekly and OVA-specific CD8^{+} T cell frequencies were monitored using MHC I tetramer (H2-K^{b} -SIINFEKL) for up to 6 weeks. At the low dose, mice injected with AAV1-OVA-TLR9i failed to generate transgene product specific T cell response (P<0.0001). Similarly, lower levels of tetramer+ cells were observed in mice injected with AAV1-OVA-CpG^{-} as compared to AAV1-OVA injected mice (P=0.0051). However, at the high dose, AAV1-OVA-CpG^{-} injected mice had tetramer^{+} cells comparable to mice injected with AAV1-OVA vector. A small, non-significant reduction of tetramer^{+} cells was observed in AAV1-OVA-TLR9i injected mice. Combining AAV1-OVA-TLR9i vector administration with IL-1 blockade significantly reduced the CD8^{+} T cell response but did not eliminate it completely. These results led us to further interrogate other innate sensors such as RNA and cytoplasmic DNA sensors for their role in these CD8^{+} T cell responses. In comparison to WT mice a non-significant reduction in tetramer^{+} cells was observed in STING$^{-/-}$ mice whereas cGAS$^{-/-}$ mice had significantly higher numbers of tetramer^{+} cells, arguing against a substantial effect of cytoplasmic DNA sensing. TRIF$^{-/-}$ and TLR3$^{-/-}$ mice showed reductions in the response that was again vector dose dependent, similar to mice deficient in TLR9 or IL-1 signaling. In summary, our data reveal that engineering of the vector genome to minimize TLR9 activation can be effective in preventing CD8^{+} T cell responses to the transgene product at lower vector doses but may require blockade of at least one other innate signaling or cytokine pathway at higher doses. IL-1 or RNA-induced signaling are promising targets for intervention.

139 Identification of Dose-Dependent Immune Landscape Signatures Following Administration of Ixo-vec in Non-Human Primates

Julian N. Ramos, Julio D. Nieves, Maryam Tarazkar, Brahim Belbellaa, Jenny Vo, Ruslan N. Grishanin, Brigit E. Riley

Adverum Biotechnologies, Redwood City, CA

Wet age-related macular degeneration (wAMD) is a retinal disease mediated by the abnormal production of vascular endothelial growth factor (VEGF), where the growth of abnormal, leaky blood vessels in the macula leads to a reduction in central vision. The anti-VEGF drug aflibercept can reverse the leakage of fluid and dry the retina but requires frequent bolus injections into the vitreous, which represent a substantial treatment burden to patients and the health care system. Also, the need for frequent bolus injections results in fluctuations in macular fluid that has shown to be associated with long term vision loss. Ixo-vec is a recombinant adeno-associated virus (rAAV) that harnesses ocular cells to become biofactories that express and secrete aflibercept. Ixo-vec demonstrated longer-term aflibercept levels out at least 3 years in the phase 1 OPTIC trial patients. Dose dependent mild to moderate inflammation that was responsive to topical corticosteroid therapy was seen at 2E11 and 6E11 vg/eye doses in the OPTIC study. Phase 2 LUNA study is evaluating 2E11 vg/eye, as well as a new, lower 6E10 vg/eye dose, to expand the known therapeutic window. Findings from nonhuman primate (NHP) studies can help optimize the risk benefit profile in humans. NHP data has demonstrated intravitreal (IVT) administration of Ixo-vec resulted in a non-dose proportional aflibercept levels across several orders of magnitude of Ixo-vec dosing. Levels at 3E10 vg/eye (human equivalent dose [HED] 6E10 vg/eye) were nearly equivalent to aflibercept levels observed at higher doses (up to 2E13 vg/eye). NHP data has also demonstrated dose-dependent inflammation, with little to no inflammation at the 3E10 and 1E11 vg/eye doses to inflammation requiring corticosteroids at 2E12 vg/eye (HED 4E12 vg/eye) or greater. We assessed potential signatures of inflammation including toxicity related to overproduction of exogenous protein and general pathways previously identified in gene therapy studies. Mechanisms were tested by systems-based transcriptomic analysis. Three months following IVT administration of Ixo-vec the choroid, retina, and anterior region tissues of NHPs were isolated for bulk RNA-seq. After determining log-fold changes in gene expression, pathway analysis was performed using three different software tools. The outcomes of these different analyses were highly convergent in identifying the same pathways of interest as dysregulated in a dose-dependent manner. Unfolded protein and endoplasmic reticulum stress responses were not upregulated, indicating that toxicity due to overproduction of exogenous aflibercept did not cause inflammation at higher doses. Furthermore, there was no evidence of disrupted ciliary body architecture or VEGF axis dysregulation. Several immunological pathways previously associated with gene therapy response were upregulated, including engagement of adaptive immune response, already known to develop from ocular and systemic rAAV vector dosing. The inflammatory signatures were dose-dependent with most pronounced upregulation in the anterior region at high doses, followed by the retina, and mostly absent in the choroid. Histological analysis demonstrated dose-dependent increase in mononuclear

infiltrates, including $CD4^+$ T-cells and $CD20^+$ B-cells. In summary, IVT administration of Ixo-vec was well tolerated up to 4E11 vg/eye (HED 8E11 vg/eye) supporting the current dose selections for human wAMD patients in the LUNA trial. These data support the lower doses being explored as well as combination of immunosuppressive prophylactics to suppress formation of adaptive immunity and prevent the development of chronic inflammation for ocular gene therapy.

140 Humoral Arms of the Innate and Adaptive Immune Systems Define the Severity of the Cytokine Storm Response to Human Adenovirus Type 5 Vectors

Svetlana Atasheva, Jia Yao, Dmitry M. Shayakhmetov
Emory University, Atlanta, GA

The occurrence of severe cytokine storm syndrome constitutes a significant clinical complication that has been observed in a subset of patients post intravenous administration of viral gene therapy vectors. The poor understanding of the molecular mechanisms underlying the development of cytokine storm and the unpredictable variability in the severity of inflammatory responses to an equivalent dose of therapeutic vectors among patients significantly hinders the advancement of new, life-saving therapies. While it is customary to exclude patients with pre-existing neutralizing immunity to a therapeutic vector from clinical trials, this method fails to address the inconsistent and unpredictable nature of the cytokine storm response with regards to its severity and magnitude. We hypothesized that pre-existing non-neutralizing cryptic opsonizing antibodies (CON-Abs), which may arise from past exposure of the patient to phylogenetically distant virus variants and the complement system, may influence the activation of innate phagocytic cells and the subsequent release of inflammatory cytokines following intravenous administration of therapeutic vectors. To experimentally test this hypothesis, we immunized individual groups of wild-type mice with human adenovirus serotypes from species B (HAdv-B3, HAdv-B11), C (HAdv-C2, HAdv-C6), and D (HAdv-D28), followed by intravenous administration of HAdv-C5-based adenovirus vectors. While the antibodies generated in these mice lacked direct neutralizing activity towards HAdv-C5, the levels of inflammatory cytokines released into the bloodstream 6 hours post HAdv-C5 vector administration showed marked variations among mouse groups pre-immunized with different virus serotypes. We further found that CON-Abs, generated towards phylogenetically distinct adenoviruses, were capable of binding to and activating C3 complement fixation on HAdv-C5 viral particles. While immunization of both wild-type (WT) and complement C3 knockout (C3-KO) mice with HAdv-C5 resulted in the generation of virus-specific neutralizing immunity, the severity of the cytokine storm following a subsequent intravenous administration of the HAdv-C5 vector was significantly greater in C3-KO mice compared to WT mice. This highlights that in the in vivo settings, complement C3 serves a suppressive role in the inflammatory response, likely by redirecting adenovirus-immune complexes away from immune phagocytic cells to non-responsive cellular compartments. The results of our study underscore the unexpected impact of CON-Abs on the severity of the cytokine storm response and emphasize the need of devising new methods for pre-screening patients for pre-existing humoral factors that have the potential to enhance inflammatory cytokine responses to therapeutic vectors.Conflict of interest: DSH is a cofounder and shareholder of AdCure Bio, which develops adenovirus technologies for therapeutic use.

141 Causal Role for Immune Response in AAV-Mediated DRG Toxicity in NHPs

Kate Henry, Judy Bai, Harsha Bhat, Linda Burkly, Su Jing Chan, Jessica Doherty, Kelly Glajch, Branka Grubor, Melissa Kirkland, Joyce Lo, Dale Morris, Alex Pellerin, Ed Plowey, Annick Prefontaine, Prasad Nadella, Mark Sheehan, Junghae Suh, Eric Tien, Nick van der Munnick
Biogen, Cambridge, MA

Adeno-associated virus (AAV)-mediated toxicities pose critical safety concerns for patients and are a major obstacle for the gene therapy field. For central nervous system gene therapy, one major toxicity observed is findings of dorsal root ganglion (DRG) degeneration in preclinical models following intra-cerebrospinal fluid (CSF) or high dose intravenous administration. DRG toxicity was one of five AAV-associated toxicities discussed during the 2021 FDA advisory committee meeting. A lesion time course study was conducted to identify molecular events occurring prior to and concurrent with lesion development. An AAV9 variant encoding a human transgene protein was administered to cynomolgus macaques at 3.68E13vg/dose via intra-cisterna magna. Necropsy was performed on Days 5, 9, 19, and 29, respectively. Histopathology confirmed the presence of DRG lesions, including DRG neuronal degeneration/necrosis, DRG mononuclear cell infiltration and nerve fiber degeneration in the spinal cord, starting on day 15 post-AAV administration and fully developing on day 29. However, immunohistochemistry and in situ hybridization revealed the presence of immune cell foci prior to the formation of DRG lesion, as early as day 5 (CD68+ macrophages, NKp46+ natural killer cells, CD20+ B cells, CD4+ T cells) or day 9 (CD8+ T cells), which increased in severity over time on days 15 and 29. Immune cell infiltration prior to neuronal degeneration suggests a causal role of an immune response in DRG toxicity. To test this hypothesis, an immunosuppressant regimen was administered orally in conjunction with intra-CSF AAV delivery. Immunosuppressants reduced the incidence and severity of DRG lesions in NHPs in three independent studies encoding three distinct transgenes. These studies confirm an instrumental role of the immune response in causing DRG toxicity and implicate a specific role for T cells in targeting DRG neurons for cell death. Underlying mechanism(s) for neuronal targeting by immune cells is currently unknown. However, preliminary data suggests transgene overexpression and innate immune pathway activation contribute to neuronal death via cell autonomous and non-autonomous mechanisms.

142 A Human PBMC Assay of Type 1 Interferon Responses to Closely Related AAV Vectors

Bradley A. Hamilton[1], Rachana Patil[1], Soohyun Kim[2], John W. Day[3], J. Fraser Wright[1]

[1]Pediatrics, Stanford, Palo Alto, CA,[2]Biochemistry, Stanford, Palo Alto, CA,[3]Neurology, Stanford, Palo Alto, CA

Toll like receptor 9 (TLR9) innate immune receptor-mediated responses to AAV gene therapy are emerging as a critical concern. Unmethylated CpG dinucleotides, abundant in unmodified AAV vector genomes, are TLR9 ligands, and are inversely correlated with clinical success. TLR9 signaling leads to type 1 interferon secretion and subsequent Cytotoxic T Lymphocyte (CTL) activation and may contribute to severe adverse events including complement activation associated thrombotic microangiopathy. Unfortunately, many current methods to measure TLR9 responses rely upon limited rodent or cell line models, cannot discriminate between related vectors, and lack an effector cell readout. Here, we present a human PBMC model capable of differentiating between closely related AAV vectors based on the magnitude of the type 1 interferon responses they elicit, and subsequent T cell activation. HEK reporter cells are widely used to predict TLR9 responses to candidate AAV gene therapy vectors. While this model can sufficiently measure TLR9 activation by oligonucleotides, it is poorly stimulated by tested AAV vector doses up to 10^4 MOI. The secretion of type 1 interferons by murine PBMCs is minimal, and vectors are indistinguishable from each other in preliminary experiments. Furthermore, AAV vectors can elicit statistically significant immune signals in human PBMCs, but this is highly donor dependent, and differences are difficult to measure between related vectors. We hypothesized that post AAV gene therapy serum will opsonize candidate vectors, increasing Fc receptor (FcR)-mediated uptake and type 1 IFN signaling. We obtained serum from patients before and after AAV9 gene therapy and observed dose-dependent increases in post therapy serum-mediated neutralization of AAV2 transduction in cell culture, compared to pre-gene therapy serum. We then exposed PBMCs from three healthy donors to empty AAV capsids or AAV2-CAG>GFP. We observed a 19.1pg increase in INF1a secretion after 24 hours in PBMCs exposed to the GFP vector, compared to empty capsid. However, when we first incubated vectors with post gene therapy serum, we observed a >3000% increase in signal, with 727.27pg secreted. Opsonization did not significantly influence empty capsid signal. We then interrogated the serum-mediated effect for FcR-dependence and found that when PBMCs were pretreated with FcR blocking antibodies, the post gene therapy serum-mediated signal increase was blunted. Interestingly, flow cytometry analysis of human PBMCs exposed to post-gene therapy serum-incubated vectors after 72hrs showed increased expression of T-cell activation markers consistent with CTL activation. As post AAV gene therapy seropositive human serum is predicted to be variable, we next attempted opsonization of AAV2 empty capsids, AAV2-CMV>null, and AAV2-CAG>GFP with AAV monoclonal antibodies. We were pleasantly surprised to observe opsonized vector-induced INF1a responses from PBMC donors that were otherwise unresponsive to stimulation, even by oligonucleotide positive control. Moreover, INF1a responses, otherwise indistinguishable by ELISA, correspondingly increased with exposure to unmethylated genomic CpGs ($p<0.0001$) when vectors were first opsonized, and this effect was recapitulated in Luminex readouts for INFg, IL1Ra, IL6, IL8, CXCL10, MCP2 and MCP3. Opsonization of AAV vectors prior to exposure on human PBMCs enables, for the first time to our knowledge, a human-based assay of TLR9-downstream cytokines that can distinguish between vectors that vary by genomic CpG content and could be an important tool for developing vectors that evade TLR9 recognition.

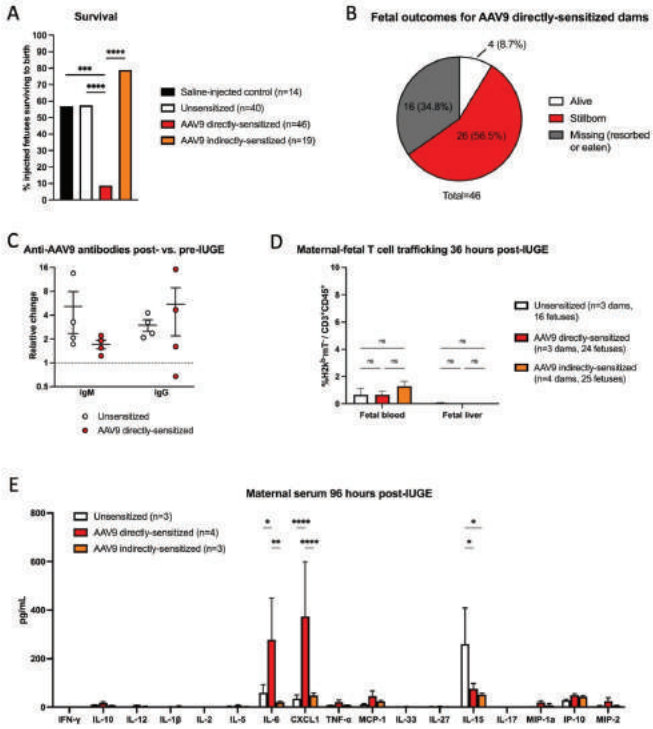
143 Pre-Existing Maternal Immunity to Adeno-Associated Virus Causes Fetal Mortality After In Utero Gene Editing Mediated by Maternal Interleukin 6 and CXCL1

John S. Riley, Valerie L. Luks, Cara L. Berkowitz, Apeksha Dave, Philip W. Zoltick, William H. Peranteau

Center for Fetal Research, Children's Hospital of Philadelphia, Philadelphia, PA

PURPOSE: In utero gene editing (IUGE) is an experimental treatment for inherited metabolic liver diseases. We have previously demonstrated that pre-existing maternal antibodies to AAV impair fetal gene editing in a mouse model of in utero CRISPR-NHEJ (Abstract 2022-A-896-ASGCT). We now investigate the effect of pre-existing maternal immunity on fetal mortality after IUGE and its potential underlying mechanisms.
METHODS: The *ROSA26*^{mTmG} mouse harbors a constitutively-expressed red fluorescent protein (mT) flanked by loxP sites. Successful cleavage at the loxP sites with NHEJ repair and gene deletion results in constitutive expression of green fluorescent protein (mG). We designed an AAV serotype 9 (AAV9) to deliver SpCas9 and a guide-RNA to target the loxP sites (AAV9.SpCas9.sgloxP). Maternal immunity to AAV was evaluated in 3 groups: unsensitized dams (no immunity); dams directly-sensitized to AAV9 by intramuscular injection of AAV9.CMV.null (resulting in active humoral and cellular immunity), and dams indirectly-sensitized to AAV9 by adoptive transfer of serum from directly-sensitized dams (resulting in passive humoral immunity only). IUGE was performed at 16 days post-coitum via fetal intravascular injection of AAV9.SpCas9.sgloxP. Fetal survival to birth was compared to saline-injected controls and among the groups using Fisher's exact test. Maternal immunoglobulin levels pre- and 96 hours post-IUGE were assessed by ELISA. Maternal T cell frequency in the maternal peripheral blood (PB) and draining lymph nodes (LNs) and maternal T cell trafficking into the fetal blood and fetal liver were assessed 36 hours post-IUGE by flow cytometry. Maternal and fetal serum cytokines were assessed 36 and 96 hours post-IUGE using V-PLEX Plus Mouse Cytokine 19-Plex Kit (MSD) and compared using ANOVA.
RESULTS: Maternal direct sensitization to AAV9 significantly increased fetal mortality after IUGE compared to unsensitized dams, indirectly-sensitized dams, and saline-injected controls (Figure 1A), with only 4 of 46 (8.7%) of injected fetuses surviving to birth and stillbirth being the most common type of demise (Figure 1B). Maternal serum anti-AAV9 IgM and IgG levels increased post-IUGE, consistent with exposure and, in the case of directly-sensitized dams, re-exposure of the maternal immune system to AAV9 as a result of fetal injection (Figure 1C). No differences in maternal T cell frequency, including activated $CD4^+$ or $CD8^+$ T cells, in the maternal PB or draining LNs were observed among the groups. Additionally, pre-existing maternal immunity to AAV9 did not result in increased trafficking of maternal T cells into the fetal blood or liver following IUGE (Figure 1D). However, directly-sensitized dams had significantly elevated levels

of 2 pro-inflammatory cytokines/chemokines, IL-6 and CXCL1 (both of which are associated with stillbirth/preterm labor) (Figure 1E). Elevated levels of IL-6 were similarly present in their fetuses. **CONCLUSION:** Pre-existing maternal immunity to AAV significantly increases fetal mortality after IUGE. The mechanism is re-exposure of the primed maternal immune system to AAV resulting in an inflammatory response characterized by interleukins/cytokines implicated in the pathogenesis of stillbirth. Pre-procedural evaluation of pre-existing maternal AAV immunity will be critical for ensuring the safe application of IUGE with AAV vectors to the clinical setting.



846 Reducing Cas9 Immunogenicity *In Vivo* Leveraging Cell-Endogenous Protein Degradation Pathway

Roberto Nitsch[1], Anna Lina Cavallo[2], Rakesh Chandode[2], Sara Feola[3], Vincenzo Cerullo[3]

[1]Gene Therapy - Safety Innovations, AstraZeneca, Mölndal, Sweden,[2]AstraZeneca, Mölndal, Sweden,[3]University of Helsinki, Helsinki, Finland

There is growing interest in the therapeutic use of CRISPR-Cas9 to correct monogenic human disorders, with a number of medicines progressing rapidly into clinical trials. However, "the golden standard" Cas9 isolated from Streptococcus pyogenes (SpCas9), is known to trigger host immunogenicity. It is reported that the continuous cytosolic presence of exogenous proteins can increase antigen presentation via MHC-I. This represents the foundation of cellular immunity, leading to the activation of cytotoxic T-Cell response. Evading cellular immunosurveillance could represent a major advancement to broaden the clinical applications of CRISPR. Here, we rationally engineered SpCas9 with a single amino acid substitution in the Rec2 domain to introduce a chaperone-mediated autophagy (CMA) binding moiety. This pentapeptide domain is recognized by the HSC70 chaperone that binds and directs target proteins to lysosomal degradation. We reasoned that a forced and selective lysosomal degradation would make SpCas9 less detectable by the MHC-I, thus reducing the antigen presentation and the subsequent CD8+ T-cell activation. We prove that the mutated SpCas9 presented an extremely low intracellular concentration after transfection in primary and immortalized cells, a feature specifically due to an acquired high degradation rate. We, therefore, called this novel mutant Fast Degrading Cas9, or simply FaDe Cas9 (fdCas9). In vitro kinetics of SpCas9 and fdCas9 were undistinguishable, indicating that the amino acid substitution does not affect the enzymatic structure or function. Moreover, the in vivo tail vein Adenovirus-delivered fdCas9 (AdV-fdCas9) demonstrated comparable editing levels with SpCas9, thus making fdCas9 the first SpCas9 mutant successfully used for somatic genome editing in adult mice. Most importantly, mice pre-exposed to fdCas9 and then infected with AdV-fdCas9 showed a markedly reduced activation of cellular immunity as measured by cytotoxic CD8+ T-cell infiltrates in the liver when compared to mice pre-exposed to SpCas9. Similarly, human peripheral blood monocyte cells (PBMCs) showed a reduced T-cell response when challenged in an ELISpot with fdCas9 compared to SpCas9. Taken together, we generated a novel version of SpCas9 that circumvents activation of host immunity, making it an attractive enzyme for therapies that require in vivo administration of CRISPR agents to patients.

1006 Immune Responses Observed to AAV Gene Therapy for the Treatment of GM2 Gangliosides

Terence R. Flotte[1], Meghan Blackwood[1], Katelyn Sylvia[1], Cynthia J. Tifft[2], Heather L. Gray-Edwards[1], Miguel Sena-Esteves[1], Allison M. Keeler-Klunk[1]

[1]Gene Therapy Center, UMass Chan Medical School, Worcester, MA,[2]National Institutes of Health, Bethesda, MD

Tay-Sachs Disease and Sandhoff disease are neurodegenerative diseases caused by lysosomal storage of GM2 gangliosides. Previously in an expanded access trial, a two vector rAAVrh8 gene therapy (rAAVrh8 HexA/HexB) was tested and found to be safe. The current trial is additionally highlighted in ASGCT abstract (#2023-A-829-ASGCT). In brief, patients were injected with bilateral intrathalamic delivery (BiTh) and with intracisternal/intrathecal (CSF) injection at three different dose ranges: starting BiTh dose (STD) of 180 mcl (5.87E+12vg BiTh; 1.42E+14vg total), a low-dose (LD) of 360 mcl (1.17+E13vg BiTh; 1.95E+14vg total), and a mid-dose (MD) of 720 mcl (2.35E+13vg BiTh; 2.18E+14 total). Patients were treated with an immunosuppressive regimen that included rituximab, corticosteroids (3 months post-delivery) and sirolimus (6 months post-delivery). Despite lack of measurable circulating CD19 and CD20 positive cells all 6 patients treated thus far seroconverted to neutralizing antibody (Nab) titers of at least 1:100 by 30 days post-delivery with some Nab titers as high as 1:1000. Nab titers were fairly stable between 30- and 180-days post-therapy. In addition to positive B-cell responses, capsid specific T-cell response were measured by interferon-gamma ELISPOT assay. All 6 patients had a positive response to AAV capsid post-injection, and all but one patient had a positive response between day 15 and day 28 post-injection. Interestingly, the patient 1 (STD) with the lowest dose did not have a positive response to AAV capsid by ELISPOT assay

until day 83 post-injection. Patient 4 (LD) had significant elevations of liver transaminases, AST and ALT, concurrently with positive IFNγ ELIPSOTs around day 14 post-injection. The patient was treated with solumedrol at 10mg/kg/day for three days and resulting T-cell responses and transaminases resolved. Additionally, other patients (LD and MD) had less pronounced elevations of both transaminases and ELISPOT responses and were treated with increases of prednisolone dosage from 1mg to 2mg/kg, resulting in reduction of IFNγ spot forming units. No positive responses were observed by ELISPOT with peptide pools generated from the transgene. Further flow cytometry characterization was run on PBMCs either directly or after culturing with AAV capsid peptides pools. Several patients at different time points showed expansion of the Treg populations after culturing with AAV capsid peptide pools suggesting induction of AAV capsid specific Tregs. To further understand local immune responses, cytokines were measured in the CSF of patients, at pre-treatment as well as 3- and 6-months post AAV infection. In all patients, CXCL10 was elevated from pre-treatment levels at 3-months and even further elevated at 6-months post-injection suggestive of a local IFN-gamma response. None of the other cytokines measured including IFNγ, IL-4, MCP-1, IL-8, IL-2, IL-1β, TNFα, IL-17A, IL12p70, TGFβ, IL-10 or IL-6 or were significantly changed. Taken together, despite the delivery route and substantial immunosuppression regimen, notable immune responses, including T and B-cell responses to AAV capsid, were observed in all patients after CNS targeted AAV gene therapy.

Next Generation CAR, TCR, and AAV Technologies for Solid Tumors

144 Adeno-Associated Virus-Mediated Targeting of HER2+ Brain Metastasis

Shweta Aras, Marcela S. Werner, Ashleigh R. Morgan, Jenny A. Greig, James M. Wilson
University of Pennsylvania, Philadelphia, PA

Twenty percent of breast cancers overexpress human epidermal growth factor receptor 2 (HER2), an oncogenic protein, and up to 50% of patients with HER2+ breast cancer develop central nervous system (CNS) metastases. The median survival of patients with HER2+ breast cancer brain metastasis (BCBM) undergoing standard-of-care treatment is 10-25 months. Trastuzumab (Herceptin®), a humanized anti-HER2 antibody, is part of the standard-of-care adjuvant regimen for patients with HER2+ disease. However, the efficacy of intravenously (IV) infused trastuzumab against intracranial metastases is limited since it does not fully cross the (intact) blood-brain barrier. Intrathecal delivery of trastuzumab improves the prognosis of patients with HER2+ BCBM, but chronic management of the disease through this approach is challenging due to the required frequency and complexity of the CNS dosing regimen. To address these shortcomings, we developed adeno-associated virus (AAV) vectors carrying codon-optimized versions of trastuzumab designed to achieve effective and stable drug concentrations in the brain following a single CNS delivery. We evaluated the anti-tumor efficacy of AAV-trastuzumab vectors in several orthotopic cell line xenograft mouse models of HER2+ BCBM (including BT-474 cell lines sensitive or resistant to trastuzumab and the MDA-MB-453 cell line). Compared with *Rag1* knockout (KO) mice treated with an AAV-isotype control vector, single intracerebroventricular (ICV) administration of AAV-trastuzumab at 10^{11} genome copies/mouse significantly extended survival in both BT-474 cell line xenograft models ($p < 0.0001$). The MDA-MB-453 xenograft model animals exhibited high sensitivity to AAV-trastuzumab treatment, including complete remission of brain xenografts in 100% of the animals. Dose-titration studies comparing ICV with IV injection of AAV-trastuzumab vector in healthy *Rag1* KO mice highlighted the benefit of direct administration to the CNS as ICV-administered mice had a ~4-fold increase in trastuzumab protein expression (by ELISA) in the brain compared with IV-administered mice receiving the same dose (10^{11} GC/mouse) with mass spectrometry analysis confirming this trend. Western blot analysis of brain lysates from AAV-trastuzumab-treated *Rag1* KO mice suggested that heavy and light IgG_1 chains were expressed at equimolar concentrations. These preclinical findings highlight the potential of an ICM delivered, AAV-based gene therapy to effectively deliver trastuzumab to the CNS for the treatment of HER2+ BCBM.

145 Safety Evaluation of Intra-Cisterna Magna (ICM) Delivery of a Novel AAV-Trastuzumab Vector to Target HER2+ Breast-to-Brain Metastasis in Rhesus Macaques

Marcela S. Werner, Shweta Aras, Ashleigh R. Morgan, Jason Lamontagne, Jenny A. Greig, James M. Wilson
University of Pennsylvania, Philadelphia, PA

In 2020, breast cancer surpassed lung cancer and became the most diagnosed malignancy worldwide. In the United States, breast cancer is the second leading cause of cancer-related deaths in women (43,500 in 2022). About 15-20% of breast tumors overexpress human epidermal growth factor receptor 2 (HER2), an oncogene and effective therapeutic target for the treatment of breast cancer. HER2-targeting using monoclonal antibodies such as trastuzumab (Herceptin®) has revolutionized breast cancer treatment and improved overall survival by controlling systemic disease. However, up to 50% of patients with advanced HER2+ breast cancer develop central nervous system (CNS) metastases, with an overall survival of 26 months. An intact blood-brain barrier limits the efficacy of systemic HER-2-targeted antibodies in the CNS by preventing large molecule diffusion into the brain parenchyma. To overcome this limitation, we developed a novel codon-optimized adeno-associated virus (AAV) encoding trastuzumab to treat HER2+ CNS disease. Intracerebroventricular delivery of AAV-trastuzumab vectors has demonstrated therapeutic efficacy against orthotopic xenograft mouse models of HER2+ breast cancer-to-brain metastasis (BCBM). To further evaluate the safety and transgene expression of AAV-trastuzumab vectors, we administered intra-cisterna magna (ICM) injections containing either the CB7 promoter (a synthetic promoter derived from chicken b-actin promoters with a CMV enhancer element) or UbC promoter (constitutive human ubiquitin C promoter) in adult female Indian rhesus macaques with pre-existing neutralizing antibodies against AAV (n=2/vector; $3x10^{13}$ genome copies/animal). These promoters can drive sustained expression of transgenic proteins in non-human primate brain regions; therefore, we compared CB7 vs. UbC promoter

strength in AAV-trastuzumab vectors in this model. Animals were euthanized at day 35 post-treatment and jugular perfusion of the brain with saline was performed. No clinical signs of toxicity were observed during the study. Biodistribution analyses showed 10- to 1000-fold-higher levels of vector genome copies and transgene RNA transcripts in the brain compared with the heart and liver. Presence of trastuzumab transcripts in the CNS was confirmed by *in situ* hybridization and single-nuclei RNA sequencing (0.6%-1% of cells in the cerebellum were positive). We quantified trastuzumab protein levels in the tissue lysates, cerebrospinal fluid (CSF), and serum of treated monkeys by ELISA, which detected the presence of trastuzumab in multiple brain regions (1-6 ng trastuzumab/mg protein) and the spinal cord (up to 40 ng trastuzumab/mg protein). Trastuzumab levels in the CSF reached 8-64 ng/mL at day 35 in macaques injected with vector containing the UbC promoter. However, in animals injected with transgene driven by the CB7 promoter, CSF trastuzumab levels peaked at 16-32 ng/mL between days 14 - 21 post-injection but were undetectable by the end of the study. Weak or no signal above background was observed for serum levels of trastuzumab, regardless of the vector administered. Virtually no anti-drug antibody (ADA) responses against trastuzumab were detected in the CSF by ELISA, although 3/4 monkeys displayed levels of 1.6-13.6 μg/mL of ADA in the serum prior to euthanasia. Overall, ICM delivery of AAV-trastuzumab vectors driven by the UbC promoter was well tolerated and led to transgene expression in the CSF and brain tissues of rhesus macaques. Importantly, CNS trastuzumab levels within the range of what was observed in macaques show significant antitumor activity against orthotopic cell line-derived xenograft mouse models of BCBM. Based on these favorable preclinical results, we believe this treatment approach for patients with advanced HER2+ BCBM could be advanced to clinical trials.

146 Designed Tumor Microenvironment Responsive Biosensors Enhance Chimeric Antigen Receptor T Cell Therapy for Cancer

Jan A. Rath[1,2], Lucas S. Powell-Rudden[3], Nazila Nouraee[4], Patrick Barth[3], Caroline Arber[1,2,4]

[1]Department of oncology UNIL-CHUV, Lausanne University Hospital and University of Lausanne, Lausanne, Switzerland,[2]Ludwig Institute for Cancer Research, Lausanne, Switzerland,[3]Interfaculty Institute of Bioengineering, Ecole Polytechnique Fédérale Lausanne, Lausanne, Switzerland,[4]Center for Cell and Gene Therapy, Baylor College of Medicine, Houston, TX

Chimeric antigen receptor (CAR) T cell therapies produce long-lasting responses in a subset of patients with B cell malignancies. However, success is limited in cancers with complex tumor microenvironments (TMEs) that impact CAR T cell persistence and function. Here we hypothesized that co-engineering CAR T cells with a second chimeric receptor (biosensor) that converts TME-associated input into signaling output that mediates enhanced CAR T cell expansion, memory and long-term persistence can improve outcomes of CAR T cell therapy. We developed a novel computational-experimental approach for the *de novo* bottom-up assembly and design of biosensors with programmable input-output behaviors and their full functional assessment in vitro and in vivo. We designed biosensors responding to vascular endothelial growth factor (VEGF) or colony stimulating factor 1 (CSF1) because of their key roles, elevated levels and association with poor prognosis in several cancers. As orthogonal signaling endodomain, we leveraged parts of the thrombopoietin receptor c-MPL which simultaneously produces co-stimulatory and γ-chain cytokine signals upon activation. The computational assembly of ligand binding domains (derived from VEGFR2 or CSF1R), linker, transmembrane and endo-domains (derived from c-MPL) generated a set of biosensor variants with programmable strength (low vs high intensity) and behavior (ligand-dependent vs baseline constitutive activity) for experimental evaluation. Biosensors targeting VEGF (VMR) or CSF1 (CMR) were highly expressed in activated human T cells upon retroviral transduction. Signaling potency of VMR and CMR variants was determined by measuring phosphorylated STAT5 levels in response to ligand (VEGF or CSF1) and correlated with the computationally predicted signal transduction propensity. Activation of VMR and CMR both mediated T cell persistence in long-term T cell cultures mimicking the effect of homeostatic γ-chain cytokine signals. To determine the impact of VMR and CMR on T cell function in response to target tumor cells we co-expressed our biosensors with CARs targeting Ephrin type A receptor 2 (EphA2) or B cell maturation antigen (BCMA) respectively. When challenged with the lung cancer cell line A549 or the multiple myeloma cell line MM.1S in vitro, VMR+ and CMR+ CAR T cells expanded and persisted significantly better in the presence of VEGF or CSF1 compared to CAR T cells without biosensor. In vivo, treatment with VMR+ CAR T cells significantly controlled VEGF high A549 metastatic tumors in mice and enhanced their overall survival compared to CAR T cells without VMR ($p<0.0001$, n=10 mice/ group). Similarly, CMR+ CAR T cells were more potent at tumor control than CAR T cells without CMR in a MM.1S-based xenograft mouse model of MM with high CSF1 expression ($p<0.0001$, n=10 mice/ group). In conclusion, we developed and validated a novel bottom-up computational-experimental approach for the assembly and design of multi-domain protein biosensors with programmable input-output behavior. We demonstrate that our strategy can overcome major challenges posed by the TME and results in potent and tumor selective enhancement of CAR T cell therapy for cancer.

147 Development of Adeno-Associated Virus (AAV) Vectors for Intratumoral Gene Replacement Therapy in a Novel Mouse Model of Neurofibromatosis Type 1 (NF1)

Rrita Daci[1], Pamela St Louis[2], Tyler Mola[2], Hannah Villeneuve[2], Julie Aguiar[2], Rob King[3], Heather L. Gray-Edwards[3], Ana Rita Batista[2], Miguel Sena-Esteves[2]

[1]Neurosurgery, UMass Chan Medical School, Worcester, MA,[2]Horae Gene Therapy Center, UMass Chan Medical School, Worcester, MA,[3]Radiology, UMass Chan Medical School, Worcester, MA

Introduction: Neurofibromatosis type 1 (NF1) is one of the most common human monogenetic diseases, with an incidence of 1 in 3000. The NF1 tumor suppressor gene encodes for the GTPase-activating protein, neurofibromin. Biallelic loss of *NF1* causes uninhibited GTPase RAS activity resulting in tumor proliferation. The current standard of care for these tumors, which include neurofibromas, gliomas and malignant peripheral nerve sheath tumors (MPNSTs), is limited to surgical debulking and small molecule inhibitors which are not curative. Development of gene replacement therapy for this disease has been hindered by the large NF1 coding sequence (~8.5

kb) which exceeds the packaging capacity of AAV vectors. Secondly, neurofibromas are diffusely distributed and arise from Schwann cells in an avascular endoneurium, making access of AAV to these cells challenging. **Methods**: Here, we describe a gene replacement approach utilizing two novel AAV9-NF1 platforms. One platform is a dual trans-splicing AAV9 system comprised of vectors that split the human NF1 cDNA to accommodate its size. Specifically, one vector contains the promoter upstream and a splice donor downstream of the 5' NF1 cDNA. The second vector contains the 3' NF1 cDNA utilizing an upstream splice acceptor site and a downstream HA tag. These vectors concatemerize into full length NF1 mRNA. Our other strategy utilizes an AAV encoding a mini-NF1 transgene (AAV-NF1^{mini}) which is the neurofibromin GTPase activating protein domain. Since the expected product will be a truncated form of neurofibromin, we added a HA-tag for *in vivo* detection. Vector transduction efficiency was measured by infecting MPNST cell lines for 72 hours and analyzing expression of full length NF1 protein and HA tag against a GFP-vector control on western blot. Tumor suppressive functionality of AAV-NF1 constructs in MPNST cells was assessed using cell proliferation and viability assessments. To evaluate our vectors *in vivo*, we created an induced neurofibroma model in the mouse sciatic nerve by injecting AAV1-Cre to *Nf1*$^{R681*/4F}$ mice carrying an inactive (*Nf1*^{R681*}) and a floxed (*Nf1*^{4F}) allele. We evaluated tumor growth at 5 and 12 weeks with 7T MRI and performed histological and immunohistochemical tumor analysis using S100*B* and Ki67 staining.**Results**: Both AAV-NF1^{dual} and AAV-NF1^{mini} showed detectable NF1 protein and HA tag, respectively, on western blot. Both systems are functional in transduced MPNST cell lines by decreasing the phospho-ERK1/2/total ERK1/2 ratio, (i.e. reducing RAS pathway activity). Additionally, both systems significantly inhibit cellular viability and proliferation of MPNST cell lines. Our Cre-inducible neurofibroma tumor model showed evidence of increased sciatic nerve volume in the right sciatic nerve when compared to non-injected contralateral nerve on 7T MRI. Histological evaluation of the AAV1-Cre injected sciatic nerve revealed spindle cells with increased cellularity and with S100*B* and Ki67 positivity, indicating tumor formation. **Conclusion**: Our data revealed that both AAV-NF1 platforms can restore neurofibromin function *in vitro* by reducing RAS pathway activity. Additionally, both systems restore tumor suppressive function in MPNST cell lines. We have established a localized induced NF1 mouse neurofibroma model in the sciatic nerve. This model will be used to test the therapeutic efficacy of intratumoral injection of AAV-NF1 vectors. Our goal is to rapidly translate this approach to treat plexiform neurofibromas that are challenging to treat surgically and/or fail to respond to Selumetinib.

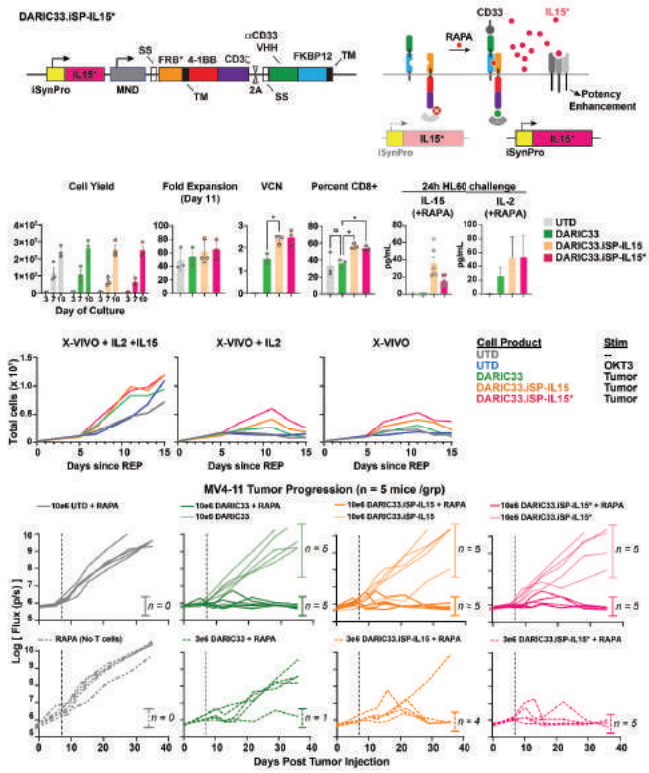
148 Enhanced Anti-AML Potency of DARIC33 by iSynPro-IL-15*: An IL-15 Expression Module Driven by a Tightly Regulated Synthetic Promoter Activated by Antigen Receptor Signaling

Jacob Appelbaum[1], Claudya Evandy[2], Kaori Oda[2], Semanti Sarkar[2], Giacomo Tampella[2], April Price[3], Joy Zhang[3], Wai-Hang Leung[3], Pauline So[3], Alexander Astrakhan[3], Jordan Jarjour[4], Michael C. Jensen[2]

[1]Hemataology, University of Washington, Seattle, WA,[2]Seattle Children's Therapeutics, Seattle Children's Hospital, Seattle, WA,[3]Oncology Discovery, 2seventy bio, Seattle, WA,[4]2seventy bio, Seattle, WA

INTRODUCTION: DARIC33, a dimerizing agent regulated immunoreceptor complex targeting CD33 that requires low doses of rapamycin (RAPA) for activity, is being studied in an ongoing phase 1 clinical trial (NCT 05105152). Genetic enhancements of CAR T cell potency may improve anti-leukemic efficacy but risk adverse effects, such as uncontrolled cell growth. We previously found that while intermittent administration of IL-15 to non-human primates is well tolerated and expands memory T cells, continuously delivered high-dose IL-15 is toxic (Berger et al, Blood 114(12):2417). Thus, we hypothesized that combining drug-controlled DARIC33 activation with regulated IL-15 secretion could enhance anti-AML potency without driving autonomous T cell growth or severe toxicity. **RESULTS:** We designed genetic modules in which, following antigen signaling a novel inducible synthetic promoter (iSynPro, iSP) transiently drives transcription of human IL-15 (iSP-IL-15) or IL-15 modified to restrict signaling to cells expressing IL-15Ra (iSP-IL-15*). We then manufactured DARIC33 CAR T cells using lentiviral vectors with or without integrated iSP-IL-15 modules. *In vitro* cell expansion, vector copy number, and CD33 antigen-binding capacity were similar among T cells transduced with DARIC33, DARIC33.iSP-IL-15 or DARIC33.iSP-IL-15*. All cell products contained high proportions of naïve T cells (CD62L+/CD45RO+). Notably, iSP-IL-15 and iSP-IL-15* augmented products exhibited higher CD8+ T cell proportions. Following *in vitro* challenge with AML cells, DARIC33.iSP-IL-15 and DARIC33.iSP-IL-15* exhibited RAPA-dependent secretion of IL-15 and other effector cytokines. Next, we cultured antigen-stimulated DARIC33 cell products in IL-2/IL-15 supplemented media and observed continued T cell expansion until day 21, highlighting the potential of IL-15 to expand T cells. Strikingly, when IL-2 and IL-15 were omitted from the culture media, both iSP-IL-15* and iSP-IL-15 DARIC33 products demonstrated enhanced expansion but normal contraction kinetics. These results illustrate the capability of the iSP transcription element to enhance T cell function through tightly regulated IL-15 production without promoting unrestrained T cell growth. Finally, we treated AML tumor bearing mice with untransduced (UTD) control T cells or graded doses of DARIC33 or DARIC33.iSP-IL-15/IL-15*. While both 10e6 DARIC33 and DARIC33.iSP-IL-15* T cells controlled tumor growth, when the effector cell dose was decreased to 3e6/mouse, both DARIC33.iSP-IL-15 and DARIC33.iSP-IL-15*continued to suppress tumor growth, whereas DARIC33 did not. Day 35 necropsies of DARIC33.iSP-IL-15* treated mice did not show tumors or evidence of uncontrolled T cell proliferation. **CONCLUSION**: We find iSynPro-IL-15* retains properties of inducible

expression and potency enhancement. Our results suggest that the triple safety features of iSynPro-regulated expression, IL-15* safety modification, and RAPA controlled DARIC33 activation prevent unrestrained T cell outgrowth. We believe this potency enhancement strategy will be applicable to next generation clinical AML CAR T cell therapeutics.



149 Preclinical Development of AB-1015, an Integrated Circuit T Cell Therapy Containing an ALPG/MSLN Logic Gate and FAS/PTPN2 shRNA-miR, for the Treatment of Ovarian Cancer

Jun Feng, Jasper Williams, Hongruo Yun, Dina Polyak, James Zhang, Michelle Nguyen, Irene Scarfo, Jessica Fuhriman, Aaron R. Cooper, Jennifer McDevitt, Stephen Santoro

Arsenal Biosciences, South San Francisco, CA

CAR T cell activity in solid tumors is limited by off-tumor toxicity, antigen heterogeneity, poor persistence, and functional suppression resulting from the tumor microenvironment (TME). To address these challenges, we have developed AB-1015, an autologous, integrated circuit T (ICT) cell product for the potential treatment of ovarian cancer. The AB-1015 transgene cassette includes two functional modules: an "AND" logic gate designed to limit off-tumor toxicity through dual tumor antigen recognition, and a dual shRNA-miR targeting FAS and PTPN2 to resist TME suppression and to improve ICT cell function. The AB-1015 DNA cassette is inserted into the T cell genome at a defined genomic site, GS94, via CRISPR integration of transgenes by electroporation (CITE). The AB-1015 logic gate consists of a priming receptor (PrimeR) against ALPG/P and an inducible MSLN-targeted CAR that is upregulated in response to PrimeR engagement. The dual-antigen specificity of the logic gate was assessed in vivo using a dual flank tumor xenograft model where one tumor expressed both ALPG and MSLN, and the contralateral tumor expressed MSLN alone. Compared with the RNP-treated group, the constitutive, benchmark anti-MSLN CAR demonstrated tumor reduction on both flanks. In contrast, the activity of AB-1015 was specific to the ALPG+MSLN+ tumor. To model priming antigen heterogeneity that AB-1015 may encounter in the tumor, we utilized an admixed co-culture system where varying proportions of ALPG+MSLN+ target cells were spiked into cultures that were otherwise MSLN+. AB-1015 was able to eliminate admixed co-cultures where as few as 5-15% of the target cells expressed ALPG+MSLN+. AB-1015 also contains a dual shRNA-miR that targets FAS and PTPN2, two critical mediators of T cells survival and function. FASL, the cognate ligand for FAS receptor, is expressed on the surface of activated T cells and is significantly overexpressed in the ovarian cancer TME. AB-1015 demonstrated resistance to FAS-mediated apoptosis in vitro. Knockdown of PTPN2, a phosphatase involved in T cell proliferation and functional persistence, resulted in enhanced AB-1015 cell expansion during an in vitro repetitive stimulation assay over a period of 14 days, as well as a 30-fold reduction in tumor outgrowth compared with logic gated T cells alone. Furthermore, the anti-tumor activity of AB-1015 was established in an intraperitoneal OVCAR3 ovarian xenograft model that resembles high-grade serous ovarian cancer histology and dissemination within the peritoneal cavity. AB-1015 demonstrated potent anti-tumor activity as demonstrated by decrease in bioluminescent signal from the tumors treated with AB-1015. To further increase the stringency of our preclinical models, we engineered the subcutaneous MSTO xenograft model to express FASL. In this model, benchmark anti-MSLN TCR Fusion Construct T cells (TRuC-T cells) failed to control tumor outgrowth. In contrast, AB-1015 resists FASL suppression via shRNA knockdown of FAS receptor on the ICT surface. As a result, AB-1015 is capable of completely clearing these otherwise difficult-to-treat tumors in this model. In summary, AB-1015 is specific for ALPG/P+MSLN+, demonstrates superior potency, expansion, and persistence compared with logic gated T cells alone, and is resistant to ovarian TME suppression in preclinical studies. Based on these promising preclinical data, AB-1015 is being studied in a phase I clinical trial (NCT05617755) to assess the safety, pharmacokinetics, immunogenicity, and efficacy for patients with platinum-resistant ovarian cancer.

150 Engineering Pharmacologically Relevant, FDA-Approved Small-Molecule-Regulated Gene Circuits for Therapeutic Applications in the Brain

Rebecca Cottman[1], Vanessa Johnson[1], Michelle Hung[1], Yin Yin Chong[1], Andrew Banicki[1], Mengxi Tian[1], Chen-Ting Lee[1], Eren Chu[1], Assen Roguev[1], Monika Avina[1], Alex Danza[1], Brett Kiedaisch[1], Raghav Kannan[2], Chandra Verma[2], Chew-Li Soh[3], Conor McAuliffe[3], Mark Tomishima[3], Russell Gordley[1], Gary Lee[1], Tim Lu[1]

[1]Senti Biosciences, South San Francisco, CA,[2]Aplomex, Queenstown, Singapore,[3]BlueRock Therapeutics, New York, NY

Background: First generation engineered cell and gene therapies have had success in the treatment of certain cancers and genetic diseases. However, limitations in their efficacy, safety and control demonstrates a clear need for improvement to expand their therapeutic potential. Small molecule (SM)-regulated gene circuits, such as transcriptional switches, can be used to address these challenges, but often do not function at pharmacologically feasible drug concentrations, a critical limitation preventing their clinical application. In addition, many SM drugs used to control gene circuits are unable to penetrate the blood-brain barrier (BBB), preventing their use in therapeutics for diseases affecting the brain. Development of SM transcriptional switches that are regulated at pharmacologically relevant concentrations of BBB-penetrant SM drugs would enable novel and previously unattainable regulated cell and gene therapies for the brain. **Methods:** We created a Regulator Dial (RegDial) gene circuit responsive to tamoxifen metabolites (endoxifen) by engineering a novel inducible promoter responsive to a synthetic transcription factor (synTF). The inducible promoter comprises zinc-finger binding sites upstream of a minimal promoter. The synTF contains a corresponding zinc-finger DNA binding domain fused to a transcriptional activator and ERT2, a modified estrogen receptor domain that translocates from the cytoplasm to the nucleus upon binding to endoxifen. Steady state concentrations of free endoxifen in the human brain were estimated based on human and rodent PK data resulting in a target sensitivity for our synTF of 2.5 nM endoxifen. The synTF was evaluated for function at a range of endoxifen concentrations in U87MGs with an inducible reporter and showed activity at concentrations > 25 nM, well above the desired 2.5nM threshold. To address this, we computationally predicted mutations based on the ERT2/endoxifen structure that could increase endoxifen binding affinity and screened the mutants for their ability to enhance the SM sensitivity of the synTF. **Results:** We designed and tested 157 ERT2 mutations in the context of the synTF, of which 15 initiated transcription of the reporter at 10 nM endoxifen. To further improve sensitivity, we created a combinatorial library of the 15 lead mutations and sorted by FACS for library members that activated a reporter beginning at 0.1 nM endoxifen. Mutants from the sorted population were identified by long-read NGS and evaluated for their ability to induce expression of a therapeutic payload, IL-12, from their cognate promoter in vitro. The lead mutant induced expression of IL-12 by over 10 fold at 1 nM endoxifen (from baseline of 8,400 pg/mL to 88,400 pg/mL per $1x10^6$ cells in 24h), well below the expected concentration of endoxifen in the brain. We evaluated the in vivo function of the RegDial with our lead ERT2 mutant by implanting NSG mice with engineered cell lines expressing the improved synTF and a nanoluciferase reporter gene. We observed significant induction of nanoluciferase luminescence in endoxifen treated mice compared to the vehicle-only condition. **Conclusions:** We have engineered a novel RegDial gene circuit that has sensitivity to an FDA-approved SM drug at pharmacological concentrations, enabling its function in a wide range of tissues, including the brain. This circuit robustly induces a therapeutic payload, IL-12, and functions in vivo in a mouse model. This technology can be used to potentially enhance the efficacy, safety, and control of a broad range of cell and gene therapies.

Gene Targeting and Gene Correction: Liver

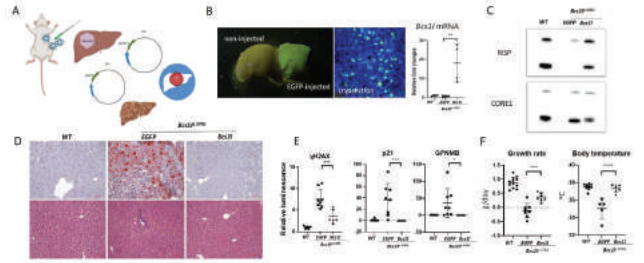
151 Effective Treatment of Mitochondrial Complex III Deficient Mice with Hepatocyte-Targeted Gene Therapy

Rishi Banerjee[1], Divya Upadhaya[1], Janne Purhonen[2], Vineta Fellman[2], Jukka Kallijärvi[2]

[1]Faculty of Medicine, University of Helsinki, Helsinki, Finland,[2]Folkhälsan Research Center, Helsinki, Finland

Mitochondrial disorders comprise a large group of monogenic inborn errors of metabolism, typically with compromised respiratory chain (RC) function, leading to a wide spectrum of manifestations from myopathies to encephalopathies and multi-organ disease. Mutations in the RC complex III (CIII) assembly factor gene *Bcs1l* are the most common cause of CIII deficiency. The most severe of them is GRACILE (Growth Restriction, Aminoaciduria, Cholestasis, liver Iron overload, Lactic acidosis, and Early death) syndrome. GRACILE syndrome patient mutation (Ser78Gly) knock-in mice show severe juvenile-onset disease with hepatopathy, kidney tubulopathy, hypoglycemia, growth restriction, kyphosis, and decreased bone mineral density and fat mass. It is unknown to which degree the systemic and metabolic phenotypes such as growth restriction, increased lipolysis and low blood glucose dependent on the liver. To interrogate the contribution of the metabolically compromised hepatocytes, we used recombinant adeno-associated viruses (rAAVs), serotype 9 and a hepatocyte-specific human ApoE enhancer and α1-antitrypsin promoter, to express wild-type BCS1L in the *Bcs1l*$^{p.S78G}$ liver starting at presymptomatic age (P21, Fig A). A single intraperitoneal injection of rAAVs targeted the liver efficiently, as shown by EGFP fluorescence in the whole liver and in frozen sections. qPCR showed approximately 20-fold increased total *Bcs1l* mRNA expression in the rAAV-Bcs1l injected liver (Fig. B). Blue Native Gel Electrophoresis (BNGE) and Western blot analyses of isolated liver mitochondria showed that CIII assembly was restored (Fig C) by rAAV-Bcs1l, as indicated by the ratio of RISP to CORE1 subunit (n=4). H&E and Oil Red O staining showed that liver histopathology and fat accumulation, respectively, were largely prevented (Fig. D). The DNA damage marker phosphorylated histone H2AX (γH2AX) decreased by more than fifty percent, while the upregulation of the cell cycle arrest marker p21 (CDKN1A) and senescence marker GPNMB were completely abolished by rAAV-Bcs1l. Strikingly, the liver-

targeted gene therapy was sufficient to correct systemic phenotypes such as hypothermia and decreased growth, indicating that these manifestations are indeed highly dependent on CIII function in the liver. We propose that liver-targeted gene therapy is an effective strategy to treat mitochondrial disease phenotypes with mainly visceral manifestations, such as GRACILE syndrome.



Effective treatment of mitochondrial complex III deficient mice with hepatocyte-targeted gene therapy A) Hepatocyte targeted gene therapy strategy to introduce wild type *Bcs1l* expression in *Bcs1l*$^{p.S78G}$ mice. As a control, rAAVs expressing *EGFP* was injected. B) The hepatocyte specific *EGFP* expression was confirmed both in the tissue level and in the cryosections. The qPCR data shows the increase in the mRNA level expression of *Bcs1l*, as a result of rAAV- *Bcs1l* injection. C) BNGE data shows a dramatic increase in the availability of RISP per CORE1 (a component of CIII). D) Oil Red O staining (the upper panel) on the liver histological sections showed that the fat accumulation was completely prevented and H&E staining (the lower panel) shows the absence of progenitor cells (dashed boundary), apoptotic cells (green arrow), the empty spaces created by fat accumulation (yellow arrow) after rAAV- *Bcs1l* injection. E) The level of γH2AX, p21 and GPNMB, which are the markers of DNA damage, cell cycle arrest and senescence, respectively, was partially of fully rectified by the gene therapy. F) The systemic phenotypes like, growth rate and body temperature were corrected by the liver targeted gene therapy.

152 An Epigenetic Hit-and-Run Platform for Durable and Effective Silencing of Pcsk9 *In Vivo*

Martino Alfredo Cappelluti[1], Valeria Mollica Poeta[1], Sara Valsoni[1], Ivan Merelli[1,2], Angelo Lombardo[1,3]

[1]SR-TIGET, Milan, Italy,[2]Institute for Biomedical Technologies, National Research Council, Segrate, Italy,[3]Vita-Salute San Raffaele University, Milan, Italy

Epigenome editing is emerging as a promising approach for DNA break-free and durable gene silencing. In this regard, we have previously developed Engineered Transcriptional Repressors (ETRs), chimeric proteins containing a programmable DNA Binding Domain (DBD) fused to either one of the following epigenetic Effector Domains (EDs): KRAB, the catalytic domain of DNMT3A and DNMT3L. Once transiently delivered, this triple ETR combination can induce long-lasting gene repression, both in cell lines and primary cells, through *de novo* deposition of targeted DNA methylation. Here, we challenged the ETR technology to *in vivo* application, focusing on *Pcsk9*, a gene involved in cholesterol homeostasis and whose hepatic inactivation is under investigation for the treatment of hypercholesterolemia. We initially compared efficacy of different ETR architectures containing either dCas9, TALE or ZFP DBDs in a *Pcsk9*-reporter cell line. These studies identified a ZFP-based ETR combination capable of inducing robust (>90%) and durable (up to 50 days) epi-silencing of *Pcsk9*. We then assessed the specificity profile of the selected ZFP-ETRs by combining whole-transcriptome and genome-wide DNA methylation analyses. Here, we found that ETR-treatment resulted in minimal transcriptional and epigenetic perturbations besides *Pcsk9*. These findings are in line with those reported in recent studies for similar epi-editing platforms. Motivated by these data, we packaged the ZFP-ETRs into a pre-selected lipid nanoparticle (LNP) and administered it to adult mice. Longitudinal analysis showed a rapid reduction in circulating levels of Pcsk9 which stabilized at ~50% of vehicle-treated levels for up to 1 year. These reductions were accompanied by *de novo* methylation at the *Pcsk9* promoter. To extend these findings, we subjected a second cohort of *Pcsk9*-silenced mice to Partial Hepatectomy (PH), a surgical procedure that promotes liver regeneration through hepatocyte proliferation. Notably, epi-silencing of *Pcsk9* was resilient to PH. In line with this data, methylation profile of the *Pcsk9* promoter from liver biopsies of mice before and after PH showed comparable levels of *de novo* DNA methylation. Finally, with the aim of reducing the molecular complexity of the triple ETR combination, we built and tested in the *Pcsk9*-reporter cell line dozens of new ETR architectures based on a single ZFP DBD, identifying new ones with improved on-target and no off-targeting activity over the standard triple ETR combination. We are profiling specificity of the remaining ETRs *in vitro* and testing *in vivo* their epi-silencing activity. In conclusion, we provided here proof-of-principle of efficient and durable epi-silencing of Pcsk9 *in vivo* upon transient delivery of ETRs, laying the foundation for the development of novel gene silencing approaches.

153 Optimizing Therapeutic Base Editing for Hereditary Tyrosinemia Type 1

Ana Maria Dumitru[1], Cara Berkowitz[1], Madelynn Whittaker[2], Xiao Wang[3], Nicole Kus[1], Valerie Luks[1], John Riley[1], Marco Carpenter[1], Nicholas F. Archer[4], Dominique Brooks[3], William Johnston[1], Mohamad Gabriel Alameh[5], Kiran Musunuru[2], William Peranteau[6]

[1]Children's Hospital of Philadelphia, Philadelphia, PA,[2]University of Pennsylvania, Philadelphia, PA,[3]Cardiovascular Institute, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA,[4]Drexel University College of Medicine, Philadelphia, PA,[5]Engineered mRNA and Targeted Nanomedicine Core, University of Pennsylvania, Philadelphia, PA,[6]The Children's Hospital of Philadelphia, Philadelphia, PA

Hereditary tyrosinemia type 1 (HT1) is an autosomal recessive metabolic liver disease that can cause death in the first months of life and incurs an increased risk of hepatocellular carcinoma. It results from mutations in the *FAH* gene which encodes fumarylacetoacetate hydrolase, the last enzyme in the tyrosine catabolic pathway, resulting in accumulation of toxic metabolites. Current treatment for HT1 involves strict adherence to daily NTBC, a repurposed herbicide that inhibits 4-hydroxyphenylpyruvate dioxygenase (HPD), the second enzyme in the tyrosine catabolic pathway, and dietary restriction of tyrosine and phenylalanine. Noncompliance rates are high, and liver transplant is the only option for patients that fail medical therapy. *In vivo* genome editing, including base editing, offers the potential for a "one-and-done" therapy for HT1. To date, 95 different disease-causing mutations have been identified in the *FAH* gene. Thus, a single therapeutic base editing strategy to correct the underlying *FAH* mutation in all patients is challenging. As an alternative, a genome editing strategy to inactivate *HPD* offers the potential for a durable, mutation agnostic therapy for all HT1 patients. We previously demonstrated the ability to rescue the lethal mouse model of HT1 via *in vivo* base editing using an adenovirus to deliver a cytosine deaminase and gRNA to introduce a nonsense mutation in the mouse *Hpd* gene. Although encouraging, an adenoviral delivery approach is clinically irrelevant and the gRNA used was specific to the mouse genome. Here, we screen human-specific gRNAs *in vitro* for inactivation of the human *HPD* gene via either cytosine deaminase or adenine deaminase base editing in HEK293 cells and HuH-7 cells, a human hepatoma cell line. This screen identified 4 potential gRNAs, that together with adenine base editor 8.8 (ABE8.8), result in high on-target editing associated with a reduction of HPD

mRNA and protein production. Furthermore, an unbiased off-target analysis assessing 151 potential off-target sites of 2 of the 4 gRNAs found only 3 sites of interest with low-level (<0.5%) off-target editing. To assess the ability of ABE8.8 base editing and candidate gRNAs to rescue the HT1 phenotype *in vivo*, gRNAs specific to the mouse genome that are orthologous to the human gRNAs were designed. ABE8.8 and the orthologous mouse gRNA were delivered systemically to either day of life 1 or adult HT1 mice maintained on NTBC via either a dual AAV8 approach or a lipid nanoparticle (LNP). NTBC was withdrawn two weeks following AAV or LNP injection and mice were monitored for weight gain and survival. At sacrifice, liver function and on-target liver editing was assessed. Control mice consisted of unedited HT1 mice maintained on NTBC and unedited HT1 mice off NTBC. In contrast to unedited HT1 mice which died within 21 days of NTBC removal, edited HT1 neonatal and adult mice demonstrated improved weight gain and survival off of NTBC to the 2 month study end point. At sacrifice, average on-target liver editing was 54% (n=16) and liver function (AST, ALT and Tbili) was normalized in 14 of 16 edited HT1 mice. This study supports adenine base editing using human specific gRNAs and clinically relevant delivery approaches as a mutation agnostic, "one-and-done" therapy for HT1 and positions us to begin IND-enabling studies to seek approval to conduct a clinical trial with a new treatment for HT1.

154 RNA Gene Writers Drive Therapeutically Relevant Levels of Correction of the PAH Gene Responsible for Phenylketonuria in Mouse and Non-Human Primate Models

Anne Bothmer, Luciano Apponi, Aamir Mir, Annie Chivatakarn, Zsanett Jancso, Mugdha Bedekar, Purba Gupta, Daniella Lu, John Labella, Ananya Talikoti, Drew Sawyer, Elizabeth English, Jane Wang, Tom Colace, Gulen Tonga, Jeff An, Gang Sun, Rachit Jain, William Querbes, Cecilia Cotta-Ramusino, Michael C. Holmes

Tessera Therapeutics, Somerville, MA

Classic phenylketonuria (cPKU) is a genetic disorder caused by autosomal recessive mutations in the phenylalanine hydroxylase gene (*PAH*) resulting in loss of protein function. PAH deficiency leads to increased blood phenylalanine (Phe) levels resulting in toxic accumulation in the brain which can lead to irreversible neurocognitive impairment. The current standard of care for PKU management consists of severe dietary Phe restriction, enzyme replacement therapy and BH4 cofactor supplementation to lower blood Phe levels. Although lowering Phe levels leads to improved neurological performance, problems in executive functioning, motor ability, social skills, and behavior can still occur despite early treatment intervention. As such there is need for new and improved treatment options. We developed RNA Gene Writers to correct the R408W mutation, a common mutation in the human *PAH* gene resulting in a severe form of PKU. RNA Gene Writers are a versatile genome engineering modality that can catalyze the introduction of gene-length DNA sequence as well as site-specific nucleotide changes. Mechanistically, RNA Gene Writers leverage target-primed reverse transcription (TPRT) biochemistry evolved by non-LTR retrotransposon mobile genetic elements, a function that is modular and can be engineered. To correct mutations in the PAH locus we deployed a high throughput screening approach and identified an RNA Gene Writer system comprised of a reverse transcriptase fused to a synthetic RNA-guided Cas nickase and a modified template RNA. We first developed reagents to correct the mutation in the Pah^{enu2} PKU mouse model. LNP-RNA delivery of these reagents achieved 40% correction of the *Pah* mutation in the liver of Pah^{enu2} mice, resulting in the normalization of Phe levels in the blood and brain. We observed a correlation between *Pah* correction and reduction in plasma Phe levels, and that 10% correction is sufficient to normalize blood Phe levels, in line with previously published work utilizing this same PKU model. A mouse model with the R408W mutation was created by making a transgenic strain with the mouse *Pah* exon 12 replaced by the human *PAH* exon 12 carrying the R408W mutation. We demonstrated an RNA Gene Writer delivered using an LNP achieved up to 35% correction of the R408W mutation in the liver of this novel PKU mouse model, leading to normalized blood Phe levels. Furthermore, we showed our RNA Gene Writing system could install a representative silent mutation in the *PAH* exon 12 of cynomolgus monkeys in up to 45% of liver alleles by LNP delivery, serving as a surrogate model to demonstrate we can achieve therapeutic levels of correction of *PAH* in non-human primates. Taken together, we show that our TPRT-based RNA Gene Writing technology is highly efficient in correcting the mutation causative of PKU in two different mouse models, leading to a phenotypic correction with a single administration of LNP formulated RNAs. Moreover, the introduction of a surrogate mutation in cynomolgus monkeys at efficiencies well above the threshold required for phenotypic rescue in rodent disease models further highlights that the RNA Gene Writing system has the potential to bring therapeutic benefit to patients with PKU after a single administration. Overall, we show that the RNA Gene Writing system can be optimized to achieve high efficiency editing in vitro and in vivo, with a wide-ranging therapeutic potential to treat severe genetic diseases.

155 Development of a Human PCSK9-Targeting Epigenetic Editor with Durable, Near-Complete *In Vivo* Silencing Efficiency

Frederic Tremblay[1], Kenneth Kelly[1], Shrijal Shah[1], Gabriel El Sebae[1], Scott Clarkson[1], Thijs Udo[1], Kendra Bayne[1], Melissa Pannone[1], Liam Lofgren[1], Tess Sevetson[1], Sahar Abubucker[1], Ricardo Ramirez[1], Erica Hildebrand[1], Christina Tarr[1], Narayan Wong[1], Kuo-Chan Hung[1], Zohan Hoque[1], Kusha Chopra[1], Shane Wright[1], Morgan L. [1]Chroma Medicine, Boston, MA,[2]SR-TIGET, Milan, Italy,[3]Chroma Medicine, Milan, Italy

Epigenetic editing is a powerful new approach to durably silence or activate genes without the risks inherent in editing approaches that use targeted DNA breaks. Epigenetic editors for gene silencing consist of a DNA targeting component fused to a transcriptional repressor

domain and a DNA methyltransferase domain. Transient exposure of the genome to a targeted epigenetic editor durably suppresses gene expression by creating a localized change in the DNA methylation of CpG dinucleotides without cutting, nicking, or altering the DNA sequence. Recent work has demonstrated the utility of epigenetic editors to durably repress gene expression in vitro and in mice. Here, we describe the development of an epigenetic editor targeting human PCSK9 (hPCSK9). Utilizing an epigenetic editor previously reported to drive durable silencing of mouse PCSK9 (mPCSK9) in vivo, we demonstrated that mPCSK9 expression remained durably silenced following a 70% partial hepatectomy, an established model of liver regeneration. To target the hPCSK9 locus, we performed a thorough screen of epigenetic editors across the hPCSK9 locus and identified several that efficiently reduced secreted hPCSK9 levels in immortalized liver cells and primary human hepatocytes. These epigenetic editors were exquisitely specific for silencing hPCSK9, as revealed by deep-read RNA-seq. To examine in vivo activity, we performed a single infusion of an LNP delivering mRNA encoding our optimized epigenetic editing construct targeting hPCSK9, into a transgenic mouse carrying the hPCSK9 genomic locus. We observed near-complete, dose-responsive, durable silencing of the hPCSK9 locus in vivo. Together, our data demonstrate in vivo proof-of-concept for the utility of epigenetic editors to effectively, specifically, and durably silence therapeutic targets in the liver without altering the DNA sequence.

156 Temporally Restricting Cas9 Expression Improves Deletion Frequency in the Liver

Jesse A. Weber[1], Jonathan F. Lang[1], Ellie Carrell[2], Mohamad Gabriel Alameh[1], Beverly L. Davidson[2]

[1]University of Pennsylvania, Philadelphia, PA,[2]Children's Hospital of Philadelphia, Philadelphia, PA

Genomic deletion using CRISPR is a viable strategy to treat disease by eliminating causal mutations including repeat expansions and early termination codon-containing exons. In the absence of guides that target specific alleles, biallelic deletions may be necessary to ensure disease correction. To investigate mono- versus biallelic CRISPR deletion, we used heterozygous Ai14(tdTomato)/Ai6(zsGreen) reporter mice wherein expression of both is induced by deletion of STOP cassette targeted by a common pair of guide RNAs. After AAV8 delivery of Cas9 and gRNAs, hepatocytes exhibited allelic heterogeneity, with mono-allelic deletions (tdTomato+ or zsGreen+) comprising 98% of successful deletions while biallelic deletions (tdTomato+ and zsGreen+) were 2%. Further studies in Ai14/Ai6 mouse embryonic fibroblasts (MEFs) showed unproductive deletions (indels) at gRNA cut sites on the non-expressing fluorescent allele, which infers there was an ineffective biallelic deletion. Because near-simultaneous double-stranded breaks are required for successful deletion prior to indel formation via DNA repair we sought to regulate Cas9 expression, placing it under control of our previously described X^{on} splice cassette (*Monteys 2021 Nature*). In X^{on}, translation is permitted only in the presence of the orally available small molecule inducer LMI070. X^{on} Cas9 was first tested in Ai14/Ai6 MEFs transfected with either an X^{on} or constitutive Cas9/gRNAs-expressing plasmid, and Cas9 translation was induced at 0, 1, 3, 5, or 7 hrs later. Delayed editing (for 5 hrs) resulted in a near 2-fold increase in both the number of overall deletions (5.2% vs 10.2%) and the fraction of deletions that were biallelic (21.2% vs 39.74%) over the constitutively expressed Cas9. To test *in vivo*, Ai14/Ai6 mice were injected with AAV8-gRNAs and either AAV8- X^{on}-Cas9 or AAV8-Cas9 with constitutive expression. Cas9 expression was induced on days 14, 28, and 32, collecting hepatocytes at 56 days post-injection for all groups. While X^{on} -SaCas9 did not alter the overall frequency of deletions compared to the constitutive version (5.3% vs 4.2%), it did significantly improve the fraction of biallelic deletions by 5-fold (0.8% vs 4.02%). In addition to AAV X^{on} based expression, lipid nanoparticles (LNPs) provide a rapid short burst of expression and may further reduce undesired indel generation prior to full deletion. To test this, Ai6 mice were injected with hepatocyte-tropic LNPs at 4mg/kg or 3mg/kg, with a 2:1:1 formulation of Cas9-mRNA : gRNA #1 : gRNA#2. Isolated hepatocytes averaged deletion frequencies of 21% (4mg/kg) and 10% (3mg/kg). Further work is in progress to ascertain the landscape of allelic heterogeneity post-LNP injection, and the potential for re-dosing. Whether the differences between LNP vs AAV X^{on} is due to transgene copies per cell expressing Cas9, or the ramping up of expression over a longer time window is under further exploration. Cumulatively these studies will help inform CRISPR/Cas9 strategies for therapy.

157 Cas-CLOVER Technology Enables Precise Gene Editing and Site-Specific Transgene Insertion in Mouse Liver

Oscar Alvarez, Lucas Homa, Stephanie Kearney, Khalid Hajj, Cindy Negron, Matthew Nitzahn, Arturo Barcenas, Joe Kubicki, Alicia Davis, Mona Connerney, Michael Bennet, Joshua Rychak, Brent Warner, Blair Madison

Poseida Therapeutics - San Diego, CA, San Diego, CA

RNA-guided nucleases such as CRISPR/Cas9 have emerged as powerful molecular tools able to precisely correct genetic diseases by directly editing the genome of patient cells and addressing the root cause of the disease. One major concern for implementing CRISPR/Cas9 for gene therapy is the relatively high frequency of off-target edits. In addition, viral vector delivery of gene editors and therapeutic transgenes can cause both insertional mutagenesis and immunogenic toxicity. Using our high-fidelity, Cas-CLOVER™ technology and proprietary lipid nanoparticles (LNP), we describe a fully non-viral, liver-directed platform. Our approach enables precise knockout editing and site-specific gene insertion of functional transgenes. To deploy this technology, we developed a novel LNP that co-encapsulates multiple nucleic acids in the same particle; this enables the efficient delivery of Cas-CLOVER mRNA and targeting gRNAs to mouse hepatocytes. We demonstrate editing of the mouse *PCSK9* gene to decrease LDL-cholesterol levels as an effective treatment for familial hypercholesterolemia. A single intravenous injection of our optimized Cas-CLOVER LNP achieved high *PCSK9* editing (65% of haploid genomes) and >85% reduction in PCSK9 protein levels. Single nuclei genotyping of liver cells showed PCSK9 editing in 64% of cells (45% biallelic and 19% monoallelic edits). Analysis of 149 computationally predicted off-target sites based on gRNA sequence homology showed no detectable off target editing. In addition, no detectable PCSK9 editing was observed in gonads from male and female mice treated with LNPs comprising Cas-CLOVER RNAs. Blood chemistry

analysis after LNP dosing showed minimal and transient elevation of proinflammatory cytokines and ALT/AST enzymes. Redosing of LNPs was well-tolerated; mice receiving three supra-therapeutic doses of the LNP did not show evidence of liver damage assessed by liver enzyme quantification and histopathological analysis. In a different set of studies designed to test our platform for site-specific gene insertion, we aimed at using Cas-CLOVER to insert a promoterless gene trap cassette encoding a luciferase reporter into a mouse albumin intron. In order to efficiently deliver Cas-CLOVER mRNA, gRNAs and donor DNA to mouse hepatocytes, we developed a second generation LNP that successfully co-encapsulated all nucleic acids in a single particle. With a single LNP injection, we achieved site-specific insertion of the DNA cassette and detected robust luciferase activity in adult, juvenile and neonate mice. Junction PCR analysis confirmed site-specific insertion of the DNA cassette at the albumin intron. In durability studies, luciferase activity persisted for up to three months with minimal loss of signal. Collectively, these results demonstrate the fidelity and tolerability of the LNP platform for targeted transgene insertion using Cas-CLOVER technology in a fully non-viral manner, which underlines the potential of this technology to develop effective therapies for rare diseases.

Synthetic/Molecular Conjugates and Physical Methods for Delivery of Gene Therapeutics II

158 Acoustofluidic Sonoporation-Mediated Gene Delivery Utilizing DNA-Encapsulated Supramolecular Nanoparticles

Yao Gong

Chemistry & Biochemistry, UCLA, Los Angeles, CA

Gene therapies where viral or non-viral methods are leveraged for delivering transgene or gene editing constructs to correct the genetic basis for a patient's disease are increasingly being added to the clinical armamentarium. However, the broader clinical expansion of these interventions is, in part, limited by issues with immunogenicity and insertional mutagenesis associated traditional viral vectors, limitations in cargo carrying capacity, and the high costs associated with Good Manufacturing Practice (GMP)-grade vector manufacturing. Non-viral intracellular delivery approaches like electroporation and lipofection are the most common alternative cell therapy manufacturing methods, but still face concerns with efficiency, cytotoxicity, and throughput. To address these concerns, we have developed and tested an acoustofluidic platform that facilitates the uptake of genetic engineering cargoes by applying acoustic waves with high frequency to biophysically manipulate the permeability of cellular membranes transiently as target cells are passed through a microfluidic channel. Here we describe efforts to optimize this methodology for manufacturing chimeric antigen receptor (CAR)-expressing human T cells. We successfully engineered Glypican-3 (GPC3) targeted CAR T cells with ~16% transfection efficiency one week post-sonoporation and stable integration of the CAR (~40% expression) after two weeks by packaging a Sleeping Beauty transposon cassette into supramolecular nanoparticle (SMNP) carriers. The SMNPs enable delivery of larger biomolecular cargoes and more precise dosing when packaging multicomponent payloads. At Day 14, over 50% acoustofluidic-treated cells remained healthy while electroporated cells showed similar viability but much lower transfection efficiency (~25% expression). Our work to improve device consistency and performance probed the kinetics and mechanisms of transient cell/nuclear membrane disruption and repair during acoustofluidic sonoporation. These studies provide insight into the parameters that influence whether delivery is successful in different cell types and how the platform configured and applied to accelerate gene therapy research and clinical translation.

159 Development of Gold Nanoparticles for *In Vivo* CRISPR Delivery - Improving Nuclease Loading and Stability with Pre-Formed RNP Complexes

Karthikeya S. V. Gottimukkala[1,2], Daniel Douglas Lane[1], Rachel Cunningham[1,2], Youngseo Jwa[1], Jennifer E. Adair[1,3]

[1]Translational Science and Therapeutics Division, Fred Hutchinson Cancer Center, Seattle, WA,[2]Department of Laboratory Medicine and Pathology, University of Washington, Seattle, WA,[3]Department of Medical Oncology, University of Washington, Seattle, WA

The current state of the art for CRISPR delivery is *ex vivo* electroporation. However, this method is cumbersome and difficult to implement globally. Multiple groups have explored methods for delivering CRISPR components *in vivo*. We previously reported passive delivery of CRISPR cargo and DNA templates into hematopoietic stem and progenitor cells using gold nanoparticles (CRISPR-AuNP) *ex vivo*. We utilized a layer-by-layer assembly, where crRNA for Cas9 or guideRNA (gRNA)

for Cas12a is synthesized with end modification including an 18-oligo ethylene glycol unit-spacer and a terminal thiol linker for conjugation to the AuNP through semi-covalent gold-thiol interactions. For Cas9, crRNA is duplexed with tracrRNA before AuNP addition. Cas9 or Cas12a nuclease protein is then added to form ribonucleoprotein (RNP) complex on the gRNA-AuNP surface. The AuNP-RNP is next encapsulated with positively charged polymer, 2000 MW branched polyethylenimine (PEI), for electrostatic conjugation of negatively charged homology-directed DNA repair template (HDT). Here we sought to analyze this CRISPR-AuNP in more detail to optimize functionality. We evaluated RNP loading and functionality following CRISPR-AuNP assembly by releasing cargo with β-mercaptoethanol (BME) and performing sodium dodecyl sulfate polyacrylamide gel electrophoresis. This showed no detectable Cas9 nuclease protein, but detectable Cas12a (Fig. 1a), possibly explaining our prior results showing superior performance of Cas12a in this system. A quantitative Qubit protein assay demonstrated CRISPR-AuNP nuclease loading equivalent to 5 ± 6 Cas9 nuclease per particle (n=2) and 16±1 Cas12a nuclease per particle (n=2). Moreover, we observed loss of tracrRNA when Cas9 nuclease was added to gRNA-AuNP, possibly due to steric crowding as gRNA is loaded in excess to stabilize and prevent AuNP aggregation. We hypothesized that pre-forming RNP complexes could ensure equivalent gRNA:nuclease ratios and increase the number of active RNP per AuNP. However, low pH conditions may compromise nuclease function and altered loading capacity could reduce AuNP stability. To test, RNP were pre-formed under standard conditions with end-modified gRNA and then added to AuNP in the presence of citrate at pH 3.7 to induce gold-thiol interaction. We show stable RNP binding to AuNP with preformed Cas12a or Cas9 RNP complexes with higher nuclease loading: 144.5±4.5 Cas9 nuclease (n=2) and 87±13 Cas12a (n=2) nuclease per particle with functional in-tubo cutting activity (Fig. 1b), despite low pH conditions. However, PEI addition to preformed RNP-AuNP caused aggregation, suggesting charge instability. Testing different PEI conjugates identified a 2000 MW polyethylene glycol (PEG)-conjugated PEI stabilized preformed RNP-AuNP and permitted loading of HDT between 100bp and 2.1kb in length. These improved CRISPR-AuNP displayed a hydrodynamic diameter of 75.75±12.59/70.06±1.46 nm and polydispersity index of 0.16±0.1/0.20±0.01 for Cas9/Cas12a AuNP respectively (Fig. 1c). The preformed AuNP were tested *in vivo* as described in abstract 2023-A-1264-ASGCT.

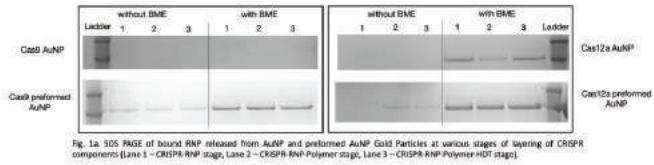

Fig. 1a. SDS PAGE of bound RNP released from AuNP and preformed AuNP Gold Particles at various stages of layering of CRISPR components (Lane 1 – CRISPR-RNP stage, Lane 2 – CRISPR-RNP-Polymer stage, Lane 3 – CRISPR-RNP-Polymer-HDT stage).

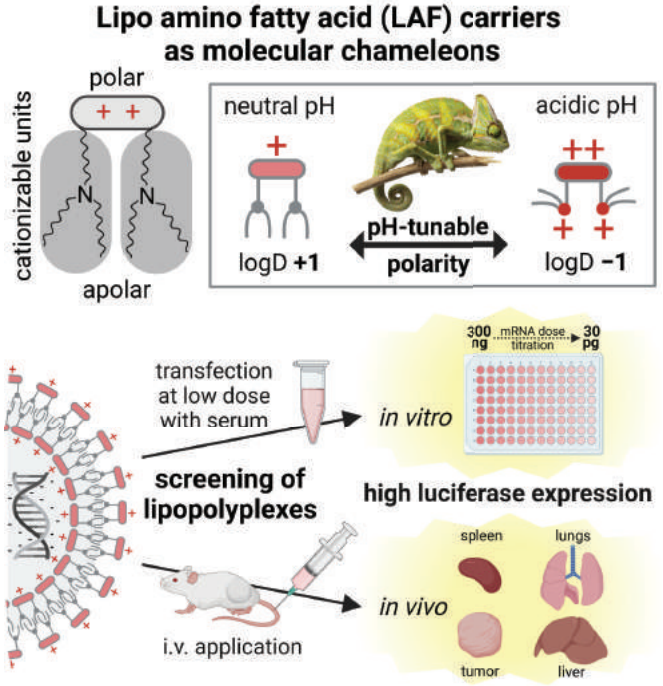
160 Molecular Chameleon Carriers for Nucleic Acid Delivery: The Sweet Spot between Lipoplexes and Polyplexes

Sophie Thalmayr, Melina Grau, Lun Peng, Jana Pöhmerer, Ulrich Wilk, Paul Folda, Mina Yazdi, Eric Weidinger, Tobias Burghardt, Miriam Höhn, Ernst Wagner, Simone Berger

Department of Pharmacy; Center for NanoScience (CeNS), Ludwig-Maximilians-Universität Munich, Munich, Germany

Taking advantage of effective intracellular delivery mechanisms of cationizable lipids and cationic polymers, highly potent nucleic acid carriers were generated by combining at least two novel lipo amino fatty acids (LAFs) as cationizable lipidic motifs with well-known polar cationizable aminoethylene units into sequence-defined molecules. The pH-dependent tunable polarity of the LAF was successfully implemented by a central tertiary amine, which disrupts the hydrophobic character once protonated, resulting in pH-dependent structural and physical changes, as evidenced by drastic changes in the logarithmic distribution logD (octanol/water) from around +1 (pH 7.4) to -1 (pH 5.5). This "molecular chameleon character" turned out to be advantageous for dynamic cargo delivery via lipopolyplexes. Chemical evolution by screening of different topologies (blocks, bundles, T-shapes, and U-shapes), different LAF/aminoethylene ratios, and different LAFs identified tailor-made carriers for various nucleic acid cargos, i.e., plasmid DNA (pDNA), messenger RNA (mRNA), and small-interfering RNA (siRNA). In the case of pDNA and mRNA, bundles with short LAF hydrocarbon chains as well as U-shapes were favorable. For siRNA, the U-shape topology was most potent. Noteworthy, the efficiency of the best performers was up to several hundred-fold higher compared to previous carrier generations and

characterized by very fast transfection kinetics. mRNA lipopolyplexes maintained high transfection activity in cell culture even in the presence of 90% serum at extremely low nucleic acid dosage of 30 picogram (around 20 nanoparticles per cell; 10,000-fold lower dose than in standard transfection), and thus are almost as potent as viral vectors. Finally, they showed great in vivo performance with high expression levels especially in spleen, tumor (N2a neuroblastoma tumor model), lungs, and liver upon intravenous administration of 1-3 microgram luciferase-encoding mRNA in mice.



161 Environmentally-Sensitive Polymer-Based Nanoparticles for Intravitreal Gene Delivery

Gijung Kwak[1], Thomas V. Johnson[2], Jung Soo Suk[1,3]

[1]Center for Nanomedicine at Wilmer Eye Institute, Johns Hopkins University School of Medicine, Baltimore, MD,[2]Department of Ophthalmology, Johns Hopkins University School of Medicine, Baltimore, MD,[3]Department of Chemical & Biomolecular Engineering, Johns Hopkins University, Baltimore, MD

An adeno-associated virus (AAV)-based gene therapy product has recently received FDA approval for treating a rare retinal disorder via the subretinal route. However, AAV has several shortcomings, including low packaging capacity, therapy-inactivating immunogenicity, and prohibitive cost. Moreover, subretinal injection is highly invasive, causes ocular damage, and limits spatial therapeutic coverage to near the injection site. Thus, a cost-effective means to provide safe, widespread, and efficacious retinal gene therapy is needed to meet the ever-increasing need. Intravitreal injection of non-viral gene delivery nanoparticles (NPs), devoid of many of the aforementioned limitations, may constitute an attractive alternative. However, intravitreally injected NPs must overcome two key extracellular barriers, the vitreous gel and inner limiting membrane (ILM), to reach the retina. We thus developed a polymer-based gene delivery NP platform capable of penetrating these barriers after intravitreal injection to mediate efficient retinal transgene expression. Specifically, we *de novo* synthesized a polyethylene glycol (PEG)-conjugated bioreducible cationic polymer, poly(disulfide amine) (PDSA), that compacts plasmids to form NPs while promoting the intracellular release of payloads. Of note, PEG endows otherwise cationic NPs with non-adhesive surfaces to minimize adhesive electrostatic interactions within the negatively charged vitreous gel and ILM, thereby facilitating their permeation through these barriers. We first confirmed the efficient compaction of reporter luciferase or ZsGreen1 plasmids by PDSA or PEG-PDSA (**A**) and the formation of NPs possessing hydrodynamic diameters of < 80 nm. We then showed that PDSA provided significantly greater *in vitro* reporter transgene expression compared to other lead synthetic materials with an excellent safety profile in human retinal pigment epithelial (ARPE-19) cells (**B-D**). Multiple particle tracking analysis revealed that PEG-PDSA NPs, unlike PDSA NPs, efficiently penetrated rabbit vitreous (**E, F**). Using a bovine vitreoretinal explant model and size-controlled polystyrene beads, we discovered that NPs sized ≤ 100 nm can efficiently penetrate the ILM only if the particle surfaces are shielded with PEG (**G**), providing design criteria for engineering ILM-penetrating NPs. Accordingly, we found that small and non-adhesive PEG-PDSA NPs efficiently penetrated the ILM (**H**) and mediated retinal transgene expression (**I**) while PDSA NPs were unable to do so. Finally, we demonstrated that PEG-PDSA NPs, due to their unique ability to penetrate both vitreous gel and ILM, provided robust and widespread retinal reporter transgene expression in mouse eyes following intravitreal injection (**J-L**). PEG-PDSA NPs, upon their further development, may serve as a broadly applicable delivery platform for retinal gene therapy.

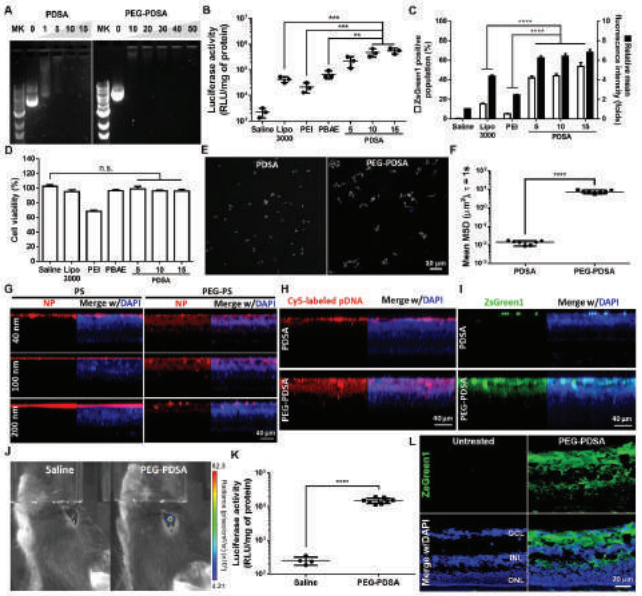


Figure 1. PEG-PDSA NPs are capable of efficiently penetrating vitreous gel and ILM to mediate robust and widespread retinal transgene expression following intravitreal injection. **(A)** Gel electrophoretic migration assay demonstrating full compaction of plasmids by PDSA or PEG-PDSA at varying polymer to plasmid ratios. **(B,C)** *In vitro* transfection efficiency and **(D)** cell viability of PDSA NPs in ARPE-19 cells. Transfection efficiency was determined by **(B)** luciferase activity and **(C)** ZsGreen1 expression. **(E)** Representative trajectories of PDSA and PEG-PDSA NPs in rabbit vitreous gel. **(F)** Mean square displacement (MSD) at a time scale (τ) of 1 second of PDSA and PEG-PDSA NPs. The MSD value is directly proportional to the particle diffusion rate. **(G)** Representative vertical images of bovine vitreoretinal (VR) explants treated with 40, 100, or 200 nm polystyrene (PS) or PEG-PS NPs. **(H, I)** Representative vertical images of bovine VR explants treated with PDSA or PEG-PDSA NPs. NPs were prepared to carry **(H)** Cy5-labeled plasmids or **(I)** ZsGreen1-expressing plasmids for microscopic observation of NP penetration (red) or transgene expression (green), respectively. **(J)** Representative IVIS images of a C57BL/6 mouse eye intravitreally treated with PEG-PDSA NPs, in comparison to a saline-treated eye. **(K)** *In vivo* transfection efficiency determined by tissue homogenate-based luciferase assay. **(L)** Representative confocal images showing ZsGreen1 transgene expression (green) in a C57BL/6 mouse eye intravitreally treated with PEG-PDSA NP. 162 Altered Localization of Plasmid DNA within the Nucleus Affects Gene Expression

Ningyang Gu, David A. Dean
University of Rochester, Rochester, NY

Upon plasmid entry into the nucleus, most assume that gene delivery has been completed, and that transgene expression levels are mostly dependent on the number of plasmids that have reached the nucleus. However, we and others have shown that robust redistribution of plasmids occurs within the nucleus. We show here that this movement can affect gene expression levels. We have previously reported that plasmids redistribute within the nucleus in a transcription-dependent manner; plasmids carrying Pol I promoters and expressing Pol I transcripts migrate to the nucleolus while plasmids carrying Pol II promoters and expressing mRNAs colocalize with nuclear speckles (Pol II promoter transcription factories). Plasmids lacking any eukaryotic promoter or that are transcriptionally inactive fail to redistribute and show diffuse staining throughout the nucleoplasm. How Pol III constructs (expressing tRNAs and shRNAs) localize within the nucleus is unknown. We microinjected cell nuclei of A549 epithelial cells with plasmids carrying either U6 or tRNA Pol III promoters, and used fluorescent in situ hybridization (FISH) to visualize the nuclear plasmid spatial location. Unlike Pol I or Pol II plasmids, Pol III promoter-containing plasmids redistribute into small nuclear foci distinct from nuclear speckles. Interestingly, a single plasmid carrying both Pol II and Pol III promoter-gene cassettes redistributes into a pattern unlike those of plasmids carrying either single promoter-gene cassette only. Inhibition of Pol II transcriptional activity causes the dual promoter-containing plasmid to be redistributed into foci that are very similar to those seen with Pol III plasmids. Similarly, Pol III transcription inhibition caused the dual promoter-containing plasmid to show more Pol II promoter-plasmid redistribution. This altered distribution of the dual promoter class plasmid required the two different classes of promoter to be in cis on the same plasmid. To determine the functional consequences of this subnuclear mislocalization, we created isogenic plasmids containing a Pol III-shRNA cassette and/or a Pol II-GFP cassette together or individually. We microinjected the same copy number of each plasmid, alone or in combination, into the nuclei of cells, and evaluated GFP expression over time. When the Pol II-GFP plasmid was injected alone or together with the separate Pol III plasmid, robust GFP expression was detected with no difference in intensity or percentage of cells expressing GFP. However, when the dual promoter plasmid (II and III) was injected, weaker GFP expression was detected and fewer cells expressed GFP. These results demonstrate that the location of plasmids within the nucleus can affect their expression level. Taken together, these results point to the need to understand and optimize the intracellular trafficking events of plasmids both in the cytoplasm and nucleus in order to maximize nonviral gene transfer.

163 Neuroprotection by Optical Delivery of Therapeutic PEDF Gene into Retina

Sanghoon Kim[1,2], Subrata Batabyal[2], Michael Carlson[1,2], Houssam Al-Saad[2], Benjamin Ferguson[2], Adnan Dibas[2], Samarendra K. Mohanty[1,2]
[1]Nanoscope Instruments, Inc., Arlington, TX,[2]Nanoscope Technologies LLC, Bedford, TX

Introduction: Vision loss and blindness associated with dysfunction/degeneration of retinal ganglion cells (RGCs, in Glaucoma), retinal pigment epithelium (RPE, AMD), or photoreceptors (Retinal degenerative diseases), are caused by genetic and/or epigenetic changes including oxidative stress (in dry-AMD, DR: diabetic retinopathy). Pigment epithelium-derived factor (PEDF) has been found to act as a neuroprotector for a wide variety of neurons including retinal cells and has potential to also act as anti-fibrotic/angiogenic agent by modulating oxidative stress and inflammatory responses. However, gene delivery using viral vectors is associated with inflammatory and immune response. Therefore, we have developed an optical coherence tomography (OCT) guided ultrafast near-infrared (NIR) laser based non-viral delivery method for spatially localized delivery of PEDF-gene into retina. **Method**: For in-vivo laser delivery into RGCs, the PEDF plasmids were injected intravitreally, and the retina was irradiated by OCT-guided ultrafast NIR laser in wild type mice. The safety of laser gene delivery to targeted retinal cells was evaluated by multiple measures including electrophysiology (ERG), intra-ocular pressure (IOP), OCT imaging, Visual evoked potential (VEP) and immunohistochemistry. Acute injury caused by KCL/NMDA insults were used to evaluate neuroprotection efficacy of laser delivered PEDF. To evaluate anti-angiogenic effect of non-viral PEDF gene therapy, laser induced choroidal neovascularization (CNV animal model of wet-AMD) was used. **Results**: In-vivo ultrafast NIR laser-based delivery of PEDF genes was confirmed by expression of fluorescence reporter in targeted cell layer and treated regions. Animals with laser delivered PEDF exhibited significantly higher ERG amplitude compared to non-treated group. Significant retention of VEP amplitude in PEDF-treated mice was observed in contrast to non-treated group demonstrating the neuroprotective effect. Further, RGC survival was higher in the PEDF-treated group. In addition, our study on CNV mouse model demonstrated anti-angiogenic effect of PEDF. Structural analysis with OCT image shows that PEDF treated mouse sustained less damage compared to non-treated group subjected to the same laser irradiation which corroborated by isolectin-IB4 staining of the retinal flat mount. **Conclusion**: The non-viral laser delivery approach provides efficient, targeted delivery of therapeutic PEDF encoding gene into spatially targeted retinal cells for neuroprotection and anti-angiogencity. We have identified/engineered PEDF mutants which has enhanced neuroprotective/anti-angiogenic properties with long lasting expression coupled with a non-viral laser delivery to address the critical need for neuroprotective/anti-angiogenic therapy of multiple complex ocular disorders.

164 Development of a Monoparticle-Based CRISPR Gene Editing and Intraparenchymal Delivery System for Neurological Applications

Victor S. Van Laar[1], Brigette Manohar[2], Vikas Munjal[1], Allison Clark[1], Meika Travis[1], Rohit Sharma[2], Sheng Zhao[2], Piotr Hadaczek[3], Lluis Samaranch[3], Niren Murthy[2], Ross Wilson[4], Krystof Bankiewicz[3]

Introduction. CRISPR-based gene editing within the central nervous system (CNS) has the potential to revolutionize the treatment of neurological disorders, including currently-incurable monogenic neurodegenerative diseases such as Huntington's, Alzheimer's, and Parkinson's diseases. However, developing CRISPR-based therapeutics for the CNS has been challenging, due in large part to drug delivery. Two key obstacles need to be overcome before gene editing in the human brain is feasible: (1) efficient and safe delivery of Cas9 and gRNA into neurons, and (2) establishment of strategies that enable targeted brain regions to be efficiently edited. The goal of this study is to develop formulations of Cas9 ribonucleoprotein (RNP) enzymes that can edit large volumes of targeted brain structures after intracranial injection. Our team - a collaboration of the Wilson, Murthy, and Bankiewicz laboratories - has developed a non-viral delivery system involving peptide-mediated intracellular delivery of a RNP complex administered via intrastriatal injection using convection-enhanced delivery (CED). This approach offers several advantages, including ease of production, transient CRISPR activity, and robust tissue distribution enabled by exceptionally small particle size. **Material and Methods.** We have developed a nuclear localization signal (NLS)-rich Cas9 nuclease protein combined with sgRNAs resulting in small particles (≤20nm), or "monoparticles." A series of different monoparticle formulations were developed that contained NLS-rich Cas9-RNPs and amphipathic peptides promoting intracellular delivery. A pair of gRNAs were used to target the cassette repressing tdTomato fluorescent reporter expression in transgenic Ai9 reporter mice. The various monoparticle (RNP:peptide) formulations were screened using a cell-based *in vitro* system. Lead Cas9 formulations were then assessed *in vivo* by administration into the striatum of Ai9 mice via CED. Three weeks following infusion, animals were euthanized and their brains were processed for immunohistological analysis of distribution and efficiency of neuronal genomic editing within the target structure. **Results and Conclusion.** Our best performing RNP:peptide monoparticle formulation exhibited an editing efficiency of approximately 82% of neurons within a coverage area involving over 33% of the striatum in Ai9 mice. This optimal formulation was then combined with sgRNAs targeting the gene expressing green fluorescent protein in transgenic GFP mice, where we observed knockdown of GFP expression in 76% of the neurons in the target area. We conclude that this monoparticle-based CRISPR reagent delivery system is efficacious in genomic editing of CNS neurons following intracranial delivery to target brain regions. We are currently advancing this technology to large animals utilizing MRI-guided CED for intraparenchymal delivery. This approach holds the promise to accelerate successful translation of CRISPR-Cas9 to the clinic for the treatment of brain diseases.

Neurological Gene Therapies in Advanced Stages of Clinical Translation

165 Lowering of Toxic Dipeptide Proteins and Phenotype Rescue in an ALS Mouse Model Treated with AAV-miQURE® Targeting the Repeat Expansion-Containing C9orf72 Transcripts

Vanessa Zancanella, Anna-Aster de Ruiter, Romy M. van Vliet, Kristel S. van Rooijen, Madhurima Chatterjee, Ines Lopes Pereira, Vlad Shtefaniuk, Sebastian N. Kieper, Irena Bockaj, Morgane Wartel, Elena de Miguel, Greg Dobrynin, Mercedes Valls Seron, Jovana Kovacevic, Ying Poi Liu

uniQure biopharma B.V., Amsterdam, Netherlands

Amyotrophic lateral sclerosis (ALS) is a progressive, fatal, neurodegenerative disorder that affects the upper and lower motor neurons in the brain and corticospinal tract leading to eventual muscle atrophy and paralysis. The most common genetic cause of familial ALS is a hexanucleotide (GGGGCC) repeat expansion in the first intron of the chromosome 9 open reading frame 72 (*C9ORF72*) gene. The bi-directionally transcribed, expanded, repeat-containing C9orf72 mRNA causes cellular toxicity due to RNA foci and dipeptide repeats (DPRs) production, both of which are the pathogenetic hallmarks of the disease. The *C9ORF72* gene contains 11 exons and is transcribed into three major transcripts variant 1 (V1), variant 2 (V2) and variant 3 (V3). The repeat expansion is located between exons 1a and 1b, and it is situated in the first intron of the toxic variants V1 and V3 and in the promoter region of the healthy variant V2. We developed therapeutic microRNAs (miRNAs) using our miQURE® platform to selectively silence the repeat-containing C9orf72 transcripts. The most potent therapeutic miRNAs (miC9Os), identified *in vitro,* have been tested for their efficacy in lowering mutant intronic C9orf72 mRNAs in two ALS mouse models. In the transgenic ALS mouse model (Tg(C9orf72_3) line 112), we have shown that intra-striatal administration of AAV-miC9O leads to significant lowering of the human intronic C9orf72 mRNAs, without affecting healthy (V2) human and total C9orf72 mRNA expression. Next we assessed functional improvement in the AAV9-(G4C2)149 repeats-induced ALS mouse model which exhibits motor deficits, hyperactivity, learning and memory dysfunction starting at 26 weeks of age. Intra-striatal administration of AAV-miC9O in the AAV9-(G4C2)149 repeats-induced mouse model resulted in a dose-dependent knockdown of mutant intronic C9orf72 mRNAs at 8 weeks post-AAV-miC9O dosing. In accordance with the strong intronic C9orf72 mRNA lowering (up to 75%) in the striatum and cortex, a significant lowering of DPRs at 18 weeks after intra-striatal administration of AAV-miC9O was measured. The behavioral assessment performed at 26 weeks of age, 18 weeks post-AAV dosing, revealed that higher proportion of mice that received a high dose AAV-miC9O retained muscle strength compared to negative control. In the fear conditioning paradigm, AAV-miC9O treatment groups showed higher immobility time during exposure to the conditioned-context compared to negative control, suggesting rescued memory of fear and cognitive function in the treatment groups. In conclusion, we have shown strong and sustained lowering of intronic C9orf72 mRNAs and

rescue of ALS phenotype in mice post AAV treatment. Current results support further investigation of AAV-miC9O distribution, efficacy, tolerability, and safety of AAV-miC9Os in small and larger animals. *miQURE is a registered trademark in the US and other jurisdictions.*

166 Long-Term Efficacy of Gene Therapy for AADC Deficiency, Including Patients with a Moderate Phenotype

Marina Hashiguchi[1], Karin Kojima[2], Mitani Tadahiro[1], Kazuhiro Muramatsu[3], Hitoshi Osaka[4], Naoyuki Taga[5], Masahiro Hirai[6], Yoshiyuki Onuki[3], Takeshi Nakajima[7], Shin-ichi Muramatsu[3], Takanori Yamagata[1]

[1]Pediatrics, Jichi Medical University, Shimotsuke, Japan,[2]Jichi Medical University, Tochigi, Japan,[3]Jichi Medical University, Shimotsuke, Japan,[4]Jichi Med Univ, Shimotsuke, Japan,[5]Anesthesiology and Critical Care Medicine, Jichi Medical University, Shimotsuke, Japan,[6]Cognitive and Psychological Sciences, Nagoya University, Aichi, Japan,[7]Neurosurgery, Jichi Medical University, Shimotsuke, Japan

Aromatic l-amino acid decarboxylase (AADC) deficiency presents with dystonia, oculogyric crisis, loss of voluntary movements, developmental delay, and autonomic symptoms caused by defects in the *dopa decarboxylase* (*DDC*) gene. Here we report long-term gene therapy results for AADC deficiency, focusing especially on patients with a moderate phenotype. Ten patients (8 severe and two moderate types) were enrolled. The patients received bilateral intraputaminal injections of an adeno-associated virus type 2 vector, harboring *DDC* (2×10^{11} vector genomes), through stereotactic brain surgery. They were then followed up for a period lasting from 6 months to 7 years. Positron emission tomography (PET) imaging with a specific AADC tracer revealed that increased uptake persisted for five years after treatment. In all patients, truncal and limb dystonia attacks disappeared. Oculogyric crisis decreased markedly. In severe patients, it persisted but only resulted in mild eye deviation. All severe patients could not move voluntarily before the treatment. After the treatment, four severe patients could walk with a walker, and one severe patient could swim (video presentation). Two moderate patients who could walk with support before the treatment began to walk and run independently. The Alberta Infant Motor Scale (AIMS) scores increased to more than 20 points in patients treated at a younger age and to more than 10 points in patients treated at an older age. In one moderate patient who was treated at four years of age, her cognitive function improved so that she could begin to make conversation, and her developmental quotient scores increased from 40 to 80. In addition, her eye movements when following objects improved, as revealed by the eye tracker. PET and MRI imaging analysis revealed that the highly transduced putaminal area connecting to the prefrontal cortex was associated with improved motor performance at 6M post-treatment, suggesting that putaminal dopamine promotes the development of an immature motor control system. In the other patient with a moderate phenotype who was treated at 12 years of age, his motor ability and cognitive function improved mildly. Cognitive and motor function improved in patients with moderate phenotypes. However, the efficacy of AADC gene therapy is limited, even in moderate patients, if treatment is delayed till they are older. In moderate patients, residual enzyme activity can create dopamine to induce neuronal network formation at some level, with the accelerated improvement of the neural network after gene therapy if treatment is provided at a younger age.

167 Intraparenchymal Convection Enhanced Delivery of AAV in Sheep to Treat Mucopolysaccharidosis IIIC

Claire O'Leary[1], Gabriella Forte[1], Nadia Mitchell[2], Amir Youshani[1], Adam Dyer[3], Martin Welby[4], Katharina Russell[4], Samantha Murray[4], Nelly Jolinon[3], Simon Jones[5], Kevin Stacey[1], Dan Davis[1], Els Henckaerts[6], David Palmer[4], Ian Kamaly[7], Brian W. Bigger[1]

[1]University of Manchester, Manchester, United Kingdom,[2]University of Otago, Lincoln, New Zealand,[3]King's College London, London, United Kingdom,[4]University of Lincoln, Lincoln, New Zealand,[5]Manchester University NHS foundation Trust, Manchester, United Kingdom,[6]KU Leuven, Heverlee, Belgium,[7]Salford Royal NHS foundation Trust, Manchester, United Kingdom

Mucopolysaccharidosis IIIC (MPSIIIC) is one of four Sanfilippo diseases sharing clinical signs and symptoms of severe cognitive and later motor decline and shortened life span. Unlike most other lysosomal diseases the missing enzyme, heparan sulfate acetyl-CoA: α-glucosaminide N-acetyltransferase (HGSNAT), is bound to the lysosomal membrane and thus cannot cross the blood-brain barrier or diffuse between cells. We have previously demonstrated behavioural, biochemical and pathological correction of this disease in the mouse model of MPSIIIC using an Adeno-Associated Vector (AAV) delivering recombinant human HGSNAT from two intraparenchymal injections into the brain using an AAV-2 derived AAV truetype (AAV-TT) serotype with improved distribution over AAV9. Current Adeno-Associated Vector (AAV) gene therapy delivery routes are sub-optimal for effective neuronal delivery in the entire human brain, which is essential in diseases characterised by global neurological pathology such as Mucopolysaccharidosis (MPS) IIIC. We describe AAV delivery using Brainlab targeted catheters or Hamilton syringes for convection enhanced delivery (CED) in sheep, designed to reduce proximal vector expression and improve spread in intraparenchymal injections. Using AAV-GFP, we found that Brainlab cranial navigation is optimal for gene therapy, although Hamilton syringes gave improved distribution over catheters, despite higher doses and titres of vector used in catheter delivery. Intraparenchymal CED gives better distribution compared to intracerebroventricular delivery for the same vector dose. We demonstrate that we can effectively deliver functional HGSNAT enzyme in 24-37% of a 140g gyrencephalic sheep brain using AAV9-HGSNAT in only 3 injections in one hemisphere. AAV serotype may also be important, as AAVTT-GFP displayed moderately better transduction compared to AAV9-GFP but both serotypes almost exclusively transduced neurons via this route. In addition, the presence of pre-existing IgG antibodies in serum does not seem to affect AAV transduction in the brain. Despite variabilities in vector purification, volume and titre, we found the primary attribute for efficient brain delivery is catheter design. These data help to inform a future potential clinical trial for MPSIIIC.

168 Subacute Liver Injury in Two Young Infants Following Gene Replacement Therapy for Spinal Muscular Atrophy

Cassie Turnage[1], Russell James Butterfield[2], Catalina Jaramillo[3], Linda Book[3], Stephanie Manberg[1], Sara Stern[4], Mouied Alashari[5], Elizabeth Wood[6]

[1]Division of Pediatric Neurology, University of Utah, Salt Lake City, UT,[2]Division of Pediatric Neurology, Univeristy of Utah, Salt Lake City, UT,[3]Division of Pediatric Gastroenterology, Hepatology, and Nutrition, University of Utah, Salt Lake City, UT,[4]Division of Pediatric Rheumatology, University of Utah, Salt Lake City, UT,[5]Division of Pediatric Pathology, University of Utah, Salt Lake City, UT,[6]Billings Clinic, Billings, MT

Introduction: Spinal muscular atrophy (SMA) is a neurodegenerative disorder resulting from irreversible loss of anterior horn cells secondary to homozygous mutations in the survival motor neuron gene, *SMN1*. Gene replacement therapy using an AAV9 vector containing an *SMN1* gene construct, onasemnogene abeparvovec-xioi (OA), was approved by the U.S. Food and Drug Administration in May, 2019. Subacute mild elevation of liver function tests following infusion of OA has been shown to be a relatively common adverse event. Additionally, there have been case reports of liver failure following administration of this therapy. The current recommendations from the drug manufacturer advise systemic corticosteroids to attenuate immune reaction and transaminitis. However, there is a paucity of data regarding management of liver injury refractory to protocol steroids. We report 2 cases of subacute severe elevation of liver function tests >10-20 times the upper limit of normal following OA administration in young infants less than 4 weeks old. **Cases:** In case 1, patient received OA on day of life 19. At 4 weeks post gene transfer, she was admitted for inpatient management of acute liver injury. Liver biopsy was completed which showed grade 2/4 hepatitis. Over the next 3 weeks she had worsening liver injury despite escalating doses of intravenous methylprednisolone (IVMP) and a 3-day course of anakinra. After high dose IVMP at 30mg/kg and concurrent tacrolimus, liver enzymes began to improve. In case 2, patient received OA on day of life 13. At 4 weeks post gene transfer, she was admitted for inpatient management of acute liver injury. She exhibited improvement on a 3-day course of IVMP at 10mg/kg, however required readmission at 6 weeks post gene transfer due to worsening liver injury. At that time, she underwent liver biopsy which showed grade 3/4 chronic hepatitis, inflammatory cells (predominantly CD3 positive T cells), and stage 2/4 fibrosis. A second course of high dose IVMP at 10mg/kg resulted in improvement of liver enzymes. Neither case met criteria for liver failure with normal international normalized ratio, and in both cases, evaluation for other causes of liver disease was unrevealing. Inflammatory markers were elevated and followed similar trends to liver markers. Corticosteroids were continued for both patients for four months post gene therapy. **Conclusion:** We present 2 cases of liver injury with moderate to severe elevations in liver function tests in young infants with SMA following treatment with OA at less than 4 weeks old. Onset of liver injury at 4 weeks post gene transfer with laboratory evidence of systemic inflammation and biopsy reflective of T cell mediated inflammation is consistent with prior case reports. Safety of OA administration in young infants (<1 month of age) has not been characterized separately from other pediatric patient populations, and established standards of care for management of immune response as manifested by liver injury refractory to protocol steroids is an area of clinical need. High doses of corticosteroids up to 30mg/kg daily may be required, and there may be indication for adjunct immunosuppressive treatment in addition to corticosteroids. These questions are pertinent to the management of SMA patients receiving OA but also have broader implications for gene therapy using AAV.

169 Efficacy and Safety of a Novel *FXN* Gene Therapy (AVB-202) for the Treatment of Friedreich's Ataxia

Grace K. Pavlath[1], Jennifer Wheeler[2], Arden Bond[1], Jennifer L. Marlowe[1]

[1]Solid Biosciences, Charlestown, MA,[2]Aclairo Pharmaceutical Development Group, Inc., Camillus, NY

Friedreich's ataxia (FA), the most common form of hereditary ataxia, is an autosomal recessive disorder caused by mutations in the frataxin (*FXN*) gene, which encodes a mitochondrial protein important for energy production. FA is a systemic disorder characterized by cardiomyopathy, gait ataxia, and sensory loss among other central nervous system (CNS) manifestations. The main cause of death in the majority of FA patients is cardiomyopathy. AVB-202, a novel AAV9 gene therapy product expressing *FXN* under the control of a CBA promoter, is intended to restore functional levels of frataxin across disease-relevant tissues using a dual route of administration (intravenous and intrathecal) with the goal of preventing progression or reversing cardiac and CNS manifestations of FA. Development of AVB-202 includes assessments in relevant animal models of cardiac and neurologic manifestations of the disease and long-term safety. Results from cardiac efficacy and long-term safety studies will be presented. A preclinical study was conducted to evaluate the efficacy of AVB-202 using a conditional knock out mouse model of FA that develops progressive cardiomyopathy and early mortality (referred to as mutant [MUT]). Untreated MUT mice exhibit abnormalities on echocardiogram as early as 6 weeks of age and mortality by 9-11 weeks of age. Mice received a single intravenous injection of AVB-202 at varying doses at 3 weeks of age. Cardiac function was assessed at regular intervals using echocardiography. Additionally, biochemical and histologic assessments were performed on cardiac tissues. Dose-dependent extension of lifespan and improvements in cardiac abnormalities occurred with AVB-202 treatment of MUT mice. Dose-dependent increases in frataxin protein were also noted in cardiac tissue. Furthermore, activity of a biomarker of mitochondrial function, the mitochondrial enzyme succinyl dehydrogenase, was also improved in cardiac tissue. Together, these results support that AVB-202 restores functional levels of frataxin in cardiac tissue and ameliorates manifestations of FA-associated cardiomyopathy. To assess long-term safety, non-human primates (NHP) received a single dose of AVB-202 either intravenously, intrathecally, or by dual route of administration at multiple dose levels. Animals were monitored for 6 months and biochemical and histologic assessments were performed at the end of the study. AVB-202 was well tolerated with a favorable safety profile across multiple doses and routes of administration. Robust expression of frataxin was noted in key FA target tissues, including the heart and CNS. The strong positive effects on survival and cardiac function in

a cardiac mouse model of FA, as well as favorable safety profile and robust transgene expression across multiple organs in NHPs, support continued development of AVB-202.

170 Preclinical Safety Assessment of NGN-401, a Clinical-Stage Gene Therapy Product for Rett Syndrome

Suzanne R. Burstein[1], Paul Ross[2], Kamal Gadalla[2], Jim Selfridge[2], Ralph D. Hector[2], Sophie Thomson[2], Dominik Biezonski[1], Juliana Benito[1], Effie Albanis[1], Stuart Cobb[1,2]

[1]Neurogene Inc., New York, NY,[2]University of Edinburgh, Edinburgh, United Kingdom

Background: Rett syndrome is a severe neurological disorder caused by loss-of-function variants in the X-linked *MECP2* gene. Females with Rett syndrome exhibit a mosaic pattern of expression whereby approximately half of cells exhibit substantial deficiency in functional MeCP2. Conversely, individuals with duplication at the *MECP2* locus also experience severe neurological disease, indicating that the gene is highly dosage sensitive and creating challenges for conventional gene therapy. NGN-401 is an investigational AAV9 gene therapy for Rett syndrome designed to provide full length and fully functional MeCP2 protein within a narrow expression range via a self-regulating miRNA circuit, termed EXACT. In preclinical studies and in the clinic, NGN-401 is delivered via intracerebroventricular administration. **Results:** Studies in male *Mecp2* knockout mice, a model that shares phenotypic features of the human disease, have shown that delivery of NGN-401 extends survival and ameliorates disease phenotypes. The safety of NGN-401 was evaluated in female mice heterozygous for the null allele and mirroring the mosaic MeCP2 expression patterns observed in female Rett syndrome subjects. Mice treated with 0.9-2.7X the clinical dose of NGN-401 had no observable in-life toxicity through 26 weeks of age. At the maximum feasible dose (6.4x clinical dose), a minimal in-life hindlimb phenotype was observed, with no progression. Moreover, no NGN-401 related histopathological findings were observed at the 2-month interim sacrifice in any of the tissues evaluated. In contrast, even at the lowest dose evaluated, severe toxicity was observed following delivery of an AAV9 vector carrying the *MECP2* transgene without EXACT regulation, requiring sacrifice by ~3 weeks of age. Vector genome levels were broadly similar between vectors, but MeCP2 expression was lower with NGN-401 administration. The safety of NGN-401 was further evaluated in nonhuman primates expressing physiological levels of MeCP2 in all cells and thus representing a high bar for evaluation of safety. In a 6-month GLP-compliant study in juvenile female nonhuman primates, NGN-401 was well-tolerated with a 4.1-fold safety margin over the clinical dose. In a separate comparative study with unregulated vector, NGN-401 was consistently well-tolerated, and biodistribution and mRNA expression in key areas of the brain involved in Rett syndrome pathogenesis was confirmed. In contrast, delivery of a conventional unregulated *MECP2* vector led to an adverse effect on sural nerve conduction, highlighting a difference in safety profile between NGN-401 and a vector without EXACT regulation. Comparison of transgene expression following delivery of both vectors demonstrated the ability of the EXACT circuit to constrain and reduce variability in expression levels in the central nervous system. **Conclusion:** Overall, the totality of data generated in multiple preclinical models demonstrated that NGN-401 allowed for MeCP2 expression that provided therapeutic benefit while mitigating the risk of overexpression toxicity, supporting FDA clearance to initiate a first-in-human pediatric clinical study.

171 Comparison of Dorsal Root Ganglion Toxicity in the Development of AAV9/MFSD8 and AAV9/AP4M1 Gene Therapies for CLN7 and SPG50

Xin Chen[1], Thomas Dong[1], Yuhui Hu[1], Terry Pirovolakis[2], Jodi Mcbride[3], Alison Weiss[3], Anne Lewis[3], Steven J. Gray[1]

[1]UT Southwestern Medical Center, Dallas, TX,[2]Cure SPG50 Foundation, Toronto, ON, Canada,[3]Oregon National Primate Research Center, Beaverton, OR

Adeno-associated viral (AAV) vector delivery has emerged as the dominant vehicle to deliver genes to patients affected with genetic disorders to permanently treat these disorders with a single treatment. To date, five AAV-based gene therapy drugs have been approved by the US Food and Drug Administration or the European Medicines Agency. Although AAV in general has a favorable safety profile, it has been reported recently that AAV, especially in high dose, can induce immune cell infiltration and neuron degeneration in dorsal root ganglion (DRG). During the development of intra-CSF (cerebrospinal fluid) AAV9/*MFSD8* (*JeT-MFSD8-SV40pA)* and AAV9/*AP4M1 (UsP-AP4M1-BGHpA)* gene therapies to treat CLN7 batten disease and spastic paraplegia 50 (SPG50) respectively, we evaluated the DRG toxicity following gene transfer in WT (wild type) animals, including 12-month long-term *non-GLP* studies in C57BL/6J mice, 3-month short-term *GLP* studies in Sprague Dawley rats, and 3-month short-term studies in non-human primates (NHPs). In the mouse studies, we treated the mice by lumbar intrathecal (IT) administration at 6-8 weeks of age with AAV9/*MFSD8* (0.447E11, 1.48E11, 4.47E11, or 9.5E11 vg/mouse) or AAV9/*AP4M1* (1.25E11 or 5E11 vg/mouse) and did not note any DRG toxicity up to12-months post administration. In the rat studies, we treated the rats IT at 7-8 weeks of age with AAV9/*MFSD8* (0.5E12, 2E12, or 6E12 vg/rat) or AAV9/*AP4M1* (0.36E12, 1.1E12, or 3.3E12 vg/rat) and noted in the lumbar DRG no neuronal and axonal degeneration with AAV9/*MFSD8* up to 6E12 vg/rat, but minimal to mild neuronal and axonal degeneration in both male and female rats with ≥ 1.1E12 vg/rat of AAV9/*AP4M1*. The degeneration in the rats treated with AAV9/*AP4M1* was apparent at day 8, was worse at day 29, and was less severe at day 91 post administration. Similar results were observed in the NHP studies, where we treated 1) naïve Japanese macaques (*Macaca fuscata*) at 3-4 years of age ICM (intracisternal magna) with AAV9/*MFSD8* (1E14 vg/monkey) or 2) Cynomolgus monkeys at 2-4 years of age IT with AAV9/*AP4M1* (0.84E14, or 1.68E14 vg/monkey), along with immunosuppression regimen (sirolimus and methylprednisolone). Once again, we noted in the lumbar DRG no neuronal degeneration with AAV9/*MFSD8*, but minimal neuronal degeneration in both male and female monkeys at days 94 post administration of AAV9/*AP4M1* at 1.68E14 vg/monkey. The degeneration in the monkeys treated with AAV9/*AP4M1* correlated with a decrease in NCV (nerve conduction velocity) and response amplitude of the sural nerve (sensory) at the high dose, but

not peroneal nerve (motor), noted on days 45 and 77. Taken together, mild neuronal degeneration was noted in the lumbar DRG in both male and female at the highest dose of AAV9/*AP4M1*, but not AAV9/*MFSD8,* in WT rats and NHPs, but not in mice. These results, along with an absence of adverse clinical signs or mortality during the entire period of all studies, suggest that utilizing weaker (JeT) or moderate (UsP or JeT+Intron) promoters could be a mitigating strategy to reduce DRG toxicity under immunosuppression and both AAV9/*MFSD8* and AAV9/*AP4M1* at the dose of 1E15 vg/patient (which equals to 2.5E11 vg/mouse, 1.1E12 vg/rat, or 0.84E14 vg/monkey) had an acceptable safety profile for CLN7 or SPG50 patients. There are ongoing clinical trials in the US and/or Canada testing AAV9/*MFSD8* and AAV9/*AP4M1* at the dose of 1E15 vg/patient.

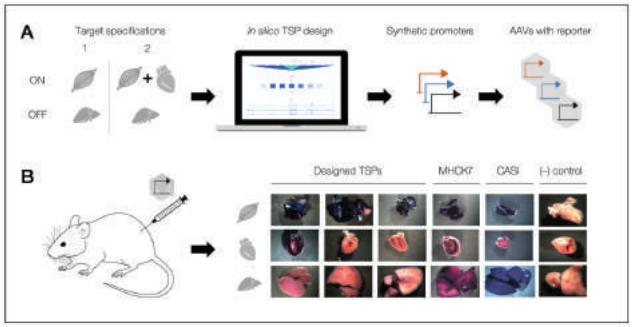

Figure 1: (A) Computational design of tissue-specific promoters (TSPs) for two target specifications. Each designed TSP was placed upstream from an alkaline phosphatase reporter gene and packaged into AAV vectors. (B) Testing three designed TSPs in vivo demonstrates that the observed expression profiles exhibit high dynamic-range between target and off-target tissue. MHCK7 shows expression in both target and off-target tissue. Four mice were dosed with each AAV payload and sacrificed after three weeks, at which point organs were harvested and stained for alkaline phosphatase activity.

AAV Vector Genome Biology and Engineering I

172 Machine-Guided Design of Tissue-Specific Promoters

Dinghai Zheng[1], D. Benjamin Gordon[1], Raja R. Srinivas[1], Nicole Zielinska[2], Yanlong Pei[2], Sarah K. Wooton[2], Alec A. K. Nielsen[1]

[1]Asimov, Boston, MA,[2]Department of Pathobiology, University of Guelph, Guelph, ON, Canada

Adeno-associated viral (AAV) vector gene therapy has shown significant potential for treating otherwise intractable diseases, with three FDA-approved therapies since 2017. Most AAV therapeutic transgenes are expressed using ubiquitous promoters, such as the cytomegalovirus enhancer/chicken beta actin promoter, which are transcriptionally active in a broad set of tissues. This indiscriminate expression increases the risk of undesired off-target effects and tissue toxicity. To address these challenges, we have developed a computational method that integrates multi-omics analysis and machine learning to design tissue-specific promoters (TSPs) for targeted expression of AAV payloads. To validate our approach, we designed three TSPs to preferentially express in heart and/or skeletal muscle with minimal expression in liver (Figure 1A). The promoters were predicted to achieve strong expression only in target tissues, while also being short enough to package into an AAV alongside a transgene. For controls, we included two promoters that are currently being used in clinical AAV therapies: CASI (ubiquitous) and MHCK7 (heart/muscle specific). AAV vectors were generated that harbored an alkaline phosphatase reporter gene driven by the TSPs, which were subsequently administered to healthy 6-week-old C57BL/6 mice at a dose of 3E11 viral genomes per animal. The mice were sacrificed after three weeks and the skeletal muscle, heart, and liver were harvested and stained for alkaline phosphatase expression. Across the three designed TSPs, we observed a >1000-fold dynamic range in alkaline phosphatase activity between target and off-target tissues (Figure 1B). Surprisingly, we observed noticeable off-target liver expression for MHCK7. These results demonstrate the power of computational methods to achieve more precise expression control for in vivo gene therapy.

173 A New cceAAV Vector without a Mutant ITR is Efficient for Reducing Subgenome Generation

Junping Zhang[1], Dylan A Frabutt[1], Ning Li[1], Lohra Mickelle Miller[2], Anh K Lam[1], Matthew Chrzanowski[3], Patrick L Mulcrone[1], Martin F. Jarrold[2], Dao Pan[4], Roland W Herzog[1], Weidong Xiao[1]

[1]Indiana University School of Medicine, Indianapolis, IN,[2]Chemistry Department, Indiana University, Bloomington, IN,[3]Lewis Katz School of Medicine, Temple University, Philadelphia, PA,[4]Division of Experimental Hematology, Cincinnati, OH

Self-complementary AAV vectors (scAAV) have an engineered AAV genome which fold back on itself to form a special double stranded DNA and facilitate fast and efficient transgene expression. The approved spinal muscular atrophy (SMA) drug, Zolgensma, is based on scAAV vector. However, scAAV vectors are not always in a double stranded DNA form since they utilize a mutant ITR (mITR) to facilitate packaging of a complementary-stranded DNA. Inefficient resolution at the mITR leads to the generation and packaging of monomeric AAV genomes and subgenomic particles. All these non-canonical particles result in reduced transgene expression efficiency and potential immunological problems. To avoid these issues, here we developed a new class of scAAV vector, namely, Covalently Closed-End double stranded AAV genomes (cceAAV). The production of cceAAV vector bypasses the resolution step of the mITR altogether. Instead of using a mutant ITR, a 56-bp recognition sequence of protelomerase (TelN) were used to covalently link the top strand and the bottom strand and the vector can be produced with only a single ITR. To manufacture cceAAV vectors, cceAAV vector plasmid DNA was first digested with TelN enzyme and followed by a typical triple transfection protocol and standard AAV vector purification procedures. The yield of cceAAV vector has a comparative yield to scAAV vector. Denatured gel analysis of vector genomes as well as Charge Detection Mass Spectrometry (CDMS) analysis showed that cceAAV vectors produced generally has a more homogenous composition and decreased non-canonical particles as compared to traditional scAAV vectors. DNA bioanalyzer analysis shows that the genome integrity of this new cceAAV vector was significantly improved as well. Furthermore, cceAAV vector were able to avoid partial genome generation which was usually presented

in scAAV vectors. In animal studies, cceAAV vector with a factor IX expression cassette showed an increased 2~5 folds transgene expression over scAAV vectors. In summary, cceAAV vectors are the next generation of scAAV vectors which may be further developed for human gene therapy.

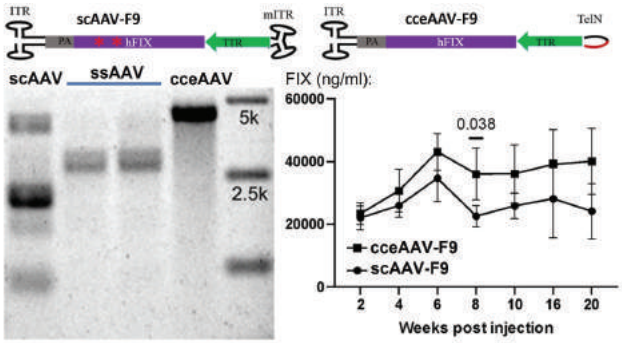

Figure: Top, Illustration of scAAV (self complementary AAV) and cceAAV. The difference is that cceAAV does not use a mutant ITR for making the complimentary genome. Left, DNA genome size distribution of AAV genomes from scAAV, ssAAV and cceAAV. Vector genomes extracted from scAAV, ssAAV and cceAAV are separated by denaturing gel and stained by cyber gold. It shows that cceAAV has a more homogenous genomes as comparing to scAAV vectors. Right, in vivo performance of cceAAV vector. Both scAAV and cceAAV vectors carrying the same factor IX expression cassette are injected into hemophilia B mice at the same dose of 1e11vg per mouse. cceAAV showed a 2-4 folds better expression than scAAV vectors.

174 Characterization of Promoter and Intron Interactions Affecting Transgene Expression in AAV Cassettes

Ferzin Sethna[1], Monika Mittal[1], Laura Buczek Orenstein[1], Joerg Votteler[1], Lester Suarez[1], Scott Hammond[1], Anna P. Tretiakova[1], R. Jude Samulski[1,2]

[1]Asklepios BioPharmaceutical, Inc. (AskBio), Research Triangle Park, NC,[2]Gene Therapy Center and Department of Pharmacology, University of North Carolina, Chapel Hill, NC

Recombinant Adeno-associated viral (AAV) vectors have tremendous potential for gene therapy. The AAV expression cassette contains several DNA elements that control the expression of the therapeutic transgene, which typically include a promoter, an intron, and a transcription terminator/polyadenylation signal. With the large number of promoters and introns that have been tested in preclinical and clinical studies, the combinatorial sum of possible cassette architectures is substantial. In many cases, these individual elements are put together in a modular manner, ignoring the possibility that interactions may affect functional outcomes. For example, we and others have shown that translation of alternative reading frames (ARFs) in AAV gene expression cassettes can result in unwanted peptides (ASGCT 2022). These ARF peptides can elicit immune responses and have been demonstrated to decrease expression of the desired therapeutic protein. Upstream ARFs can result from cryptic start codons in 5' untranslated regions, or from retained intron sequences due to splicing inaccuracies. To investigate these outcomes, we systematically evaluated cassette architectures for splicing accuracy, transgene expression, and ARF production. We constructed a set of AAV cassettes that contained three promoters and ten introns that drive expression of a reporter gene. We performed Ribo-Seq on cells that were transfected with these constructs. Next generation sequencing (NGS) libraries were sequenced on an Illumina NextSeq 1000, and ribosome protected fragment (RPF) reads were mapped to the plasmid sequence. Protein products were analyzed by western blot (WB) using an antibody against the reporter. In parallel, we analyzed splicing patterns by RT-PCR. We observed that expression levels of the reporter gene by WB were markedly different from constructs with different introns, even with the same promoter. Low expression from some introns was attributed to inefficient splicing as measured by splice PCR. Importantly, we detected the presence of upstream ARF peptides from multiple intron constructs. Reporter gene expression was substantially diminished from constructs that expressed upstream ARF peptides. Furthermore, we noticed a marked difference in splicing efficiency of the same intron in the context of a different promoter. These data collectively demonstrate that there are complex interactions between promoters, introns and transgenes that remain to be understood and that a universal plug and play system for expression cassette design may not always be optimal. Selection of introns is particularly important, and we believe plays a vital part in determining transgene expression and avoiding potential immunogenic ARF peptides. The methods we describe here, including Ribo-Seq, splice PCR and reporter gene assays, are valuable analytical tools and may be used to optimize performance of therapeutic cassettes.

175 Improving Codon Optimization for Gene Therapy Vectors Using Deep Learning

Sandhiya Ravi[1,2], Tapan Sharma[1,2], Mitchell Yip[1], Guangping Gao[1,3], Phillip WL Tai[1,3]

[1]UMass Chan Medical School, Worcester, MA,[2]Co-first Authors, Worcester, MA,[3]Co-corresponding Authors, Worcester, MA

Gene therapy seeks to introduce, modify, or manipulate the levels of genes in a patient to alter the biological properties of host cells for therapeutic purpose. One way to improve the efficiency of protein-coding transgene expression is by codon optimization. Current approaches for codon optimization, such as using a codon usage table or a biological index, are centered on eukaryotic versus prokaryotic usage rules, or are generalized to enhance mammalian expression. Differences among species, transcript abundances, protein length and structure, and differential expression of aminotransferases and transfer RNAs (tRNAs) between tissues or cell types are typically not considered in most codon optimization algorithms. These unmet considerations highlight the need for further research in the area, and are an unexplored facet for gene therapy vector engineering. It has been hypothesized that there are tissue-related synonymous codon biases that may allow sequence optimization to be effective in one tissue type but not in another. We have developed a novel recurrent-neural-network (RNN)-based codon optimization tool for cell type-specific codon optimization. We compiled a dataset of highly expressed genes in mouse myocytes (708), neurons (651), and hepatocytes (733) and extracted their corresponding codons and trained a deep neural network to predict the optimal codon usage patterns for the three independent cell types. Through the RNN architecture, we found that the sequential context of codons in highly expressed genes drove codon selection that was more similar to those observed in a set of 120 validation genes (40 genes from each cell type). We evaluated the outcomes of the codon-optimized sequences for each cell type by the distribution of codon frequencies, CpG dinucleotide content, GC content, and codon adaptation index (CAI), which compares the frequency of synonymous codons between the optimized genes

and those appearing within the reference set of highly expressed genes. We then used our model to optimize the sequences for two standard reporter genes, firefly luciferase (*FLuc*) and green fluorescent protein (*GFP*) for expression in neurons, hepatocytes, and myocytes. The codon-optimized constructs were tested in three mouse cell lines representing neuroblasts (Neuro-2a), myoblasts (C2C12), and hepatocytes (AML12). Expression of the codon-optimized *FLuc* transgene for each specific tissue type was enhanced in the correct corresponding cell line when compared to the non-optimized wildtype counterpart as evaluated by luciferase activity assays and Western blots. In addition, expression was superior to those conferred by codon-optimized transgenes obtained by a popular and publicly available algorithm. An unintended, but welcomed, consequence of our Deep Learning (DL)-driven codon-optimization trials was the reduction of CpG dinucleotides in the output sequences. Therefore, codon optimization using our algorithm does not directly counteract efforts to reduce or deplete CpG dinucleotides in vector designs. Current efforts to optimize therapeutically-relevant transgenes and evaluation with AAV vectors in mice are underway. Our novel approach was able to achieve improved protein expression compared to non-optimized and codon-optimized sequences produced by commercially available tools. Importantly, our DL approach confirmed that synonymous codon biases exhibit tissue specificity. DL-driven codon-optimization has the potential to drastically improve the efficiency of gene addition or gene replacement therapies for tissue-restricted diseases.

176 Searching the Hairpin in the Haystack: Tracing the Impact of AAV-ITR Mutations

Felix Bubeck[1,2], Conradin Baumgartl[1,2], Dirk Grimm[1,2,3]

[1]Department of Infectious Diseases/Virology, Section Viral Vector Technologies, Medical Faculty, University of Heidelberg, Heidelberg, Germany,[2]BioQuant, University of Heidelberg, Heidelberg, Germany,[3]German Center for Infection Research (DZIF) and German Center for Cardiovascular Research (DZHK), Heidelberg, Germany

In Adeno-associated viral (AAV) vectors, engineering of the ITR (inverted terminal repeat, i.e., replication and packaging cis element) sequences may enhance vector productivity, safety and efficacy. Strikingly, however, the impact of the ITR sequence and structure on these parameters remains largely unexplored. To facilitate manipulation of the ITRs, we developed a toolbox for AAV ITR engineering which includes a vector construct design that allows easy modification of plasmid ITR sequences. This is complemented by a strategy for plasmid ITR sequence confirmation that can be used with conventional Sanger sequencing chemistry. To trace the ITR mutants during production and transduction, each ITR variant is associated with a specific DNA barcode in the 5‘ UTR of a transgene cassette on the virus genome. Titers of the resulting vectors based on this alternative design are similar to the traditional vector backbone. The integrity of the produced viral genomes and the presence of ITR mutants was examined by Nanopore sequencing. There, we discovered a previously undescribed and biologically highly interesting trans-acting ITR-repair mechanism in which ITR variants derived from different plasmids can serve as repair template. Consequently, by avoiding the presence of different ITR variants during vector production, this ITR repair mechanism can be circumvented, permitting AAV vector generation with mutant ITRs that are maintained in the virus genome. Subsequent barcode interrogation by deep sequencing enables the determination of barcode distribution at high resolution, which, in turn, allows to quantify the impact of the mutations on AAV genome replication and packaging. Barcode sequencing in extracted RNA can also serve as a qualitative and quantitative measure for effects of the ITR on vector transduction efficiency, despite the potential loss of the ITR by recombination in the nucleus. Altogether, the novel pipeline for ITR modification and tracing reported here forms the basis for the comprehensive analysis of alternative ITR designs and their function during AAV production and transduction, which should ultimately benefit the creation and optimization of next-generation AAV vectors not only on the capsid but also on the genome level.

177 Engineering mRNA Stability with Flaviviral Genomic Elements to Improve AAV Transduction

Roza Ogurlu[1], Rita M. Meganck[2], Leo O. Blondel[1], Alan Rosales[1], Aravind Asokan[1]

[1]Duke University, Durham, NC,[2]UNC Chapel Hill, Chapel Hill, NC

Current AAV-based gene therapies require high vector doses, which may result in undesirable clinical side effects. Several constituents of the recombinant AAV genome such as promoter elements, introns, short DNA hairpins, and other regulatory elements have been engineered to enhance and control translational output. However, diversity and functional significance of post-transcriptional regulatory elements have yet to be investigated. Notably, strategies to increase nuclear mRNA export, improve rate of viral transcription, or significantly extend mRNA half-life, with respect to AAV transcript biology, are of particular interest. Here, we engineer AAV vector genomes containing sub-genomic flaviviral RNA (sfRNA) elements that boost transduction efficiency. Specifically, we appended sfRNA elements from Dengue virus serotype 2 (DENV2), Japanese Encephalitis virus (JEV), Murray Valley Encephalitis virus (MVEV), West Nile virus serotype, (WNV2), Yellow Fever virus (YFV), and Zika virus (ZIKV) to the 5’ and 3’UTRs of an AAV vector genome encoding firefly luciferase. Earlier results indicated that sfRNA elements from all tested flaviviruses dramatically increase transduction efficiency *in vitro* by extending mRNA half-life, with DENV2 sfRNA located in the 3’UTR exerting the greatest effect. We further investigate the DENV2 sfRNA and discover that only two dumbbell structures (DBs) were necessary and sufficient to increase AAV transgene expression *in vitro*. We then evaluated AAV9 vectors packaging a firefly luciferase cassette with DENV2 sfRNA, DENV2 DBs, or a control WPRE in the 3’UTR followed by intravenous dosing in mice. *In vivo* results corroborate the ability of flaviviral sfRNA elements to improve transgene expression compared to WPRE in a tissue specific manner, suggesting a potential for lowering vector doses. Engineered sfRNA elements hold promise for improving AAV gene expression, can potentially be substituted for traditionally used synthetic poly-A tails, and warrant further testing in larger animal models and human tissues.

178 Long Read Sequencing of rAAV Vectors Illuminates Origins of Contaminating Genomic Species

Lauriel F. Earley, W. Daisy Han, Kevin C. Stein, Timothy G. Johnstone, Robert Lloyd, Ken Prentice, Ramsey A. Saleem

Shape Therapeutics, Inc. - Seattle, Seattle, WA

AAV has become an increasingly important vector for gene therapy, with three approved products in the United States and over a hundred ongoing clinical trials. An extensive understanding of the composition of packaged genomes is critical to ensure the safety of AAV-based gene therapy products. While heterogeneity in the form of short, non-unit length genomes in packaged AAV genomic species has been known for decades, it has traditionally been assessed by gel-based methods that quantify size but not full sequence composition. Recent advances in sequencing technology, namely single-molecule long-read sequencing, have resulted in unprecedented insight into AAV replication and packaging. In this work, we used single-molecule long-read sequencing to examine self-complementary vector payloads containing varying regions of complex and homologous sequences. These vectors were produced from two commercial vendors using triple transfection in HEK293 cells and purified by ultracentrifugation. Our bioinformatic analysis identified two novel classes of contaminating genomic species. In our first observation, we found that repetitive elements with strong secondary structures can compromise genomic integrity by facilitating a loss of DNA between the regions of homology, possibly through slipped-strand mispairing during genome replication. This is distinct from previously described 'snap-back' genomes, which were also observed. The second observation contained plasmid backbone sequence in a configuration that cannot be accounted for by previously described 'reverse packaging' mechanisms. This genomic species originated from the nickable ITR, contained a small portion of payload, and had a chimeric sequence that joined to the plasmid backbone. These genomes were frequently packaged as concatemers linked by unnicked double-D ITRs. To our knowledge, the mechanism of reverse-packaging leading to these species is undescribed in the literature and would not be prevented by current vector engineering strategies such as enlarging the plasmid backbone or adding hairpins outside the ITRs. Work is currently underway to understand if these same species are also found in single-stranded rAAV vector preps. Our work presented here demonstrates the value of implementing a long-read sequencing pipeline for rAAV characterization, illustrated by the identification of novel genomic contaminants. While more work is needed to confirm the mechanism by which these genomic species arise, these observations suggest new strategies to maintain homogeneity and safety of rAAV preps.

Pharmacology/Toxicology Studies: Methodology

179 Assessing *In Vivo* Recombinant AAV DNA by Long-Read Sequencing after Gene Therapy

Jason Lamontagne, Rucha Fadnavis, Kelly Martins, Qi Zheng, Jenny A. Greig, James M. Wilson

University of Pennsylvania, Philadelphia, PA

Multiple *in vivo* studies have demonstrated reductions in long-term transgene expression as a potential drawback for recombinant adeno-associated virus (rAAV)-delivered gene therapies. While long-term reductions in transgene expression most likely arise from multiple factors, such as direct regulation of gene expression and vector loss due to cell turnover, it is becoming increasingly clear that potential heterogeneity in the sequence and structural integrity of rAAV DNA may also play a significant role. Fully understanding the underlying biology and potential heterogeneity of rAAV DNA requires better methods for interrogating both episomal and integrated rAAV DNA. Here, we optimized an assay harnessing the power of long-read sequencing and applied this approach to tissues from multiple nonhuman primates (NHPs) treated with rAAV vectors. Utilizing a hybridization-based approach with biotinylated probes tiled against the primary units of an rAAV genome (inverted terminal repeats [ITRs], promoters, transgenes, polyA signals, etc.), we specifically enriched for rAAV DNA in a way that minimizes the biases introduced by other approaches. This resulted in a pool of sequences directly representative of individual rAAV DNA molecules present in the samples. Using this approach and a custom bioinformatic pipeline, we assayed liver tissue samples from six NHPs collected approximately 2 years after dosing with rAAV vector to directly investigate *in vivo* rAAV sequences. These NHPs received vectors expressing a non-self transgene (enhanced green fluorescent protein, n=2) and a rhesus (n=2) or human (n=2) version of a transgene (low-density lipoprotein receptor). We identified differing amounts of rAAV reads from the samples based on the administered transgene, following the same trends observed via traditional assays such as genome copy number determined by quantitative PCR (qPCR) and consistent with transgene immunogenicity. In addition, the large majority (>90%) of the rAAV reads were identified as non-integrated, implying that the majority of AAV DNA at this ~2-year timepoint was maintained episomally. As the average high-fidelity read length in this study was ~6 kb, this approach enables a deeper investigation of the rAAV structure that is not easily provided by other techniques. In these samples, the large majority of rAAV DNA had undergone a dramatic rearrangement, with less than 40% of overall enriched rAAV reads across all samples containing an intact transgene. Very few reads show the expected pattern of concatemer formation (head-to-head or head-to-tail). Instead, different sections of the rAAV genome repeat multiple times in no discernable order, an observation that is seen across all samples and represents the most common outcome when individual long-reads are examined at the single-nucleotide level. Importantly, the samples with the highest identified transgene expression upon reverse transcription qPCR also had the most reads containing a functional transgene sequence, supporting the relationship between loss of transgene expression and potential rAAV DNA rearrangements *in vivo*. Together, the use of this hybridization and

long-read sequencing approach has broad applications for elucidating rAAV vector heterogeneity, including the finding that much of the *in vivo* rAAV DNA identified lacked the factors necessary to allow successful transgene expression. The generation of large unbiased data that is not dependent on only a few specific sequences, such as only the ITRs or transgene, as this assay allows, could help answer many questions pertaining to our overall understanding of rAAV-mediated gene therapy.

180 Retrieval and Quantification of Vector Integration Sites by Sonication Linker Mediated-PCR (SLiM-PCR): Efficiency and Applications

Fabrizio Benedicenti[1], Andrea Calabria[1], Daniela Cesana[1], Alessandra Albertini[1], Sergio Arevalo[1], Giulia Pais[1], Simona Esposito[1], Stefania Giannelli[1], Erika Tenderini[1], Laura Rudilosso[1], Carlo Cipriani[1], Giulio Spinozzi[1], Victor Neduva[2], David Dow[2], Luigi M. Naldini[1,3], Alessandro Aiuti[1,3,4], Eugenio Montini[1]

[1]SR-TIGET, Milan, Italy,[2]GlaxoSmithKline, Stevenage, United Kingdom,[3]Università Vita-Salute, Milan, Italy,[4]Pediatric Immunohematology and BMT, San Raffaele Hospital, Milan, Italy

Specialized PCR-based techniques combined with next generation sequencing (NGS) and bioinformatics analyses allow the retrieval and mapping of vector integration sites (IS) in the genome of transduced cells. Because IS are stable genetic marks, distinctive for each independently transduced cell and its progeny, their characterization in gene therapy (GT) applications allows to track transduced cells in different tissues or cell lineages over time, evaluate the clonal composition of the engrafted population, identify the targeted genes and quantify the relative abundance of clones harboring a specific IS to detect or exclude sustained clonal expansions. Here, we present our method for IS retrieval, Sonication Linker mediated- PCR (SLiM-PCR), in which vector/genome junctions are specifically PCR amplified from sheared genomic DNA and sequenced by NGS. The identification and quantification of IS is realized by dedicated software (VISPA2) while the analyses are performed by ISAnalytics, an R tool for comprehensive and integrated IS analysis. The abundance of each IS is obtained by counting the number of DNA fragments containing the same IS but variable in size depending on the shear site position. Hence, the number of shear sites assigned to an IS will be proportional to the initial number of contributing cells, avoiding the biases introduced by PCR amplification. We validated SLiM-PCR for quantitative LV and γ-RV IS retrieval, by setting up an experimental framework in which the genomic DNA of monoclonal samples harboring one LV or γ-RV vector IS in known genomic positions were mixed at different ratios (70-0%) with the genomic DNA of samples with IS randomly distributed in the genome. By applying SLiM-PCR on the different DNA mixes, we calculated the relative abundance of the clones with known IS versus the expected value, that was measured by digital PCR. SLiM-PCR showed a high correlation between the number of retrieved and expected IS ($R2 \simeq 0.9$). Indeed, the observed values of monoclonal samples' IS matched the expected (observed/expected = 0.96 ± 0.1) for all the dilutions up to the detection limit of 0.16% for LV and 0.1% for g-RV genomes over the total. Beside the experimental part, we have implemented Standard Operating Procedures and automated the whole SLiM-PCR process in 96/384-well plates with liquid handlers able to process hundreds of DNA samples per week. A laboratory information management system supports tracking the process and records all the relevant samples metadata used in the analytical bioinformatics process. In the last 2 years, our approach was successfully applied on DNA samples transduced by different vector types like gamma-retroviruses, LV, Sleeping Beauty Transposons and adeno-associated viruses. More than 4500 independent samples coming from 7 different GT clinical trials (97 patients) and more than 30 research and preclinical studies have been processed, generating a dataset of millions of IS. In conclusions, our results showed that SLiM-PCR is a reproducible, accurate and versatile method that combined with state-of-the-art infrastructures, automated laboratory procedures and novel bioinformatics and statistical tools allows to perform fast and high-throughput IS analyses.

182 Cell Isolation Following Apheresis Using an Immunomagnetic Beads Approach in Non Human Primates

Srishti Vats, Cristina Ballesteros, Amina Dahmani, Selly Hung, Clotilde Leblond Lecrux, Nisreen Ibrahim, Simon Authier

Charles River, Laval, QC, Canada

We evaluated a method used in a pre-clinical setting for hematopoietic replacement therapies and in the future, to produce cell therapies including CAR T for allogenic applications. Clinically, apheresis can be used to collect a blood component from an autologous donor through one of two methods: continuous mononuclear collection (CMNC) method, which employs outflow from one venipuncture and return flow through a second site or a dual lumen catheter, or the peripheral blood mononuclear cell (MNC) method which has a smaller dead volume and only a single venipuncture. In macaques, Neupogen (G-CSF, 50 µg/kg/day; administered on days 1 to 5) and Mozobil (Plerixafor, 1.0 mg/kg/day; administered on day 5, three hours prior to apheresis) were used to mobilize CD34+ hematopoietic stem cells from the bone marrow compartment. This 5-day process increased the CD34+ cell concentration in peripheral whole blood ranging from 1.8 to 15.5 x 10^3 cells/mL, up to values between 55.7 to 200.9 x 10^3 cells/mL prior to apheresis. CD11b-CD45+CD34+ cell concentration measurements were performed by flow cytometry at prior to mobilization, prior to Mozobil administration on Day 4 and 3 hours post Mozobil administration. Apheresis was performed using the Spectra Optia Apheresis System with outflow from the catheterized femoral or saphenous vein and return flow through the catheterized carotid or tibial artery. The system was initially primed with whole blood and then a CMNC collection was performed to harvest peripheral white blood cells, and adjusted to collect the buffy coat fraction rich in CD34+ cells. The subject can undergo the procedure for up to 6 hours, during which ionized calcium levels (targeted level of 1.0 to 1.3 mmol/L) were closely monitored and calcium gluconate was administered as needed to maintain safe ionized calcium levels in order to prevent citrate toxicity. In addition to the apheresis product bag, several microsamples for flow cytometry analysis were collected during the apheresis procedure to assess the effect of sample density (based on the collection color),

collection rate and time from Mozobil administration. Following the completion of the apheresis procedure, the apheresis product was subjected to a ficoll density gradient separation to isolate mononuclear cells. The mononuclear cell fraction was then immunomagnetically depleted of CD11b+ cells and the CD11b- fraction was once more stained, this time with anti-CD34 immunomagnetic beads to allow positive selection of CD34+ cells. Our methods have produced 73 to 95% purity of CD34+ cells across our studies, with a cell yield between 1.34 to 53.4 x 10^6 CD34+ cells across studies. Preliminary analysis of samples collected during the apheresis procedures suggested that while total cell counts were comparable across collection conditions, there were higher concentrations of CD45+CD34+ cells in samples collected within 5-6.20hrs post-mozobil administration, than later collections (up to 7.30hrs post-mozobil administration). In addition, when collected during the earlier timeframe, a higher concentration of CD45+CD34+ cells was obtained in a sample with a collection rate of 0.5mL/min, as compared to 1mL/min. Finally, the collection color (used as an index of cells density during collection), howed a trend to greater CD45+CD34+ concentration in samples collected in the following order: dark and middle then pale red patterns. We demonstrate high degrees of purity (>70%) in isolating CD34+ cells from apheresis product of non-human primates by immunomagnetic bead separation. This method can be harnessed to produce a large variety of cells for immunotherapies, as well as to develop, test, and bring to market CAR T cells produced though allogenic methods.

183 Characterization of AAV Integrations and Rearrangements from Long and Short Reads with RAAVioli

Carlo Cipriani[1,2], Giulio Spinozzi[1], Laura Rudilosso[1], Fabrizio Benedicenti[1], Dhwanil Dalwadi[3], Markus Grompe[4], Eugenio Montini[1], Andrea Calabria[1], Daniela Cesana[1]

[1]San Raffaele Telethon Institute for GT (Sr-Tiget), IRCCS San Raffaele Scientific Institute, Milan, Italy, Milan, Italy,[2]Department of Electronics, Information and Bioengineering, Politecnico di Milano, Milan, Italy,[3]OHSU, Portland, OR,[4]Yecuris Corporation, Tualatin, OR

Recombinant Adeno Associated Viral (rAAV)-based gene therapy (GT) applications have been successfully exploited for the treatment of several disorders. rAAV mainly remains episomal in the nucleus of transduced cells, however, numerous studies demonstrated integration of fragmented or full-length AAV DNA within the transduced cell genome where double-strand DNA breaks (DSBs) or nicks have occurred. Yet, preclinical studies revealed the occurrence of hepatocellular carcinoma and clonal expansion events consequent to rAAV insertions, posing safety concerns for their clinical use. However, bioinformatics tools able to identify AAV integration sites (IS) and characterize vector rearrangements are still missing. Here, we collected data from a humanized liver mouse model, where human primary hepatocytes have been transduced ex-vivo or in-vivo with a tomato expressing AAV. PCR amplicons or DNA fragments containing AAV vector portions were sequenced by both short paired-end and long reads and then analyzed by RAAVioli (Recombinant Adeno-Associated Viral IntegratiOn analysis), to characterize vector rearrangements and IS. Python and R scripts parse the alignments to identify IS and reconstruct rearrangements using CIGAR strings. We retrieved 811 and 370 IS from short paired-end Illumina reads and long PacBio reads respectively, confirming the higher efficiency of PCR-based approach in IS retrieval. The distribution of AAV IS was sparse in the human genome similarly in both datasets, and Albumin gene was the most targeted gene as expected. Furthermore, 32 ISs were in common between the two datasets, demonstrating the reliability of RAAVioli independently from sequencing platform adopted. Both datasets showed a similar percentage (~25%) of fragments with AAV rearrangements, however more than 2 rearrangements per fragment were retrieved only in long PacBio reads. Precision and accuracy of RAAVioli pipeline was assessed through simulated datasets obtaining scores >0.95 in IS identification and rearrangement characterization. These data demonstrated that RAAVioli is a comprehensive and flexible bioinformatic tool that can efficiently map AAV IS using long and short paired ends sequencing reads. These approaches are fundamental to characterize AAV integration and recombination events in gene therapy and gene editing applications, allowing and improving the assessment of safety in AAV studies.

184 CISC: A Multi-Purpose Enrichment Tool for HDR-Edited Human T-Cells Applicable for Treg and CAR-T Therapeutic Cell Products

Annaiz Grimm[1], Peter J. Cook[1], Su Jung Yang[1], Gene I. Uenishi[2], Samuel E. West[3], Chester Jacobs[1], Noelle Dahl[1], Karen M. Sommer[1], Andrew M. Scharenberg[4], David J. Rawlings[5]

[1]Seattle Childrens Research Institute, Seattle, WA,[2]GentiBio, Inc, Cambridge, MA,[3]Seattle Children's Research Institute, Seattle, WA,[4]Casebia Therapeutics, Seattle, WA,[5]University of Washington, Seattle, WA

Engineered T cells represent an emerging therapeutic modality. However, complex engineering strategies can present a challenge for enriching and expanding therapeutic cells at clinical scale. Additionally, lack of in vivo cytokine support can lead to poor engraftment of transferred T cells, including regulatory T cells (Treg). We have established a cell-intrinsic selection system that leverages the dependency of primary T cells on IL-2 signaling. Novel FRB-IL2RB and FKBP-IL2RG fusion proteins, referred to as chemically inducible signaling complex (CISC), were identified permitting selective expansion of transduced primary CD4+ T cells in rapamycin supplemented media when delivered as a lentivirus. LV-transduced cells strongly activated the STAT-5 signaling pathway in response to CISC heterodimerization. The CISC was subsequently incorporated into HDR donor templates designed to drive expression of the Treg master regulator FOXP3 at the endogenous *FOXP3* locus or introduce a CD19-CAR and delete the endogenous T Cell receptor at the *TRAC* locus. Following FOXP3 editing of CD4+ T cells, CISC+ engineered Treg (CISC EngTreg) were selectively expanded using rapamycin and maintained Treg activity. Significantly, CISC EngTreg cells adoptively transferred into immune deficient mice showed increased engraftment and retention, and improved therapeutic efficacy in a xenogenic graft vs host disease model when mice were treated systemically with dimerizer. *TRAC* edited CD4+ T cells displayed efficient endogenous TCR knockout in combination with CD19-CAR expression, and functional CISC CAR-T Cells were selectively enriched in the presence

of rapamycin. In summary, CISC provides a robust platform for the in-vitro selection of multiple HDR edited therapeutic T Cell products and can promote in-vivo efficacy of engineered Treg cells.

185 Novel Tools for Gene and Cell Therapy Safety: Optical Long-Read Genomics for Detection and Characterization of On- and Off-Target Transgene Integrations and Off-Target Structural Variants

Saumyaa Saumyaa[1], Gargi Roy[2], Roberto Nitsch[3]

[1]Astrazeneca, Gothenburg, Sweden,[2]AstraZeneca, Gaithersburg, MD,[3]AstraZeneca, Mölndal, Sweden

During the development of gene and cell therapy products, especially the strategies involving a 'transgene' delivered to patients or cells, to repair a gene or rescue its function, integration of said transgene raises safety concerns. For gene repair via integration in gene therapy, or transgene knock-in approach in cell therapy, on-target, and any potential off-target transgene integration needs to be well characterized. For example, the genomic locations of such integrations, frequency, size (full length or not), copy number, and possibly orientation are a few of the parameters that need to be determined. AAV-based gene therapies, relying on the episomal expression of the delivered transgene need to be screened for possible unintended integration of such transgenes into the host genome. Additionally, genome-editing manipulations can generate other non-transgene-related structural variants (SVs) in the host genome, which can pose safety risks. In cell therapy candidates, the cellular expansion step can induce further genomic changes. Some commonly employed approaches for measuring these genetic changes either suffer from PCR biases and short read lengths (150-300bp) which miss capturing larger SVs (e.g. NGS-based targeted assays) or have too low resolution (e.g. karyotyping, FISH for chromosome-level changes). We are addressing these concerns by employing optical genome mapping (OGM) approach, which involves imaging and analyzing ultra-long (150kb-Mbp) single molecules of DNA, to detect SVs >0.5kb. It can capture the entire SV and long stretches of neighboring DNA in one read, thus presenting a complete picture of the genetic change. It is a PCR-free, target-agnostic approach and allows genome-wide mapping of the detected SVs. Using this approach we were able to accurately detect and characterize multiple variants of on-target integrations, their respective frequencies, size and copy number, in our studies. We also captured genome-wide off-target SVs, ranging from a few kb in size to chromosomal level, both post-genome-editing and during the cell expansion stage. Thus we demonstrate that this approach fills a gap in the safety evaluation and deeper characterization of gene and cell therapy candidates and can be a simple and efficient approach for such purposes.

Metabolic, Storage, Endocrine, Liver and Gastrointestinal Diseases II

186 Phase 1/2 Clinical Trial of Autologous Hematopoietic Stem and Progenitor Cell Gene Therapy for Cystinosis

Stephanie Cherqui

University of California, San Diego, La Jolla, CA

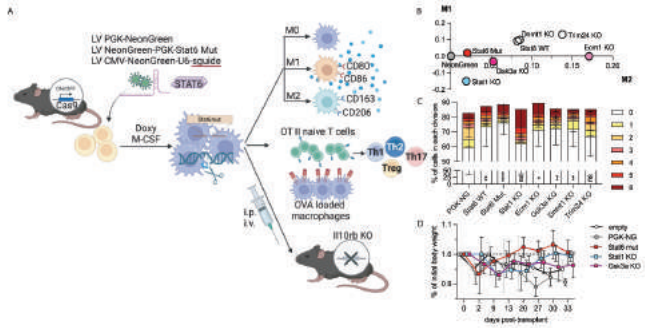
Cystinosis is a lysosomal disorder characterized by cystine accumulation within the lysosomes of all organs caused by mutations in the *CTNS* gene encoding the transmembrane lysosomal cystine transporter, cystinosin. Major complications of cystinosis include early renal Fanconi syndrome, chronic kidney disease, renal failure, and ocular pathology that can lead to blindness. Cystinosis also affects the heart, thyroid, skeletal muscle, pancreas, and CNS, eventually causing premature death in early adulthood. Cysteamine delays, but does not stop, disease progression. Here we report results from the phase 1/2 open-label clinical trial (NCT03897361) evaluating safety and efficacy of CTNS-RD-04 in adult patients with cystinosis. CTNS-RD-04 consists of autologous $CD34^+$ hematopoietic stem and progenitor cells (HSPCs) transduced with a lentiviral vector (LV) carrying the *CTNS* cDNA encoding for cystinosin (CCL-EFS-CTNS-WPRE). Peripheral blood $CD34^+$ HSPCs are collected via apheresis after mobilization with G-CSF and Plerixafor and transduced with CCL-EFS-CTNS-WPRE LV. Myeloablative-busulfan conditioning at a targeted AUC of 90 mg×h/L is followed by CTNS-RD-04 infusion. Oral and topical cysteamine are withdrawn prior to infusion. The trial is fully enrolled, and six participants (ages 20 to 46 years) have been treated with CTNS-RD-04 with follow-up ranging from 1 to 36 months. CTNS-RD-04 cell doses ranged from 3.63×10^6 to 9.59×10^6 $CD34^+$ cells/kg with VCNs ranging from 0.6 to 2.9 copies/dg. In all five infused patients with 42+ days of post-CTNS-RD-04 infusion follow-up, polyclonal hematopoietic reconstitution occurred. Peripheral blood VCN at 12 months post-gene therapy ranged between 0.43 to 1.99. In the five first treated patients, white blood cell cystine and tissue cystine crystals in skin and rectal mucosa decreased compared to Baseline. All subjects are no longer taking oral cysteamine. Patient 2 restarted eyedrop cysteamine one-year post-infusion. No adverse events related to drug product and no serious adverse events have been reported to date. Updated data will be presented.

187 Manipulating Macrophage Phenotype to Improve Inflammatory Bowel Disease Outcomes

Adele Mucci[1,2], Nora Knopf[1], Davide Mangani[3], Denise Klatt[1], Izabel Patik[4], Kayla Wright[1], Ana C. Anderson[3], Scott B. Snapper[4], Bruce Horwitz[4], David A. Williams[2], Christian Brendel[1,2]

[1]Dana Farber/Boston Children's Cancer and Blood Disorders Center, Harvard Medical School, Boston, MA,[2]Division of Hematology/Oncology, Boston Children's Hospital, Harvard Medical School, Boston, MA,[3]Ann Romney Center for Neurologic Disease and Evergrande Center for Immunologic Diseases, Brigham and Women's Hospital and Harvard Medical School, Boston, MA,[4]Division of Gastroenterology, Hepatology, and Nutrition, Department of Pediatrics, Boston Children's Hospital, Boston, MA

Inflammatory bowel disease (IBD) is a chronic inflammatory condition that affects the intestine. Environmental factors, infectious microbes, genetic susceptibility, and a dysregulated immune system can result in mucosal inflammation. The mechanisms behind establishing and maintaining intestinal tolerance are complex, involving anatomy, cells, and humoral factors. Intestinal macrophages (Mφ) play a key role in controlling gut immune responses and maintaining homeostasis. Substitution of Mφ with healthy ones improves IBD symptoms in a genetic mouse model of IBD (*Il10rb* deficiency). Depletion of endogenous Mφ was necessary to achieve therapeutic benefit. We surmised that this step was necessary to reset the Mφ niche and to prevent the polarization of incoming cells by the hyper-inflammatory environment. We hypothesized that locking Mφ before injection into an anti-inflammatory (M2) phenotype could improve therapeutic efficacy and eliminate the need for conditioning. In this study, we used CRISPR/Cas mediated knock-out (KO) of 12 genes or lentiviral addition of one gene to enforce an M2 phenotype in Mφ. Based on cell surface marker expression and cytokine secretion, we selected KO of *Stat1*, *Ecm1*, *Gsk3a*, *Dnmt1* and *Trim24*, or overexpression of constitutively active *Stat6* as promising candidates for promoting tolerance in IBD (A). All these candidates except *Stat1* KO led to an up to 3-fold upregulation of cell surface markers associated with M2 polarization. In contrast, KO of *Stat1* led to impaired acquisition of the inflammatory (M1) markers CD80 and CD86 in response to LPS and IFNγ (B). All candidates led to reduced expression of pro-inflammatory cytokines and chemokines upon LPS and IFNγ stimulation compared to control Mφ. Next, we evaluated the capability of genetically engineered Mφ to modulate naïve T-cell activation and polarization *in vitro*. For this, OVA-peptide stimulated macrophages were mixed with OT-II naive CD4+ T cells (C). *Stat1* KO did not change the proliferation of OVA-specific T cells compared to control Mφ but drastically increased the percentage of Gata3+ T cells, indicating increased differentiation towards Th2. While no significant changes were observed in T-reg induction, expression of mutant *Stat6* or KO of *Gsk3a* and *Dnmt1* led reduction of T cell proliferation. Finally, we evaluated the therapeutic potential of genetically engineered Mφ in *Il10rb*-deficient IBD mice. Transplantation of Mφ engineered to express mutated *Stat6* or KO of *Stat1* or *Gsk3a* led to improved clinical symptoms of IBD. We observed body weight gain (D), improved colon histopathology, and altered T cell activation in the mesenteric lymph nodes. This study highlights the potential of targeting Mφ polarization as a therapeutic strategy for IBD and possibly other inflammatory disorders, particularly those that are unresponsive to conventional anti-inflammatory therapy.



188 Impact of Genetic Diversity on Gene Therapy Efficacy

Joerg Votteler[1], Alma Chanelo[1], D'Shawna Burwell[1], Thao Tran[1], Youjun Chen[1], Charles Krause[1], Lorne Celentano[1], Abbie Svancarek[1], Haley Grooms[1], Alea Powell[1], Kelsey Higgins[1], Angela Mote[1], Layth Awartani[1], Rohini Sheth[1], Christine Daniels[1], Rachel Hedinger[1], Alan Curtis[1], Audry Fernandez[1], Shari N. Gordon[1], Xintao Zhang[2], Scott Hammond[1], Chengwen Li[2], Anna Tretiakova[1], Jude Samulski[1,2]

[1]Asklepios BioPharmaceutical, Inc. (AskBio), Durham, NC,[2]University of North Carolina, Chapel Hill, NC

Adeno-associated virus (AAV) vectors have been successfully applied in clinical trials in patients with many genetic disorders. Although promising results have been achieved, variable transgene expression and immune related adverse events remain a concern. Preclinical studies typically rely on inbred mouse disease models. The lack of genetic diversity in these inbred mice, in contrast to the human patient population, may limit the predictive ability of mouse models for therapeutic efficacy and immune responses in patients. To address this, we utilized the collaborative cross (CC) mouse strains to elucidate the role of genetic background on transgene expression and immune responses to AVV gene therapy. The CC is a panel of more than sixty recombinant inbred mouse strains derived from eight founder strains. These strains provide a reproducible source for genome-wide genetic variation for studies of human disease and drug development. For our study, we administered 3E11 particles of AAV8/GAA (acid α-glucosidase) vectors, *via* retro-orbital injection into 16 collaborative cross strains and the eight founder strains. This clinical vector, used in our Pompe program, directs liver expression of secreted GAA, which can be measured in serum by immunoblot or enzymatic activity. We monitored serum GAA activity over a six-month period. At month six, mice were euthanized, and we collected tissues to detect AAV genome copy numbers and to measure the phenotype and function of T cells in the spleen and antibody levels in serum. Overall, we observed a dramatic difference in transgene expression and immune response across the different CC and founder strains. Serum GAA activity varied by >100 fold across strains and displayed strain-specific expression kinetics. GAA expression in all strains increased in the first weeks and plateaued after week four. In distinct genetic strains, GAA expression

decreased over time. In some strains, higher GAA activity correlated with increased vector genomes in liver, suggesting differences in biodistribution and/or liver transduction were responsible. In other strains, however, there was discordance between transgene expression and liver transduction. Founder strains also differed in transgene expression and kinetics, to a lesser extant than the CC strains. Genetically diverse strains also demonstrated vast differences in the proportions of innate, B and T cell subsets in the spleen and varied in their reactivity to polyclonal T cell stimulation. AAV8 binding and neutralizing antibodies were detected in all animals, with some genetic strains having significantly higher anti-AAV antibody levels. In addition, one genetic strain demonstrated an AAV8 specific T cell response. GAA expression was inversely associated with the magnitude of anti-GAA antibodies in serum. A GAA specific T cell response was observed in two genetic strains, one of which had the lowest levels of GAA in serum. In summary, the data generated from this study shows that the genetic background of mouse strains has a substantial impact on gene therapy efficacy and immune response. This study argues for the use of diverse mouse strains on preclinical drug development. Since the parentage of CC strains is defined, it is possible to map phenotypic outcomes to genomic regions. More detailed knowledge about these influences may enable us to screen patients to ensure therapeutic efficacy, predict the immunological response and adjust the treatment to the individual patient.

189 Effective Readministration of AAV Gene Therapy Prevents Tumorigenesis in Infant PFIC3 Mice, a Mouse Model Prone to Hepatocellular Carcinoma

Nicholas D. Weber[1], Leticia Odriozola[2], Irene Ros-Gañán[1], Guillermo García-Porrero[3], David Salas-Gómez[2], Josepmaria Argemi[3,4,5], Jean-Philippe Combal[6], Kei Kishimoto[7], Gloria González-Aseguinolaza[1,2]

[1]Vivet Therapeutics, Pamplona, Spain,[2]Cima, Universidad de Navarra, Pamplona, Spain,[3]Clinica Universidad de Navarra, Pamplona, Spain,[4]University of Pittsburgh, Pittsburgh, PA,[5]Centro de Investigacion Biomedica en Red (CIBER-Ehd), Madrid, Spain,[6]Vivet Therapeutics, Paris, France,[7]Selecta Biosciences, Watertown, MA

Introduction: Treating pediatric patients with liver-targeted AAV-based gene therapy faces the significant obstacle of a loss of therapeutic effect over time. Indeed, natural liver growth and hepatocyte regeneration result in a decline in AAV episome-driven expression therefore necessitating readministration to restore AAV episome pools. Readministration is only feasible if steps are taken to prevent or overcome immunological memory which hampers AAV infection of target cells due to the presence of neutralizing antibodies. The development of a strategy for successful readministration may be essential for many pediatric liver disorders. For example, progressive familial intrahepatic cholestasis type 3 (PFIC3) is a rare hepatic condition that typically presents during infancy or early childhood and results from improper transport of phosphatidylcholine from hepatocytes into the bile due to mutations in the *ABCB4* gene. We have previously demonstrated successful therapeutic reversal of disease manifestations in a mouse model of PFIC3 with a single administration of VTX-803(8), a recombinant AAV8 carrying a codon optimized version of the human *ABCB4* gene. However, the long-term effects of VTX-803(8) treatment, including any effect on the development of hepatocellular carcinoma frequently observed in PFIC3 mice, had not been examined. **Methods:** We thus carried out further testing of VTX-803(8) in infant PFIC3 mice. Immunotolerogenic rapamycin-containing nanoparticles (ImmTOR) were co-administered with VTX-803(8) with the aim of inducing immune tolerance for AAV in very young mice (2 weeks old). Two weeks later VTX-803(8) was readministered to gauge immunological tolerance to a second AAV infection following a first administration admixed with ImmTOR. Long-term effects on PFIC3 disease manifestations and evidence of tumorigenesis were analyzed 8 months later. **Results:** Only animals given ImmTOR on the first administration and treated with a second VTX-803(8) administration achieved a long-term therapeutic effect as evidenced by normalization of serum biomarkers of cholestasis, hepatosplenomegaly, phospholipid content in the bile and liver fibrosis. At 8 months post-injection, control saline-treated animals and animals treated only one time with VTX-803(8) (either with or without ImmTOR) or two times without ImmTOR presented with liver lesions, gallstones (41%), and atypical hepatocellular neoplasms or dysplastic nodules detected via histopathological analysis (52%). In contrast, all mice that achieved successful transgene expression and reversal of cholestasis following repeat VTX-803(8) administration with ImmTOR did not show any sign of tumorigenesis. Further immunohistochemical and gene expression analyses of preneoplasia markers supported these findings, including differences in hepatocyte proliferation, bile duct proliferation and incidence of DNA double strand breaks. **Conclusions:** These outcomes support AAV-mediated gene therapy as a highly efficient and safe modality for a curative approach to inborn errors of metabolism including in very young patients. It also provides evidence countering the strong-held belief that AAV treatment is liable to increase the risk of hepatocellular carcinoma particularly when given to pediatrics or in patients with liver damage, which is an essential evaluation for the safety determination of this powerful therapy.

190 mRNA-3927 Therapy for Propionic Acidemia: Interim Data from a Phase 1/2 Study

Stephanie Grunewald[1], Saikat Santra[2], Dwight Koeberl[3], Andreas Schulze[4], Neal Sondheimer[4], Ayesha Ahmad[5], Gerald S. Lipshutz[6], Tarekegn Geberhiwot[7], Min Liang[8], Lerong Li[8], Ruchira Glaser[8], Nuria Carrillo[8]

[1]Great Ormond Street Hospital for Children and Institute for Child Health, NIHR Biomedical Research Center, London, United Kingdom,[2]Birmingham Women's and Children's NHS Foundation Trust, Birmingham, United Kingdom,[3]Duke University Medical Center, Durham, NC,[4]Hospital for Sick Children and University of Toronto, Toronto, ON, Canada,[5]University of Michigan, Ann Arbor, MI,[6]David Geffen School of Medicine at University of California at Los Angeles, Los Angeles, CA,[7]University of Birmingham, Birmingham, United Kingdom,[8]Moderna, Inc., Cambridge, MA. On behalf of the Paramount Trial Investigators

Background: Propionic acidemia (PA) is a rare and severe inherited metabolic disorder caused by pathogenic variants in the propionyl-coenzyme A carboxylase (PCC) α or β subunits (*PCCA* and *PCCB* genes, respectively) leading to PCC deficiency and subsequent accumulation of toxic metabolites. PA is characterized

by recurrent life-threatening metabolic decompensation events (MDEs) and multisystemic complications. Currently, there are no effective therapies for PA that target the underlying enzyme defects. mRNA-3927 is an investigational dual mRNA therapy that encodes for PCCA and PCCB that has shown to restore functional PCC activity in preclinical models. Results from an interim analysis of the first-in-human trial of mRNA-3927 are reported here. **Methods:** This ongoing global, phase 1/2, open-label, multicenter, dose-optimization trial (NCT04159103) evaluates the safety, tolerability, and pharmacology of mRNA-3927 in participants aged ≥1 year with genetically confirmed PA. The trial uses a staggered enrollment, dose-escalation approach to evaluate the intravenous administration of mRNA-3927. The initial dosing regimen was 0.3 mg/kg administered every 3 weeks (Q3W); subsequent doses were administered every 2 weeks (Q2W). Participants who complete the dose optimization trial (10 doses) are eligible to continue treatment in an open-label extension study (NCT05130437). Primary outcomes are safety and tolerability; secondary and exploratory outcomes include pharmacology and evaluation of potential plasma biomarkers and frequency and duration of MDEs, respectively. **Results:** As of January 5, 2023, 14 participants were enrolled across 5 dose cohorts: 0.3 mg/kg Q3W (n=4), 0.3 mg/kg Q2W (n=3), 0.45 mg/kg Q2W (n=3), 0.6 mg/kg Q2W (n=3), and 0.9 mg/kg (n=1). Nine participants completed the study and enrolled in the open-label extension (0.3 mg/kg Q3W [n=3], 0.3 mg/kg Q2W [n=3], 0.45 mg/kg Q2W [n=3]). A total of 214 doses were administered across both studies with a median treatment duration of 27.3 weeks (range, 3.0-85.6). No dose-limiting toxicities or study discontinuations due to drug-related treatment-emergent adverse events (TEAEs) have occurred. Across both studies, drug-related TEAEs were reported in 5 patients; all were grade 1 or 2. Preliminary analyses for patients administered mRNA-3927 suggest reductions in plasma biomarker levels. Additionally, in participants who reported MDEs in the 12 months prior to dosing, reductions in number and duration of MDEs were observed after the start of treatment with mRNA-3927. **Conclusion:** To date, mRNA-3927 has been well-tolerated at the doses administered, with encouraging early signs of dose-dependent pharmacology and potential clinical benefit.

191 A Pancreatic Gene Therapy Delivery Platform for the Treatment of Type 2 Diabetes

Jason A. West[1], Jacob Wainer[1], Alice Liou[1], Rebecca Reese[1], Nidhi Khanna[1], Suya Wang[1], Keiko Ishida[1], Nicole Picard[1], Camila Lubaczeuski[1], Christopher C. Thompson[2,3], Linda S. Lee[2,3], Roberto Trasolini[2,3], Emily Cozzi[1], Jay Caplan[1], Harith Rajagopalan[1]

[1]Fractyl Health, Inc., Lexington, MA,[2]Brigham and Women's Hospital, Boston, MA,[3]Harvard Medical School, Boston, MA

The pancreas plays a key role in regulating metabolism and is central to the pathogenesis of diabetes. Local delivery of adeno-associated virus (AAV) may represent a strategy to durably modulate pancreatic function and improve the risk-benefit profile of gene therapy for type 2 diabetes (T2D). We developed a novel AAV-based gene therapy platform to enable local and durable production of therapeutic proteins by the pancreas. Our aim was to assess the efficacy of AAV-driven beta-cell (β-cell) restricted production of a glucagon-like peptide 1 receptor agonist (GLP1RA) in a murine T2D model and establish the feasibility of a novel, endoscopic, ultrasound-guided, automated delivery system and route of administration (ROA) to enable local pancreatic gene therapy delivery in a porcine model. A GLP1RA transgene was chosen for proof-of-concept (POC) efficacy analyses. In db/db mice, a standard T2D model, we showed durable and dose-dependent improvements in glycemic control after a single intraperitoneal injection of an optimized AAV-based GLP1RA vector with a β-cell-restricted promoter (AAV-GLP1RA; n=8 per group). A 70% reduction in fasting blood glucose ($p<0.0001$), a 1.9-fold increase in fasting insulin ($p<0.01$), and improvements in glucose tolerance were observed to 10 weeks post-injection compared to controls. GLP1RA protein was islet-restricted with an average of 4.6% of cells staining positive by immunohistochemistry. Serum levels of GLP1RA were undetectable, suggesting that durable improvements in glycemic control were due to local intra-islet GLP1RA production and signaling. To enable local AAV delivery, an endoscope integrated with a proprietary delivery system was used to optimize direct pancreatic injections in Yucatan pigs. Over 20 pigs (30-40kg) have been injected with AAV via our ROA; and parameters including serotype (AAV8, AAV9), promotor (CMV, β-cell restricted), and dose (5E12-1.5E14 VG, ~1E11-5E12 VG/kg) were evaluated. We observed dose-dependent transduction activity of the pancreas by AAV as determined by green florescent protein (GFP) expression 3-4 weeks post-injection. In high dose (1.5E14 VG, ~5E12 VG/kg) AAV9-infused animals (n=4), an average of 46.7% of pancreatic cells were transduced with some regions showing over 95% activity, suggesting that this ROA holds promise for high on-target transduction by AAV-based pancreatic therapies. To establish the on- and off-target safety for AAV via this ROA, we assessed parameters including serum levels of pancreatic enzymes, AAV biodistribution, and organ histopathology. A dose-dependent elevation in serum lipase (up to 2.5-fold above baseline) was observed in some AAV-CMV-GFP treated pigs, which resolved by 72 hours post-injection. Biodistribution data from multiple tissues support high AAV exposure to the pancreas with limited off-target transduction for most of the assessed tissues. Dorsal root ganglia (DRG) transduction was also noted across multiple doses, with a relatively low dose of scAAV9-CMV-GFP (5E13 VG, ~1.3E12 VG/kg) leading to hindlimb ataxia in one pig. Corresponding histopathology showed pancreatic and DRG inflammation, which was attributed to GFP reporter immunogenicity, as using a β-cell-restricted promoter eliminated these findings (n=7). In aggregate, these studies provide POC for the durable efficacy of pancreatic gene therapy and establish the feasibility of a novel delivery system and ROA to directly target the pancreas. Further transgene, serotype, promotor, delivery system, and safety studies are ongoing toward the advancement of our platform for the treatment of metabolic diseases, including T2D.

192 Rescue of Glutaric Aciduria Type I Mice by Liver Directed Therapies

Mercedes Barzi[1], Collin G. Johnson[2], Tong Chen[1], Ramona M. Rodriguiz[1], Madeline Hemmingsen[1], Trevor J. Gonzalez[1], Alan Rosales[1], James Beasley[1], Cheryl K. Peck[3], Yunhan Ma[1], Ashlee R. Stiles[1], Timothy C. Wood[3], Raquel Maeso-Diaz[1], Anna Mae Diehl[1], Sarah P. Young[1], Jeffrey I. Everitt[1], William C. Wetsel[1], William R. Lagor[1], Beatrice Bissig-Choisat[1], Aravind Asokan[1], Areeg El-Gharbawy[1], Karl-Dimiter Bissig[1]

[1]Duke University, Durham, NC,[2]Baylor College of Medicine, Houston, TX,[3]Children's Hospital Colorado, Aurora, CO

Glutaric Aciduria Type I (GA-1) is an inborn error of metabolism with a severe neurological phenotype caused by the deficiency of Glutaryl-CoA dehydrogenase (*GCDH*), a downstream enzyme of the lysine catabolism pathway. GA-1 is an autosomal recessive disorder that affects 1:100,000 live births and is more common in certain populations with a founder mutation such as the Lumbee, the Oji-Cree and the Amish communities. Lysine catabolism pathway disruption by GCDH deficiency causes neurodegeneration and serious neurological problems in patients with GA-1. Currently, the only treatment option available for patients with GA-1 is lysine restriction, carnitine supplementation and emergency care during acute crisis. Previous literature suggests that the toxic catabolites responsible for the neuropathological phenotype of GA-1 are produced locally in the brain. As dietary lysine is mainly catabolized by hepatocytes, we hypothesized that restoring lysine catabolism in the liver is sufficient to restore GA-1 phenotype and propose a liver-directed gene therapy approach. 4-6-week-old *Gcdh*$^{-/-}$ mice exposed to high protein diet die within 5 days showing signs of lethargy and failure to thrive. In a series of experiments using knockout mice and hepatocyte transplantation, we first demonstrated that GA-1 catabolites in the brain originate from the liver and can cross the blood brain barrier. Next, we performed liver directed therapies to restore hepatic lysine catabolism function. For the first therapeutic approach, we injected *Gcdh*$^{-/-}$ mice with an Adeno-Associated virus (AAV) expressing *Gcdh* gene under a liver specific promoter. Introducing *Gcdh* cDNA in GA-1 adult mice rescued them from high protein-induced lethality, while mice injected in the neonatal phase succumbed when exposed to the diet at 4 weeks of age, possibly because of hepatocyte proliferation and consequent dilution of the viral episomes. As a second therapeutic approach, we blocked the production of toxic catabolites by deleting hepatic Aminoadipate-Semialdehyde Synthase (*Aass*), the first enzyme in the lysine catabolic pathway, using CRISPR/Cas9 genome editing tools delivered by AAV vectors. Liver specific *Aass* deletion in neonates protected GA-1 mice from high protein exposure at 4 weeks of age. Both therapeutic approaches could also reverse the typical neuropathological phenotype and restore the motor performance of GA-1 mice. Our results show that the neurological and metabolic phenotype of GA-1 mice can be rescued by different liver-directed gene therapies. Our findings question current pathophysiological understanding of GA-1 and reveal for the first time a targeted therapy for this devastating disorder.

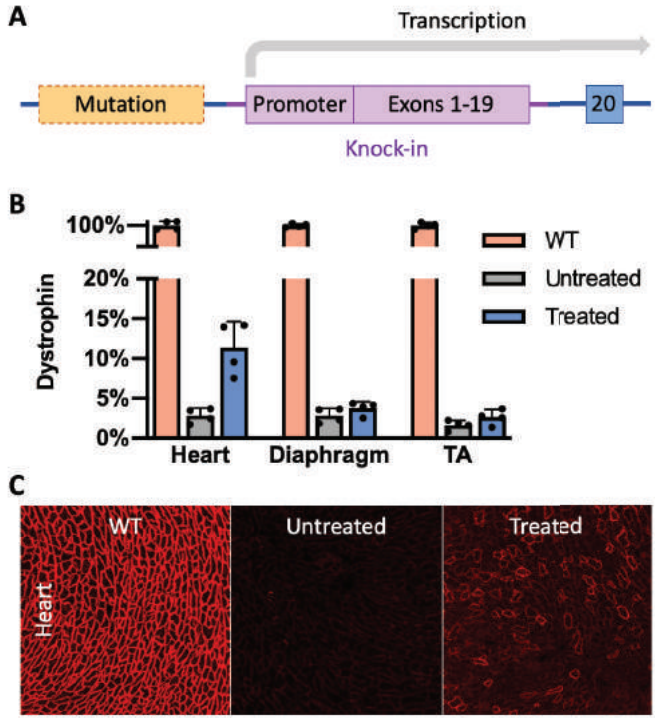
Novel Genetic Approaches for Muscle Diseases

193 CRISPR/Cas9 Homology-Independent Targeted Integration of Exons 1-19 Restores Full-Length Dystrophin in Mice

Stefan Nicolau, Anthony A. Stephenson, Tatyana A. Vetter, Gabrielle P. Dufresne, Emma C. Frair, Jessica E. Sarff, Gregory L. Wheeler, Benjamin J. Kelly, Peter White, Kevin M. Flanigan

Nationwide Children's Hospital, Columbus, OH

Background: Duchenne muscular dystrophy is an X-linked disorder typically caused by out-of-frame mutations in the *DMD* gene. Most of these mutations are deletions of one or more exons, which can theoretically be corrected to the wild-type sequence through CRISPR/Cas9-mediated knock-in of DNA fragments in *DMD*. Homology-independent targeted integration is a mechanism for achieving such a knock-in without reliance on homology-directed repair pathways, which are inactive in muscle. **Aims:** We designed a system based on insertion into intron 19 of a DNA fragment containing a pre-spliced mega-exon encoding *DMD* exons 1-19, along with the MHCK7 promoter (Figure A). In a series of experiments, we optimized the design of the system and demonstrated its ability to restore dystrophin expression in a mouse model of Duchenne muscular dystrophy. **Methods:** A pair of AAV vectors was used for systemic delivery of the gene editing system in neonate and adult mice carrying a *Dmd* exon 2 duplication. One vector encoded the guide RNA and knock-in construct, while the other encoded the *S. aureus* Cas9 enzyme. Biodistribution, knock-in efficiency, and transcript correction were measured by digital droplet PCR. Dystrophin expression was measured by quantitative immunofluorescence and capillary western immunoassay. Next-generation sequencing was used to assess editing outcomes at the target site and to screen for off-target activity. **Results:** Optimization experiments demonstrated that a Cas9:donor AAV ratio of 1:5 was more effective than a 1:1 ratio. Meaningful gene editing efficiency could be achieved with Cas9 under the control of the CMV, MHCK7, or SPc5-12 promoters, with a trend towards higher efficiency with SPc5-12. The CK8 promoter was ineffective. In all experiments, efficiency was higher in the heart than in skeletal muscles. Following optimizations, this system achieved editing of 1.4% of genomes in the heart, leading to 30% correction at the transcript level (measured as a fraction of all *Dmd* transcripts) and restoration of 11% of normal dystrophin levels (Figure B), as well as an increase in percent dystrophin positive fibers (Figure C). These data provide proof-of-concept for a gene editing system that could restore full-length dystrophin in individuals carrying mutations upstream of intron 19, accounting for approximately 25% of Duchenne muscular dystrophy patients.

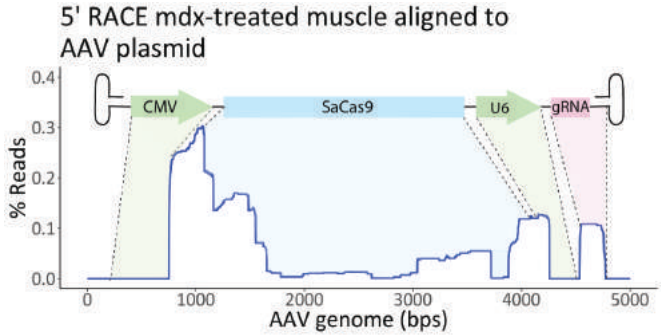


194 Orthogonal Long- and Short-Read Sequencing after AAV-CRISPR Reveals On-Target Heterogeneity and Chimeric AAV-*Dmd* Transcripts

Mary S. Jia[1], Made Harumi Padmaswari[2], Landon A. Burcham[1], Shilpi Agrawal[1], Christopher E. Nelson[1]

[1]Biomedical Engineering, University of Arkansas, Fayetteville, AR,[2]Cellular and Molecular Biology, University of Arkansas, Fayetteville, AR

Adeno-associated virus (AAV)-mediated delivery of CRISPR components has yielded promising preclinical results for treating Duchenne muscular dystrophy (DMD). However, the post-transduction consequences of AAV-CRISPR, including AAV integration, require further characterization to develop a comprehensive screening method. The common method for screening CRISPR-edited outcomes involves PCR-enriched short-read sequencing at cut sites. However, PCR bias produces unreliable quantification of on-target edits. Here, we analyze orthogonal long- and short-read sequencing approaches to determine the comprehensive outcome of CRISPR technologies at the DNA and RNA-level in DMD. These approaches have been replicated with *in vitro* mouse myoblast AAV and electroporation edited samples to determine editing outcome differences *in vitro* and *in vivo*. We performed intramuscular injections of AAV-CRISPR or liposomes containing SpCas9 mRNA excising exon 23 using dual gRNAs at intron 22 and 23, in *mdx* and wild-type mice. PCR-amplified short-read sequencing revealed indels at both cut sites. While tagging with unique molecular identifiers (UMIs) can ameliorate some PCR bias, this solution fails to detect large structural variants or the breadth of AAV-integration events. In comparison, Nanopore-sequencing results of a 10kb PCR-enriched amplicon at the target site produces a broader catalog of editing events but similarly excludes quantification of large structural on- and off-target modifications. To reduce bias, we developed short- and long-read sequencing libraries for PCR-enriched samples with UMI's to compare with nanopore Cas9-targeted sequencing (nCATS) samples of similar lengths. Using nCATS, we were able to successfully detect structural modifications and large integrations. To compare with a previously identified quantification standard, we developed a Tn5 tagmentation library loaded with UMI's and internally PCR-amplified within cut sites to quantify on-target deletion percentages. We also examined the transcriptional impact of AAV-CRISPR on *Dmd* in *mdx* and wild-type mice. Nanopore-sequencing of 3kb PCR-enriched cDNA libraries failed to provide sequencing depths necessary to detect editing events. However, 5' RACE nanopore libraries revealed the presence of AAV integration at the RNA-level ranging up to 0.3% of reads creating a Cas9-dystrophin chimeric RNA with the transcriptional start site originating downstream of the internal CMV promoter in the AAV genome. To further examine AAV-integration profiles in the genome, we performed 3' RACE using the integrated AAV genome as the gene-specific primer to detect alternative off-target locations of AAV integration and additional chimeric transcripts. Owing to transcriptional regulation differences between *mdx* and wild-type mice, investigating the outcomes of AAV-CRISPR in both lines produced differing results. We also used next-generation enrichment approaches to investigate prime editing-mediated exon skipping or targeted integration by PASTE for DMD *in vitro*. Our results indicate that double-stranded break-free methods are more precise but have a low efficiency at target sites. Our results contribute significant considerations for the translation of AAV-CRISPR for DMD or similar monogenic diseases and facilitates the redefinition of sequencing standards for CRISPR readout.



195 AAV-NoSTOP Gene Therapy for Nonsense Mutation Mediated Dysferlinopathy

Mengyao Xu, Jiaming Wang, Jialing Yang Liang, Lingzhi Ren, Nan Liu, Chen Zhou, Guangping Gao, Dan Wang

Horae Gene Therapy Center, University of Massachusetts Chan Medical School, Worcester, MA

Dysferlinopathy is a group of heterogenous autosomal recessive muscular dystrophies caused by loss-of-function mutations in the *DYSF* gene, which encodes dysferlin, a 237-kDa transmembrane protein involved in membrane repair. Currently, there is no treatment available for dysferlinopathy. Our lab previously reported AAV-NoSTOP (Wang J. et al. *Nature* 2022), an *in vivo* gene therapy approach that uses AAV-delivered suppressor tRNA (sup-tRNA) to promote readthrough of a pathogenic premature termination codon (PTC) causing mucopolysaccharidosis type I (MPS-I). One advantage of

AAV-NoSTOP is that it obviates the need to deliver a cDNA that may exceed the packaging limit of AAV vectors, such as the 6.2 kb *DYSF* cDNA. Intriguingly, a sup-tRNA may be broadly applicable to target the same PTC (e.g., UAG) underlying various diseases. Here, we generated a knock-in mouse model of dysferlinopathy carrying a *Dysf* nonsense mutation, and tested the therapeutic efficacy of the same sup-tRNA that we originally developed in the context of MPS-I. Using CRISPR-based genome editing, we generated mice harboring the *Dysf* p.Y522* mutation (TAT to TAG) that is commonly found in Korean patient population. In homozygous mice ($Dysf^{KI/KI}$), dysferlin protein in the heart and skeletal muscle was undetectable by Western blot, and *Dysf* mRNA was significantly reduced due to nonsense-mediated mRNA decay (NMD). To target muscle, we packaged the UAG-targeting, tyrosine tRNA-derived sup-tRNA gene (sup-$tRNA^{Tyr}$) into AAVMYO, a muscle-tropic capsid. In a pilot experiment, we treated adult $Dysf^{KI/KI}$ mice with AAVMYO.sup-$tRNA^{Tyr}$ via systemic tail vein injection, and found that dysferlin protein was restored to 15% of wild-type level in the heart, although only 2% restoration was observed in skeletal muscles. These preliminary results suggest that the $Dysf^{KI/KI}$ mouse model is suitable to test AAV-NoSTOP, and that the sup-$tRNA^{Tyr}$ is potentially efficacious to target UAG PTCs in various gene and disease settings. It was recently shown that 10-20% of normal dysferlin expression in mice is sufficient to prevent the disease phenotype. To further increase PTC readthrough and dysferlin restoration in the skeletal muscle, we are testing more potent muscle-tropic capsids, optimizing the transgene design, and exploring other sup-tRNAs.

196 Development of Myorganoids for Therapeutic Evaluation of Gene Therapy Products in Duchenne Muscular Dystrophy

Laura Palmieri, Isabelle Richard, Sonia Albini
GENETHON, Evry, France

Duchenne Muscular Dystrophy (DMD) is a rare genetic disease that affects the skeletal and cardiac muscles, leading to progressive muscle wasting and premature death. DMD is caused by the lack of Dystrophin, a muscle structural protein required for the biomechanical support of myofibers. Despite the enormous progression done in the gene therapy field using a short form of dystrophin (micro-dystrophin), there is still no cure for the disease. Moreover, the immunogenic risk associated to the high dose of AAV makes necessary the identification of other therapeutic options beyond or in support of gene therapy. This clearly indicates that animal models, although particularly important for pilot studies, do not recapitulate in full human DMD pathology and cannot predict the real efficiency and safety of a treatment, thereby highlighting the urgent need to develop *in vitro* model mimicking human DMD phenotype suitable as screening platform for test therapeutic products. The generation of reliable DMD human models in a dish would also limit animal wasting as it would allow a preselection of therapeutic candidates for further in vivo investigation (toxicology, immunological studies). Among the *in vitro* cellular models, organoid-like structures are becoming an appealing resource for disease modeling and replacement of animal models. As such, the use of 3D cultures and biomaterials allows the reconstitution of tissue architecture and microenvironment that are instrumental for pathophysiological studies Here, we describe the generation of MYOrganoids based on the optimization of a previously reported protocol that allows rapid generation of a pure population of myogenic precursors cells. MYOrganoids were generated by 3D culture of patient-specific iPSC-derived muscle precursors and isogenic fibroblasts within a collagen-based scaffold and silicone stretchers which supports the growth of ring-shaped tissues under mechanical load. MYOrganoids showed structural and functional maturation that allowed force analysis studies upon electrical stimulation. We proved that DMD-derived MYOrganoids recapitulate salient features of DMD pathogenesis, such as membrane fragility and force drop upon eccentric contraction. We then employed our system to evaluate the therapeutic efficiency of micro-dystrophin, a gold standard in the AAV-gene therapy, as a proof of concept. Interestingly, we showed that DMD MYOrganoids, subjected to eccentric contraction, better retain muscle force after micro-dystrophin treatment. This indicates that our system has the potential to be a valuable human *in vitro* counterpart to animal *in vivo* studies, to test the real efficacy of gene therapy and alternative treatments.

197 CRISPR-Mediated Insertion of a Transferrin Receptor-Targeted *GAA* Transgene into Hepatocytes Provides Effective, Long-Lasting Treatment of Muscles and the Central Nervous System in Neonate and Adult Pompe Disease Mice

Maria Praggastis[1], Kirsten Gale[1], Andrew Baik[1], Nina Aaron[1], Nyanza Rothman[1], Xiaoli Zhang[1], Nicholas Giovannone[1], Elizabeth Hwang[1], Sven H. Moller-Tank[1], Aris Economides[2], Christos Kyratsous[1], Leah Sabin[1], Katherine Cygnar[1]
[1]Regeneron Genetics Medicine, Regeneron Pharmaceuticals, Tarrytown, NY,[2]Synthetic Biology & Cell Engineering, Regeneron Pharmaceuticals, Tarrytown, NY

Pompe disease is a lysosomal disease caused by mutations in the acid alpha-glucosidase (*GAA*) gene. Loss of GAA results in toxic accumulation of lysosomal glycogen in tissues. Pompe disease manifests as muscle weakness, respiratory failure, increased risk of aneurysm and stroke, and in severe cases intellectual disability. The prevalence of central nervous system (CNS) manifestations of Pompe disease is much higher in severe, late-onset Pompe disease and infantile-onset Pompe disease. The current standard-of-care enzyme replacement therapy treats the peripheral pathologies in Pompe patients, but this therapeutic requires lengthy biweekly infusions, high doses of drug as GAA has weak tropism to muscle tissues and does not treat the central nervous system. Liver-directed AAV gene therapy may improve muscle phenotypes due to high continuous expression of GAA but is also unlikely to robustly treat the CNS as GAA poorly crosses the blood brain barrier (BBB). Additionally, conventional AAV gene therapy utilizes AAV episomes to express GAA, which will be lost as hepatocytes divide due to liver growth or damage. As such, episomal gene therapy has limitations for treating the significant pediatric population of Pompe patients. Here, we present: **(1)** A rapid *in vivo* screen of 31 anti-human TfR1 antibodies in *TfRC* humanized mice for their ability to deliver GAA across the BBB. Based on hydrodynamic delivery, this screening strategy effectively identified top antibodies which delivered GAA

to the CNS without needing to generate AAV or purified protein. In contrast to some previous literature on anti-TFR antibodies, we found that high-affinity antibodies rather than low-affinity antibodies imparted the best delivery to both the CNS and muscles. **(2)** A CRISPR-mediated insertion approach for both infantile and late-onset Pompe disease, where a transgene is inserted into the first intron of the albumin locus to express anti-hTfR1:GAA under control of the endogenous albumin promoter. The insertion template DNA encoding anti-hTfR1:GAA is delivered by an AAV, and an mRNA encoding Cas9 and a gRNA specific for a site in the 1st intron of albumin is delivered by a lipid nanoparticle. Insertion of anti-hTfR1:GAA in this manner provided robust expression from a single dose, and **complete or near-complete clearance of pathogenic glycogen from the heart, skeletal muscles, the dorsal root ganglion, spinal cord, and the brain** in Pompe disease model mice within 3 weeks after delivery. We have previously presented that CRISPR-mediated insertion of muscle targeted antibody-GAA fusion (anti-CD63:GAA) in **neonatal mice** resulted in stable expression throughout a 15 month study, whereas expression from episomal AAV decreased over time. Here, we further show that this approach is a platform which can be translated to across transgenes, as well as to non-human primates. By administering a BBB-crossing GAA fusion via CRISPR-mediated insertion, this approach has the potential to be a true single-dose therapy with life-long efficacy for both late-onset and infantile-onset Pompe disease.

198 Improved AAV-Mediated Systemic Gene Therapy to Striated Muscles through Increased Tissue Perfusion

Fatemeh (Ellie) Khadir[1], Monika Chauhan[1], Audrey L. Daugherty[1], Jennifer A. Tinklenberg[1], Peter B. Kang[1], W. Todd Cade[2], Christina A. Pacak[1]

[1]Department of Neurology and Paul and Sheila Wellstone Muscular Dystrophy Center, University of Minnesota, Minneapolis, MN,[2]Doctor of Physical Therapy Division, Duke University, Durham, NC

One of the most common and efficient gene delivery vectors is adeno-associated virus (AAV). For many disorders, systemic delivery of gene therapy is necessary to gain the desired distribution of vector and achieve a therapeutic effect in target tissues. As this typically requires high doses of AAV which can have safety concerns, methods to improve efficacy and reduce gene therapy doses are highly desirable. A potential solution for certain diseases could be to induce a rebalancing of tissue perfusion in the body to favor specific target organs via low-intensity acute aerobic exercise prior to systemic intravenous (IV) AAV administration. To test this, we assessed systemic IV delivery of the marker gene vector AAV9-CBA-Luciferase (AAV9-Luc) at a dose of 5 ×1012 vg/kg via the jugular vein in adult wild-type C57/BL6 mice following 1) no intervention, 2) a single bout of acute, low-intensity, aerobic treadmill exercise, 3) a single bout of acute, high-intensity, aerobic treadmill exercise, and 4) administration of Dobutamine (a beta-1 agonist drug) to provide increased ventricular contractility and, decreased afterload as a potential exercise surrogate. Vital measurements including heart rate, perfusion index, temperature, and oxygen saturation (SpO2) were acquired immediately following the intervention and for up to 10 minutes following AAV administration. Non-invasive, in vivo bioluminescence imaging of the luciferase reporter was performed every other week until the completion of the study at 6 weeks post-administration. Full necropsies were performed and tissues were being assessed for vector genome (vg) uptake, transgene transcription levels, luciferase activities, and immunofluorescence imaging to determine the location and quantification of expression within tissues. Our results show that the low and high intensity exercise and dobutamine groups all display a significant increase in tissue perfusion and heart rate at the time of AAV IV administration (10 minutes post-intervention). Based on our tissue assessments thus far, in vivo bioluminescence imaging data revealed an increase in luciferase expression based on detected relative luciferase units in the low intensity exercise and dobutamine groups. Luciferase RNA transcript levels were found to be significantly increased in the heart, liver, brain cortex, gastrocnemius, and extensor digitorum longus (EDL) in the low intensity group, the quadriceps in the high intensity exercise group, and the heart, liver, and tibialis anterior in the dobutamine group each as directly compared to no-intervention, AAV treated control mice. Ongoing studies include completion of vector genome and RNA transcript assessments, evaluations of luciferase expression within tissue sections, and luciferase protein expression levels. Additional mice are being added to each cohort to evaluate the effects of each intervention on AAV receptor expression. Our results suggest that an increase in heart rate and tissue perfusion caused by either one bout of exercise or dobutamine administration can significantly increase the effectiveness of systemic AAV gene therapies targeting striated muscles.

199 PGN-EDODM1 Nonclinical Data Demonstrate Potential for Meaningful Impact in Myotonic Dystrophy Type 1 (DM1): Support for Phase 1 Clinical Trial Design

Ashling Holland[1], Arnaud Klein[2], Caroline Godfrey[1], Jane Larkindale[1], Niels Svenstrup[1], Sonia Bracegirdle[1], Denis Furling[3], Brijesh Garg[1], James McArthur[4], Jeff Foy[1], Michelle Mellion[1], Jaya Goyal[1]

[1]PepGen, Cambridge, MA,[2]Sorbonne Université, Inserm, Institut de Myologie, Centre de Recherche en Myologie, Paris, France,[3]Centre de Recherche en Myologie Sorbonne Université & Inserm Institut de Myologi, Paris, France,[4]Pepgen, Cambridge, MA

Background: PepGen's Enhanced Delivery Oligonucleotide (EDO) cell-penetrating peptide technology is engineered to optimize tissue delivery and cellular uptake of therapeutic oligonucleotides. Delivery of oligonucleotides to affected tissues is a major challenge that limits their efficacy. PGN-EDODM1 is being evaluated for the treatment of DM1. PGN-EDODM1 binds to the pathogenic trinucleotide repeat expansion in *dystrophia myotonica protein kinase* (*DMPK*) mRNA and reduces sequestration of muscleblind (MBNL) proteins to the myonuclear RNA foci through a steric blocking mechanism. Release of MBNL1 protein is hypothesized to correct DM1 spliceopathy; a central cause of DM1. **Objectives:** To develop a nonclinical dataset, including in vitro and in vivo pharmacology studies, to support initiation of clinical studies of PGN-EDODM1. **Methods:** In vitro studies: DM1 patient derived myoblasts with 2,600 CTG repeats and control myoblasts were treated with PGNEDODM1, and nuclear RNA foci profiles, splicing events and levels of *DMPK* transcript were evaluated after 24 hours. In vivo studies: PGN-EDODM1 or vehicle control were administered

intravenously to the DM1 mouse model HSA^{LR} (containing ~220-250 CTG repeats in the *HSA* gene). Splicing events and myotonia were measured, as well as effects on select off-target transcripts containing CUG repeats. Long-term effects of PGN-EDODM1 were investigated by splicing changes over 24 weeks after a single dose. Studies in non-human primates (NHPs): Three doses of 10, 30 or 60 mg/kg of PGN-EDODM1 were administered every two weeks or every four weeks (60 mg/kg only) to NHPs and one week following the final dose, *DMPK* transcript levels were evaluated by RT-PCR and normalized to *RPLP0*. **Results:** PGN-EDODM1 administration resulted in a dose-dependent reduction in toxic RNA foci and correction of mis-splicing in DM1 differentiated myotubes. *DMPK* levels remained unchanged in differentiated myotubes after administration of PGN-EDODM1. In the HSA^{LR} model, a single dose resulted in high muscle concentrations of PGN-EDODM1, resolution of myotonia at 2-weeks postdose and dose-dependent correction of mis-splicing. Correction of splicing has a long duration of action persisting up to 24 weeks. Off-target effects were not observed in other transcripts containing more than 10 CUG repeats in mice. In NHPs, PGN-EDODM1 resulted in no decreases in *DMPK* expression. **Conclusions:** There are no approved therapies for DM1. PGN-EDODM1 shows considerable therapeutic potential both in vitro and in vivo, including correction of myotonia in an established mouse model of DM1 and correction of key mis-spliced transcripts without the degradation of *DMPK* (or *HSA*) both in vitro and in vivo. Nonclinical data of PGN-EDODM1 support a Phase 1 single-ascending dose study in adults with DM1 that we plan to initiate in 2023. Details of the clinical trial design will be presented.

Breaking Gene Editing and Other Barriers for Cardiovascular and Pulmonary Diseases

200 Gene Transfer Efficiency in Models of Increased Secreted Airway Mucins

Kenan Najdawi, Christian Brommel, Ashley L. Cooney, Patrick L. Sinn

University of Iowa, Iowa City, IA

Airway mucus is essential for lung health by trapping inhaled small particles and transporting them out of the lung via mucociliary transport. Viral-based vectors, such as adenovirus, adeno-associated virus, and lentivirus, have all shown promise at delivering CFTR cDNA (gene addition) or gene editing machinery, such as CRISPR-Cas9, to airway epithelial cells. Given the role of airway mucus in host defense, one can easily envision mucus as a possible barrier to efficient viral vector mediated gene transfer, particularly in CF airways. Many studies use CF sputum as a model for the mucus barrier; however, this model may not accurately represent the dynamic *in vivo* environment. The goals of this study are to: 1) determine the degree to which mucus prevents viral vector mediated transduction; 2) advance physiologically relevant *in vitro* and *in vivo* models of mucus barriers to gene therapy reagents; and 3) determine if mucolytic interventions can improve vector transduction of airway epithelial cells. We first tested an ex vivo model using tracheal explants from CF and non-CF pigs. Explants maintained on surgifoam retain their tissue and cellular morphology for at least four weeks; additionally, they remain capable of mucus secretion from both goblet cells and submucosal glands. Explants were treated with methacholine, a cholinergic agonist that stimulates glandular mucus secretions. We observed that Ad5 vector expressing mCherry readily transduced methacholine treated tracheal explants. Using microscopy and ImageJ, we quantified Ad transduction following treatments with the reducing agent dithiothreitol (DTT) or the airway surfactant lysophosphatidylcholine (LPC). The addition of LPC had the greatest impact on gene transfer efficacy. We next investigated Ad5 transduction in a mouse model of goblet cell metaplasia. IL-13 treatment induces goblet cell metaplasia and increases mucus secretion. IL-13 vs saline pre-treated mice were instilled intratracheally with Ad5 expressing firefly luciferase ± LPC. Similar to the results in methacholine treated explants, the IL-13 treatment group did not result in a decrease of transgene expression; however, the addition of LPC improved transduction. Although these models do not fully recapitulate the complex inflammatory environment of the CF lung these results do suggest that mucus hypersecretion is not a significant impairment to Ad5 transduction, especially in conjunction with an LPC vehicle. Ongoing studies are investigating the impact of mucus hypersecretion on lentiviral and AAV-based vectors.

201 *SCN10A-short* Gene Therapy for the Treatment of Cardiac Conduction Disorders

Jianan Wang[1], Arie O. Verkerk[1], Ronald Wilders[1], Mischa Klerk[1], Arie R. Boender[1], Osne F. Kirzner[1,2], Klaus Neef[2,3], Hanno L. Tan[1,2], Harsha D. Devalla[1], Vincent M. Christoffels[1], Phil Barnett[1], Gerard Boink[1,2]

[1]Amsterdam UMC, Amsterdam, Netherlands,[2]PacingCure B.V., Amsterdam, Netherlands,[3]UMC Utrecht, Utrecht, Netherlands

The cardiac voltage-gated sodium channel $Na_V1.5$ is an important therapeutic target to treat cardiac conduction disorders, such as Brugada syndrome and isolated cardiac conduction defect. However, the large size of *SCN5A* encoding $Na_V1.5$ imposes a substantial challenge to gene therapeutic interventions. Alternatively, small proteins that modulating sodium current can be good gene therapeutic targets. We previously reported that a naturally occurring short transcript encoding a C-terminal portion of neuronal *SCN10A (SCN10A-short)* increases sodium current in an *SCN5A*-dependent manner. In the present study we developed an AAV-based *SCN10A-short* gene therapy for the treatment of cardiac conduction disorders. First, we studied the effect of *SCN10A-short* overexpression in wild-type mouse cardiomyocytes using single cell patch-clamp. *SCN10A-short* overexpression resulted in a significantly larger sodium current and faster action potential upstroke. We next studied whether *SCN10A-short* gene therapy could improve cardiac conduction in $Na_V1.5$ haploinsufficient mice. Heterozygous *Scn5a* mutant mice were treated with either moderate dose or high dose *SCN10A-short* gene therapy and mice that received treatment with moderate dose GFP gene therapy were used as control. Two weeks post injection, hearts were isolated and perfused on a Langendorff setup, where optical mapping was performed to measure epicardial conduction. Compared with controls, mice receiving moderate dose *SCN10A-short* gene therapy showed significantly increased conduction velocity in the left ventricle. Strikingly, the high dose *SCN10A-short* gene therapy led to faster

conduction velocities in both ventricles, which was comparable to wild-type hearts. Electrocardiogram (ECG) analyses revealed significantly shorter QRS duration which is similar to wild-type, in high dose *SCN10A-short* treated animals as compared with controls, reflecting the improved cardiac conduction. To validate our gene therapy in human cells, we also tested the effect of *SCN10A-short* overexpression in cardiomyocytes obtained from human induced pluripotent stem cells. Single cell patch-clamp experiments showed a significantly higher action potential upstroke velocity compared with GFP-treated control cells, demonstrating a substantial increase in *SCN10A-short* induced sodium current in a human background. Finally, we tested the *in silico* effects of *SCN10A-short* on human ventricular conduction velocity and excitability in case these were affected by a severe loss-of-function mutation in *SCN5A*. In a linear strand of left ventricular cells, the conduction slowing and excitability loss caused by the mutation were largely restored with *SCN10A-short.* In a linear strand model with multiple branches, the mutation-induced partial conduction block in the branched part of the strand was fully restored by the application of *SCN10A-short.* In summary, our results highlight the potential of *SCN10A-short* gene therapy as an effective therapeutic intervention to normalize cardiac conduction in inherited and acquired conduction disorders.

202 EV-AAVs as a Novel Gene Delivery Vector to the Heart: New -Evaluations for EV-AAVs and Free AAV Separation

Sabrina La Salvia[1], Xisheng Li[1], Shweta Lodha[1], Tina Chen[2], Anh Phan[1], Nikhil Raisinghani[1], Shihong Zhang[1], Edgar Gonzalez- Kozlova[2], Navneet Dogra[2], Roger J. Hajjar[3], Sahoo Susmita[1]

[1]Department of Cardiology, Icahn School of Medicine at Mount Sinai, New York, NY,[2]Department of Pathology, Icahn School of Medicine at Mount Sinai, New York, NY,[3]Flagship Pioneering, Cambridge, MA

Introduction: Adeno-associated viruses (AAVs) are one of the best vectors to deliver genes to the heart due to high transgene expression and safety in clinics. However, pre-existing AAV neutralizing antibodies (NAbs) in patients binds to AAVs, prevent efficient gene transduction and limits the number of patients eligible for gene therapy. Here, we have shown that extracellular vesicle-encapsulated AAVs (EV-AAVs) are a superior cardiac gene delivery vector that delivers more genes and offers higher NAb resistance comparted to free-AAVs. Presence of free AAV contaminants in EV-AAV preparations may reduce effective EV-AAV dosing, lower their NAb resistance, and cause unwanted side effects. Therefore, novel methods are required to efficiently remove free AAVs from EV-AAV preparations to improve their efficacy. **Methods and Results:** We use a two-step iodixanol density-gradient ultracentrifugation method (UC+DG) to purify EV-AAVs from free of AAV contamination. We comprehensively characterized the isolated EV-AAVs for their morphology, presence of EV specific markers, size, concentration and AAV genome titer using WB, nano (EV)-flow cytometry, qPCR, TEM, DLS. To develop a scalable EV-AAV production for clinical applications, we compared the UC+DG method with two new, fundamentally distinct technological solutions — a nanofluidic deterministic lateral displacement (nanoDLD) device and size-exclusion chromatography (SEC). We ranked the techniques by their output for EV-AAV enrichment, runtime, reproducibility, processing volume and ease of use. We comprehensively compared all 3 technologies for EV-AAV isolation using a combination of experimental and computational modeling and report that ~25-50% of AAV vector genome is secreted via tetraspanin positive, NAb-resistant, ~80nm EV-AAVs. In addition, our results demonstrated NAb evasion and therapeutic efficacy of EV-AAVs. Intramyocardially injected EV-AAV9-SERCA2a, a known therapeutic cardiac gene, to post- infarcted (LAD ligated), pre-immunized mouse hearts significantly improved ejection fraction and fractional shortening compared to free AAV9-SERCA2a delivery. Using PKH67-fluorescent dye or pH sensitive (CypHer) dye, we show that EV-AAVs were internalized into acidic endosomal compartments before reaching the nucleus in human cardiomyocytes.**Conclusion:** We confirmed efficient separation of EV-AAVs from free AAVs using UC+DG as EV gold standard method, and we provided valid and alternative EV-AAV isolation technologies highly adoptable for clinical use. We also show significantly higher potency and therapeutic efficacy of EV-AAVs compared to free AAVs. Our results establish the potential of EV-AAVs as a state-of-the art gene delivery vector to treat heart failure and our study demonstrates a successful approach to technology development for isolating EV-AAVs providing innovative solutions to a critical barrier in gene therapy.

203 Proliferation and Differentiation Potential of CFTR-Expressing Epithelial Cells in Mouse Airways

Jia Ma, Meihui Luo, Feng Yuan, Shuang Wu, Xiaoming Liu, John F. Engelhardt

Department of Anatomy and Cell Biology, University of Iowa, Iowa City, IA

Cystic fibrosis (CF) is an inherited disease caused by mutations of *Cystic Fibrosis Transmembrane Conductance Regulator (CFTR)* gene. Lung diseases is the main cause of death in CF patients. Genetic therapy targeting airway epithelial stem cells thus holds considerable promise for permanent cure of CF disease. CFTR is heterogeneously expressed in distinct airway epithelial cell types including basal cells, secretory cells, and pulmonary ionocytes. CFTR protein was largely undetectable in airway basal cell membranes, however, a subset of airway basal cells destined to be secretory cells expresses CFTR mRNA. The role of these CFTR-expressing basal cells in airway epithelial regeneration and maintaining physiologic homeostasis of airway epithelium remain unclear. To better define the role CFTR-expressing basal cells in the airway epithelial regeneration, a mouse model capable of fate mapping CFTR-expressing cell types was created by inserting an ires-CreERT2 cassette into the 3'UTR of the *Cftr* gene. Rosa26nTnG::*Cftr*-ires-CreERT2 (Rosa::*Cftr*Cre) reporter transgenic mouse were created fate map CFTR expressing cells. CFTR-expressing cells in Rosa::*Cftr*Cre mice when genetically labeled with tamoxifen converts nuclear tdTomato (nT) to nuclear GFP (nG) expression. The CFTR-expressing cell lineages could be identified by immunolocalization of nG and airway epithelial cell markers in native mouse airway and using an air-liquid interface (ALI) cultures generated from primary surface tracheal basal cells and submucosal gland (SMG) cells of Rosa::*Cftr*Cre mouse airways. Results showed that rare GFP-labeled cells were mainly confined to the proximal tracheal epithelia and SMGs in the trachea of transgenic mice. Labeled secretory and intermediate basal cells were absent in the trachea and only rare club labeled cells were present in the intralobar

airways. Notably, GFP-labeled cell colonies were observed along the distal tracheal epithelia in mice following naphthalene-induced airway epithelial injury. In addition, a high frequency of GFP+ Type II alveolar cells were observed lung paryncyhma. Immunolocalization analysis demonstrated that majority of GFP-labeled cells also express ionocyte marker Bsnd and FoxI1 in the proximal trachea, and surfactant protein-C in alveoli. The observation in native transgenic mouse trachea was further corroborated in ALI cultures generated from cells of surface airway epithelium (SAE) and SMGs. Fate mapping of CFTR expressing during *in vitro* airway epithelial cell differentiation in the presence of hydroxytamoxifen demonstrated that >80% of GFP-labeled lineages expressed ionocyte markers Bsnd and FoxI1, but not major epithelial cell types such as ciliated, secretory and basal cells. Notably, SMG-derived progenitors generated significantly more lineage-labeled cells than SAE progenitors, the majority of which also expressed Bsnd and FoxI1, suggesting that SMGs may be enriched in progenitors of pulmonary ionocytes. Interestingly, FACS sorted GFP-labeled epithelial cells from ALI cultures of primary airway epithelial cells Rosa::*Cftr*Cre mice demonstrated the ability to differentiate into airway ciliated, secretory, and ionocytes, when they were reseeded on ALI membrane for epithelial cell differentiation. These data suggest that a subset of CFTR-expressing basal cells and/or club secretory cells are multipotent progenitors. Further studies of the GFP-labeled cells at single cell resolution may help to better define pulmonary CFTR-expressing progenitors in airways.

204 AAV Gene Editing Extends Survival in a Mouse Model of Surfactant Protein B Deficiency

Sylvia P. Thomas[1], Jakob M. Domm[1], Liqun Xu[2], Arul Vadivel[2], Yanlong Pei[1], Jake G. E. Yates[1], Khalil Karimi[1], Wei Zhang[3], Martin H. Kang[4], Bernard Thebaud[5], Sarah K. Wootton[1]

[1]Department of Pathobiology, University of Guelph, Guelph, ON, Canada,[2]The Ottawa Hospital Research Institute, Ottawa, ON, Canada,[3]Department of Molecular and Cellular Biology, University of Guelph, Guelph, ON, Canada,[4]Medical University of South Carolina, Summerville, SC,[5]The Ottawa Hospital Research Institute, Ottawa, ON

Surfactant protein B (SP-B) deficiency (OMIM#265120) is a monogenic disorder that demonstrates lethality in the neonatal stage. Infants diagnosed with this disorder display respiratory distress and survival is limited to the 1-year post birth. The disorder is caused by a mutation in the *SFTPB* gene and leads to lung atelectasis due to improper surfactant production. Current treatment options include exogenous drug delivery, a transient manner to treat the disease, but successful long-term treatment is dependent on a lung transplant. Due to the risks involved with transplantation, alternative treatments are needed for this afflicted pediatric population. One proposed concept is treating patients with gene therapy. Viral based gene therapy vectors, such as adeno-associated viral vectors (AAV), have gained popularity in the past decade, due to their strong safety and efficacy profile. We previously demonstrated that survival can be significantly extended in surfactant protein B knockout mice when an engineered AAV6.2FF vector expressing the SP-B gene is administered into the lungs. With this gene addition platform survival can be extended to 294 days, however further advancements to this vector-based gene therapy are needed to address the waning expression observed. Due to the immunity developed upon AAV exposure, repeat administration with the same capsid has been shown to be ineffective. Therefore, a more permanent form of gene therapy is required to obtain sustained expression in this pediatric population, ensuring long term expression in the developing organ targeted without expression dilution overtime from cell turnover. Gene editing tools allow for permanent gene correction and here we investigated whether our AAV-CRISPR platform could extend survival in SP-B -/- mice. Using our AAV-CRISPR platform we achieved gene insertion efficiencies from 6% up to 25% in lung epithelial cells that increased in a dose dependent manner. Here we applied both the donor and nuclease templates in separate AAV capsids with the aim of permanently modifying the genome to insert a functional SP-B gene. Treatment groups were as follows: control groups of untreated mice either on or off dox (n=6 for each) and a group of mice delivered the gene addition form of the SP-B platform (n=4), in addition to, gene editing groups that consisted of mice delivered either 1e12 vg of the donor template (n=3) or 1e12 vg of donor template and 5e11 vg of the nuclease (n=6). In this proof-of-concept trial, we were able to see significant extension in median survival (P=<0.0001) in the gene corrected mice administered both donor and nuclease template. Median survival for this groups was approximately 16 days in comparison to the 6-day survival seen in the donor template only group. As of February 1st, 2023, there is still one mouse remaining in the donor and nuclease gene edited group, still surviving at 231 days. This data demonstrate the safety and efficacy of this AAV-CRISPR platform for lung gene editing and establishes a baseline for further improvements of this promising gene editing platform.

205 LX2020-An AAV Based Gene Therapy Improves the Arrhythmogenic Right Ventricular Cardiomyopathy Phenotype in a Severe Mouse Model Harboring Human PKP2 Mutation

Farah Sheikh[1], Jing Zhang[1], Anju Nair[2], Aryanne Do[1], Lena Nguyen[1], Erika Gutierrez Lara[1], Anthony S. Fargnoli[2], Jie Wang[1], William H. Bradford[1], Sonia Gutierrez Granados[2], Ken Law[2], Tim Fenn[2], Paul McCormac[2], Nithya Selvan[2], Richie Khanna[2]

[1]University of California San Diego, La Jolla, CA,[2]LEXEO Therapeutics Inc., New York, NY

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is a fatal genetic-based cardiac disease that increases risk of sudden cardiac death and can progress to heart failure. Clinical studies have established that mutations in the desmosomal gene, plakophilin-2 (PKP2), represent the most frequently mutated gene (>60%) in ARVC. To date, no effective treatment or cure is known to exist for ARVC. Through CRISPR-Cas9 methods, a novel knock-in mouse model was generated harboring a human equivalent PKP2 splice site mutation (IVS10-1 G>C) that impacted PKP2 RNA splicing, with consequences on cardiac PKP2 protein quality (presence of mutant protein) and levels (decreased), resulting in all classic postnatal ARVC disease features in PKP2 homozygous mutant (Hom) mice. LX2020 is a novel AAVrh.10 based gene therapy designed to overcome cardiac deficits in PKP2 levels via the cardiac expression of human PKP2 protein and is being developed for patients with ARVC due to a mutation in

the PKP2 gene. Research grade LX2020 was leveraged to establish proof-of-principle based expression of hPKP2 in the heart that when administered at early postnatal stages in PKP2 Hom mice translated to improvements in cardiac dimensions and function in adult PKP2 Hom mice. To test the efficacy of clinical grade LX2020 in mild and severe ARVC disease settings, LX2020 was produced using the LEXEO manufacturing process and administered intravenously to young postnatal Day 5 mice as well as 3-4 week-old diseased adult PKP2 Hom mice. A dose-dependent increase in hPKP2 expression was seen in young PKP2 Hom mouse hearts that superseded endogenous wild-type (WT) mouse levels. LX2020 administration in young postnatal PKP2 Hom mice translated into restoration of cardiac PKP2 levels and prevention of cardiac cell-cell desmosome and junctional protein deficits in adult PKP2 Hom mice. Histological analysis of adult PKP2 Hom heart tissue treated with LX2020 revealed substantial prevention of left and right ventricle chamber dilatation and remodeling (fibrosis), when compared to controls, with PKP2 Hom hearts treated with the highest dose of LX2020 being indistinguishable from WT controls. Most importantly, LX2020 administration in severely diseased adult PKP2 Hom mice also translated to a dose-dependent increase in hPKP2 expression in PKP2 Hom hearts that resulted in reduction in cardiac cell-cell junction deficits as well as improvements in left and right chamber dimensions and function as well as survival. Collectively, these data indicate that LX2020 overcomes cardiac PKP2 deficits in ARVC settings by driving human PKP2 expression and that this is sufficient to prevent and stabilize the progression of a rapid ARVC disease in young and adult PKP2 Hom mice, respectively. LX2020 thus represents a potentially effective clinically relevant gene therapy approach to treat patients with ARVC disease.

206 Efficient *In Vivo* Base Editing Prevents Hypertrophic Cardiomyopathy in Mice

Gregory A. Newby[1], Daniel Reichart[2], Hiroko Wakimoto[3], Mingyue Lun[3], Joshua M. Gorham[3], Justin J. Curran[3], Aditya Raguram[1], Daniel M. DeLaughter[3], David Conner[3], Julia D. C. Marsiglia[3], Sajeev Kohli[1], Lukas Chmatal[4], David C. Page[5], Nerea Zabaleta[6], Luk H. Vandenberghe[7], David R. Liu[8], Jonathan G. Seidman[3], Christine Seidman[9]

[1]Broad Institute of MIT and Harvard, Cambridge, MA,[2]Department of Medicine, University Hospital, LMU Munich, Munich, Germany,[3]Genetics, Harvard Medical School, Boston, MA,[4]Whitehead Institute, Cambridge, MA,[5]Whitehead Institute and HHMI, Cambridge, MA,[6]Mass Eye and Ear/ Harvard Medical School, Boston, MA,[7]Harvard, Boston, MA,[8]Harvard University and HHMI, Cambridge, MA,[9]Harvard Medical School, Boston, MA

Dominant missense pathogenic variants in cardiac myosin heavy chain cause hypertrophic cardiomyopathy (HCM), a currently incurable disorder that increases risk for stroke, heart failure, and sudden cardiac death. We assessed two different genetic therapies, an adenine base editor (ABE8e) and a potent Cas9 nuclease delivered by AAV9, to prevent disease in mice carrying the heterozygous HCM pathogenic variant myosin R403Q. One dose of dual-AAV9 vectors, each carrying one half of RNA-guided ABE8e, corrected the pathogenic variant in ≥70% of ventricular cardiomyocytes and prevented fibrosis while maintaining durable, normal cardiac structure and function. An additional dose provided more editing in the atria but also increased bystander editing. Single-cell RNA-seq confirmed that cardiomyocytes in animals receiving base editor treatments had a significantly reduced signature of hypertrophy-associated expression profiles. Due to the use of a cardiomyocyte-specific promoter in the AAV9 vector, genome editing was restricted to the heart. CIRCLE-seq identified sites of off-target base editing using this genome editing strategy. Off-target editing following AAV9 delivery at five sites was observed to increase during the seven-month follow up, reaching over 8% at one site. However, off-target base editing did not appear to reduce the fitness of the heart or mouse. AAV9 delivery of RNA-guided S. aureus Cas9 nuclease effectively inactivated the pathogenic allele, albeit with dose-dependent toxicities, necessitating a narrow therapeutic window to maintain health. High doses of Cas9 nuclease led to the disruption of the non-targeted wild type allele over the course of the seven-month follow up, and these animals displayed reduced heart function. These preclinical studies identify limitations and demonstrate considerable potential for single-dose genetic therapies to correct or silence pathogenic variants and prevent the development of HCM.

Modulating and Engineering Immune Responses to Gene Therapy and Vaccines

207 Combination Immunosuppression Prevents Toxicity and Increases Liver Transduction in Cynomolgus Macaques Administered with High Dose AAV Vector

Kruti Patel[1], Waijiao Cai[1], Arpana Khatri[1], Lucy Marie[1], Marla Bazile[2], Erin Lopez[1], David Karanian[3], Sandra Casinghino[3], Ramesh C. Kovi[2], Sirivelu Madhu[2], Gabriel C. Brooks[1], Jatin Narula[4], Bin Li[1], Lisa R. Keyes[5], John Graves[3], Linda Marie Hutter[3], Karen Ericson[3], Jessica Anderson[3], Michael Binks[1], Laurence Whiteley[2], Sury Somanathan[1]

[1]Rare Disease Research Unit, Pfizer Inc, Cambridge, MA,[2]Pfizer Inc, Cambridge, MA,[3]Pfizer, Groton, CT,[4]BioMedicine Design, Pfizer Inc, Cambridge, MA,[5]Pfizer, Morrisville, NC

Adeno-associated virus (AAV) based genetic medicines have been transformational in treating several genetic disorders. The widespread adoption of AAV vectors for in vivo gene delivery was based on the safety and efficacy of vector in targeting multiple tissues. However, clinical trials using AAV gene therapies have observed severe adverse events (SAE's) owing to the innate and adaptive immune responses against the AAV capsid antigens and/or the transgene products. Furthermore, recent clinical trials have observed complement activation, thrombotic microangiopathy/Hemolytic Uremic Syndrome (aHUS), and hepatotoxicity in subjects intravenously administered high AAV vector doses. The use of prophylactic or reactive glucocorticoids has been ineffective in completely ablating or reducing high-dose vector induced toxicity. Instead, intervention with additional

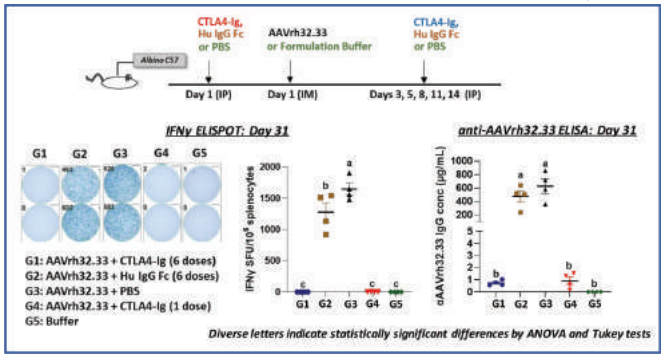
immunosuppressants (IS) have provided clinical benefit in reducing toxicity associated with complement activation. Here we studied the effect of different IS drug combinations to reduce toxicity following intravenous administration of high dose (5E13 vg/kg) vector in Cynomologus Macaques. Animals (N=3/group) received either an AAV9 vector expressing GFP from a ubiquitous promoter or vector along with one of the following IS regimens: 1) methylprednisolone (MP), 2) MP and rapamycin, 3) MP, rapamycin and rituximab (triple IS). The study was terminated 56 days post vector administration and tissues were collected for further evaluation. During the in-life phase of the study, animals that received vector without any IS were lethargic and demonstrated signs of hindlimb dysfunction 30 days post vector infusion. In contrast, animals that received triple IS showed normal behavior with no functional deficits. The triple IS regimen prevented hepatotoxicity with no significant transaminitis. The triple IS treated animals had reduced DRG toxicity and cardiac troponin I levels were normal. Immunotoxicity assessment demonstrated reduced innate and adaptive immune activation in triple IS regimen treated animals. First, there was a 100x reduction in anti-AAV9 neutralizing antibodies and a significant reduction in anti-AAV9 IgG and IgM binding antibodies. Serum levels of C5b9 and Bb were lower suggesting reduced complement activation in these animals. Next, immunophenotyping revealed significant decreases in B cells, T cells, and NK cells in triple IS treated animals when compared to non-IS controls. IFN-g ELISPOT assays revealed reduced transgene-specific cytotoxic T cells in the triple IS treated group. Finally, immunosuppressed animals had delayed blood vector clearance and higher liver transduction with increased transgene expression. Overall, the findings here support the use of these or similar regimens to reduce toxicity and increase safety of AAV gene therapy in the clinic.

208 Inhibition of AAV-Specific Adaptive Immune Response by Co-Stimulation Blockade with CTLA4-Ig Fusion Protein

Audry Fernandez[1], Rachel Hedinger[1], Alea Powell[1], Haley Grooms[1], Rohini Sheth[1], Layth Awartani[1], Dylan Southers[1], Alan Curtis[1], Angela Mote[1], Sherif Gabriel[1], Anna Tretiakova[1], Shari Gordon[1], R. Jude Samulski[1,2]

[1]Asklepios BioPharmaceutical, Inc., Durham, NC,[2]University of North Carolina, Chapel Hill, NC

One of the major limitations to the use of Adeno-Associated Virus (AAV) gene therapy is the adaptive immune response that contributes to immune related adverse events and prevents AAV redosing. Thus, there is a need for efficient strategies to reduce or prevent the generation of neutralizing antibodies and to inhibit T cell responses. CTLA4 is an inhibitory immune checkpoint receptor that competes with CD28 for binding to CD80/CD86 on antigen presenting cells and consequently limits T cell co-stimulation. A recombinant protein that consists of the CTLA4 extracellular domain linked with the Fc domain of a human immunoglobulin (CTLA4-Ig) has shown to limit adaptive immune responses in preclinical models. CTLA4-Ig variants like Abatacept and Belatacept have been approved for clinical use in patients with autoimmune conditions or in organ transplant settings. Previous evidence has shown that CTLA4-Ig can modulate the immune response in the context of AAV8 or rAAV2/1 vectors, when delivered as a transgene or in combination with other immune modulators (Adriouch et al. 2011; Zhong et al. 2022). In this study we evaluated the effect of CTLA4-Ig on the adaptive immune response induced by AAVrh32.33, a highly immunogenic AAV variant that generates strong B and T cell responses when administered intramuscularly in C57BL/6 mice (Mays et al. 2009). Single administration of CTLA4-Ig on the same day of AAVrh32.33 injection (day 1) was compared with a multiple dose regimen where another five CTLA4-Ig doses were inoculated separated 2-3 days until day 14. A first group of control mice received AAVrh32.33 and six doses of a human Ig Fc domain while other control animals were given PBS and formulation buffer. A single dose of CTLA4-Ig was sufficient to abrogate the generation of AAVrh32.33-specific CD8$^+$ T cells 30 days after vector dosing in 100% of the treated mice, as demonstrated by both IFNγ ELISPOT and flow cytometry staining of antigen experienced AAV dextramer positive T cells. AAVrh32.33-specific serum IgG antibodies were significantly inhibited at this time point by both CTLA4-Ig dose schedules. Interestingly, serum IgM antibodies specific for AAVrh32.33 measured at an earlier time point (day 9) were also significantly decreased in the animals treated with either one or six doses of CTLA4-Ig. Multiple CTLA4-Ig doses were required to maintain significantly reduced AAV-specific CD8$^+$ T cell frequencies and IgG antibody levels in 75% of the treated mice 90 days after vector inoculation. No difference in luciferase transgene expression was detected in the vector injection site (right tibialis anterior muscle) between any of the treatment groups throughout the study. In conclusion, co-stimulation blockade with CTLA4-Ig represents a promising immune modulation strategy for inhibiting AAV induced B and T cell responses with the potential to reduce immune related adverse events and facilitate re-dosing.



209 Engineered Human B Cells Respond to Antigen-Specific Immunization in a Tonsil Organoid Model

Geoffrey L. Rogers, Chun Huang, Atishay Mathur, Chan-Hua Chang, Paula M. Cannon

University of Southern California, Los Angeles, CA

B cells are emerging as an exciting immune therapy, with the potential to combine long-term expression of custom therapeutic antibodies with other functions of the humoral immune system. For example, memory B cells undergo clonal expansion in response to antigen, creating a system that is intrinsically self-tuning, while somatic hypermutation facilitates the ongoing evolution of antibodies. Most of these features depend on expression of the antibody from the natural immunoglobulin locus. We have previously described a genome editing strategy to reprogram the heavy chain locus of human B cells

to express custom heavy-chain only antibodies (HCAbs) based on IgG1. These antibodies mimic a natural antibody type expressed by camelids and can be engineered with a variety of antigen-recognizing domains, including VHHs, scFvs, and receptor domains. Engineered HCAbs maintain the antigen specificity of their inserted cassette and the edited cells support a range of normal B cell functions during *ex vivo* differentiation. In addition, sequence changes characteristic of somatic hypermutation develop in HCAb-edited B cell lines over time. However, a lack of robust *in vivo* models makes it challenging to confirm that engineered human B cells will respond appropriately to antigens in an immunologic context. Indeed, such studies typically rely instead on editing mouse B cells. Here, we report the use of a tonsil organoid model that represents a 'human immune system in a dish' to evaluate HCAb-engineered human B cells. Exposure of such organoids to antigen induces clonal expansion of antigen-specific B cells and drives both class-switch recombination and somatic hypermutation (Wagar *et al.* Nat Med 2021). To assess the functionality of our edited cells, we reprogrammed tonsillar B cells to express an anti-HIV HCAb, based on the broadly neutralizing llama VHH, J3. Tonsil organoids were supplemented with J3-edited B cells and immunized with recombinant HIV gp120 protein plus adjuvant. The frequency of edited B cells increased after gp120 exposure, but not following a control immunization with PE, indicating an antigen-specific response. Further, gp120 immunization increased the frequency of mutations in the J3 sequence at AID hotspot motifs, suggesting somatic hypermutation. Several of these mutated clones were expanded up to 600-fold in immunized vs. non-immunized organoids and expansion of unique clones was observed across multiple donors, suggesting that these were *de novo* mutations that expanded after immunization. In sum, these data provide evidence that HCAb-engineered human B cells can functionally respond to their specific antigen, undergoing clonal expansion and somatic hypermutation. To our knowledge, this is the first report of an antigen-specific immune response by engineered human B cells, suggesting that the tonsil organoid model will be a valuable tool to assess engineered B cell functionality in the absence of a suitable animal model.

210 Newly Engineered IgM and IgG Cleaving Enzymes for AAV Gene Therapy

Timothy Smith, Joshua A. Hull, Robert M. Fusco, Leo Blondel, Zachary Elmore, Aravind Asokan

Duke University, Durham, NC

Clinical translation of systemic AAV-based gene therapies is restricted in scope due to preexisting immunity to natural AAV serotypes in prospective patients. In addition, humoral immunity to AAV vectors has been implicated in triggering complement activation often resulting in adverse clinical events. Strategies to mitigate undesirable side effects and antibody-mediated AAV neutralization have included plasmapheresis, B cell depletion (e.g., Rituximab), complement inhibition (e.g., Eculizumab), and most recently, IgG-degrading enzymes such as IdeS and IdeZ. Despite these efforts, the negative impact of IgM, a critical component of humoral immunity to AAV vectors remains unaddressed to date. Here, we describe newly engineered enzymes that can selectively cleave IgM and/or IgM + IgG that could potentially impact clinical AAV gene therapy. The novel IgM-cleaving enzyme (IceM) efficiently cleaves IgM with a high degree of specificity. IceM cleaves human and NHP IgM, but not IgM from other species such as dog, pig, or mouse. Further, IceM cleaves IgM from the surface of B lymphocytes *in vitro*. To expand on the clinical applicability of IceM, we further engineered a novel IgM + IgG cleaving enzyme (IceMG) that effectively cleaves antibodies in human and NHP sera. Notably, both IceM and IceMG block complement activation elicited by either AAV9 capsids or Platelet factor 4(PF4)/heparin complexes in human sera. In mice passively immunized with pooled human sera, we demonstrate efficient and rapid (within 24h) clearance of circulating human IgM with a single intravenous dose of recombinant IceM. Results demonstrating clearance of neutralizing human IgM + IgG upon dosing recombinant IceM and IceMG accompanied by rescue of AAV transduction in passively immunized mice will be presented. Taken together, our newly engineered enzyme platform has implications for expanding the patient cohort and vector redosing in AAV gene therapies.

211 A Biosynthetic Approach for CpG Methylation of AAV Expression Cassettes

Fabian Huellen, Rachana Patil, Bradley A. Hamilton, J. Fraser Wright

Stanford, Palo Alto, CA

Adeno-associated virus (AAV) based therapies have the potential to provide transformative treatments for genetic diseases. However, immune responses induced by AAV remain a significant barrier. Immune responses potentiated by binding of unmethylated CpG dinucleotides in AAV vector genomes to the microbial DNA pattern recognition receptor TLR9 are thought to play a role in the loss of therapeutic transgene expression due to the destruction of the transduced cells by cytotoxic T cells (CTLs). Current strategies to reduce TLR9 activation include codon modifications to remove CpGs in the transgene sequence. However, one risk of modifying codon usage is the potential for trans protein misfolding when wild-type translational kinetic are changed. We are investigating strategies that increase vector genome CpG methylation to a level comparable to methylation patterns in humans to remove the main stimuli for TLR9 activation. Our strategy to increase AAV genomic CpG methylation employs an efficient methyl transferase (MT), MSssI from *Spiroplasma*, at two steps in the vector production process. First, because vector plasmid encoded expression cassette DNA can be directly packaged into capsids, vector plasmids were methylated prior to transfection into production cells. Second, because expression cassettes are also generated through replication, MT was integrated into production cells and expressed after triple transfection. We previously described an acellular method using MT, which efficiently methylated the CpGs in AAV vector plasmids and significantly decreased TLR9 activation in HEK reporter cells. Plasmid methylation also decreased GFP transgene expression when transfected into HeLa cells, compared to non-methylated controls. Furthermore, acellular plasmid methylation is not scalable for vector manufacturing. To address these two challenges, we hypothesized that i) promoter methylation silenced transgene expression, and ii) that genomic MT integration in *E.Coli* would better facilitate scalable production of methylated AAV vector plasmids. Here, we compared acellular methylation of CpG-containing promoter driven GFP vector plasmid (pAAV2-CAG>GFP) and CpG-free promoter driven GFP vector plasmid (pAAV2-CpGfreeEF1a>GFP) and found that MT

efficiently methylated both vector plasmids. We then transfected these plasmids, and non-methylated counterparts, into HEK293. After staining cell nuclei, we observed a marked decrease in GFP expression when driven by the CpG containing CAG promoter; however, GFP expression driven by CpG-free EF1a was not significantly altered by methylation. These preliminary results demonstrate that methylation-dependent silencing of transgene expression can be addressed by CpG-free promoters. To address scalability, the MT sequence was codon optimized for *E. coli* and non-canonical stop codons were removed. MT was integrated into the *E.coli* genome under control of an inducible Tet promoter using a Tn7 transposase downstream of the bacterial glmS gene locus and verified by sequencing. The MT expressing *E. coli* was transformed with vector plasmid pAAV2-CpGfreeEf1a>GFP and upon expansion and induction provided high yield of the vector plasmid that after purification and transfection expressed GFP in cell culture. Digestion with methylation insensitive vs sensitive restriction enzymes confirmed plasmid DNA methylation. Parallel studies to integrate MT into HEK293 genomes by lentiviral transduction were also performed yielding MT positive cells that are currently being characterized. These results support the feasibility of biosynthetic approaches to generate recombinant AAV vectors with increased CpG methylation, providing a novel vector and process approach to address the challenge of TLR9-associated innate immune activation caused by the inherent hypomethylation of AAV vector genomes.

212 B-cell Targeted Therapies Deplete Neutralizing Antibodies to AAV

Bhavya S. Doshi[1,2], Noelle Novak[1], Caroline Markmann[2], Robert Davidson[1], Juliana Small[1], Benjamin Samelson-Jones[1,2], Vijay Bhoj[2], Lindsey A. George[1,2]

[1]Raymond G. Perelman Center for Cellular & Molecular Therapies, Children's Hospital of Philadelphia, Philadelphia, PA,[2]Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA

Background: A major barrier to adeno-associated viral (AAV) vector gene therapy is the presence of persistent, multi-serotype cross-reactive neutralizing antibodies (NAbs) that develop following wildtype AAV infection and AAV vector infusion that render patients ineligible for initial or repeat AAV dosing. Prior human studies have evaluated plasmapheresis and various immunomodulatory agents to remove NAbs to allow therapeutic vector administration. These studies have been limited by an incomplete evaluation of the B-cell compartments essential to AAV NAb persistence. Understanding the anti-AAV B-cell response would aid in the development of rational strategies to reduce or eliminate AAV NAbs. Here, we aim to systematically investigate the ability of B-cell immunomodulation strategies, including engineered T-cell immunotherapy, to deplete pre-existing AAV NAbs and facilitate AAV gene therapy. **Methods:** AAV NAb titers were measured via a transduction inhibition assay using an AAV8 luciferase reporter vector. Wild type C57Bl/6 mice were immunized with an AAV8 vector at 1 x 10^{11} vg/mouse to establish AAV NAbs. Two weeks later, animals were administered chimeric antigen receptor (CAR) T-cells that were either non-transduced (NTD, controls) or targeted mouse CD19, mouse B-cell maturation antigen (BCMA), or both (Fig 1A). Elevent weeks after CAR-T infusion, mice were re-challenged with an AVV8 vector carrying factor VIII (FVIII) at 1 x 10^{11} vg/mouse. Plasma FVIII antigen levels were measured by ELISA to assess transduction capacity. **Results:** Initial AAV exposure resulted in NAb titers prior to CAR-T therapy that were not different between experiment groups (median 1:336, range 1:95 - 1:1653, Fig 1B). Significant and persistent B-cell aplasia was noted after CD19 (12.4 ± 10.6 cells/μL) and CD19+BCMA (1.8 ± 3.5) CAR-T infusion in contrast to NTD or BCMA alone CAR-T infusion (129 ± 80 and 106 ± 80, respectively, $p < 0.05$). Following CAR-T infusion, NAb titers in the NTD and BCMA-only CAR-T groups continued to rise to greater than 1:3200 whereas mice treated with CD19-targeting CAR-T regimens had mean titers below 1:5 (Fig 1B, $p < 0.05$). There was no difference between the CD19-only and CD19+BCMA regimens. Upon AAV8-FVIII re-challenge, FVII antigen levels inversely correlated with NAb titer (Spearman r -0.47, $p < 0.05$) with CD19-targeting CAR-T regimens resulting in significantly higher expression of FVIII antigen compared to NTD or BCMA CAR-T regimens (19.9 ± 28.1 vs 5.6 ± 3.8 ng/ml, respectively, $p < 0.05$). **Conclusions:** These data support that CD19-targeted therapy can sufficiently reduce AAV NAb titers to below 1:5 and enable AAV vector transduction in pre-exposed mouse models. Additionally, the data support that a CD19+ B-cell population is important in the ongoing AAV NAb response in mice. The lack of difference in NAb titers between the NTD and BCMA-only CAR-T groups or between CD19-only or CD19+BCMA CAR-T groups suggests that CD19-BCMA+ long-lived plasma cells are not the primary cellular reservoir of anti-AAV humoral immunity. However, given the longevity of the AAV NAb response in humans, ongoing studies of samples from patients treated with B-cell targeting biologics and CAR-T regimens will inform the significance of the plasma cell compartment in AAV immunity in humans.

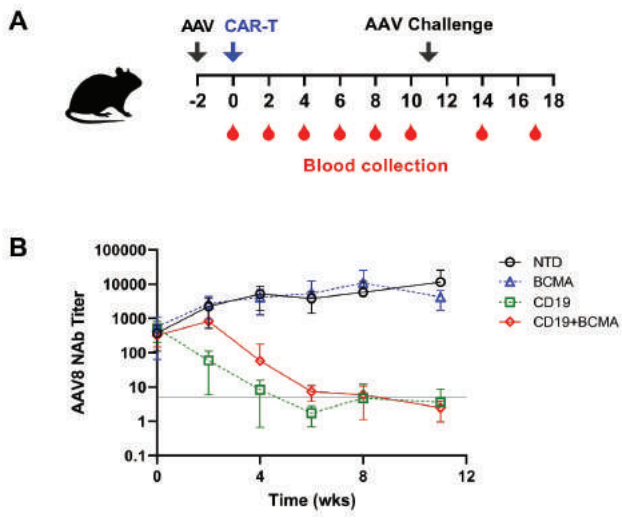


Figure 1. A) Experimental schema. **B)** AAV8 NAb titer after CAR-T injection.

213 Redosing of AAV Vectors Containing TLR9 Inhibitory Oligonucleotides Improves Survival in a Mouse Model of Respiratory Surfactant Deficiency

Martin H. Kang[1], Sylvia P. Thomas[2], Caralyn Westley[1], Liqun Xu[3], Arul Vadivel[3], Kennedy Nangle[3], Janani Ramamurthy[3], Yanlong Pei[2], Erin Lisk[1], Sarah Allen[1], Jeffrey A. Whitsett[4], Sarah Wootton[2], Bernard Thebaud[3]

[1]Pediatrics, Medical University of South Carolina, Charleston, SC,[2]Pathobiology, University of Guelph, Guelph, ON, Canada,[3]Ottawa Hospital Research Institute, Ottawa, ON, Canada,[4]Cincinnati Children's Hospital Medical Ctr, Cincinnati, OH

Surfactant protein B (SP-B) deficiency (OMIM#265120) is a lethal genetic lung disease that impairs pulmonary surfactant production, with affected individuals dying of respiratory distress three to six months after birth. We previously identified a genetically engineered adeno-associated viral (AAV6.2FF) vector (AAV-hSPB) capable of transducing alveolar epithelium and improving lung structure, physiology, and survival in a mouse model of SP-B deficiency. Although median survival improved to **140 days** compared to **2-7 days** without gene therapy, the effects of AAV-hSPB waned, and the mice eventually died of respiratory distress. A potential reason for this loss in vector efficacy is the immune response (IR) to AAV. The toll-like-receptor 9 (TLR9) pathway plays a critical role in the initial IR against AAV, and strategies have been developed to suppress TLR9 activation in the hopes of improving gene therapy efficacy. One strategy is the incorporation of oligonucleotide sequences (TTAGGG) into the AAV vector genome to inhibit the TLR9 pathway, which has shown promise in prolonging transgene expression and suppressing the IR in the liver, muscles, and retina. To test the potential effects of TLR9 inhibition in the lungs, we inserted TLR9 inhibitory oligonucleotide (io) sequences into AAV-hSPB (AAV-hSPB-io2). A single dose of AAV-hSPB-io2 significantly improved median survival to **205 days** compared to only **134 days** in mice administered a single dose of AAV-hSPB (P=0.0043). The eventual decrease in survival could be overcome if AAV-hSPB could be redosed. However, the adaptive IR that develops after an initial dose prevents efficient AAV readministration. The suppression of the IR by TLR9 inhibition led us to propose that redosing of gene therapy vectors into the lungs is possible using this strategy. Readministration of AAV-hSPB resulted in a median survival of **122 days**. In sharp contrast, repeated dosing of AAV-hSPB-io2 every 90 days improved median survival to **296 days** (P<0.0001), with the longest surviving mouse living for **357 days**. Treatment with AAV-hSPB-io2 results in no adverse effects in mice as observed by steady increases in body weight and the lack of an inflammatory cytokine profile. Gene expression analyses reveals that redosing with AAV-hSPB significantly alters the expression of 136 out of more than 750 genes that were measured from the murine immune and inflammatory response pathways. This includes several genes (*Cxcl9*, *Cxcl10*, *Tap1*, *Stat1*, *Psmb9*, and *Isg15*) from the type II interferon pathway (adjusted P=0.038). However, the changes in gene expression are suppressed when mice are readministered with AAV-hSPB-io2. Only 9 genes demonstrate significant changes out of the same 750 genes measured. TLR9 inhibitory sequences also impedes the expression of gene markers associated with T helper cells, but does not affect expression of B cell markers or serum antibody levels against AAV. These findings demonstrate that TLR9 inhibitory sequences allow for AAV readministration in the lungs through the broad disruption of multiple but not all components of the IR against AAV.

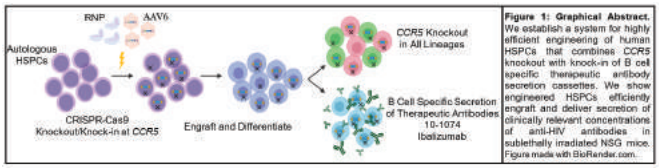
367 Establishing Multilayered Genetic Resistance to HIV-1 by Engineering Hematopoietic Stem and Progenitor Cells for B Cell Specific Secretion of Therapeutic Antibodies

William Feist[1], Sofia Elena Luna[2], Kaya Ben-Efraim[2], Maria Filsinger Interrante[3], Nelson A. Amorin[1], Nicole Marie Johnston[2], Amanda Dudek[2], Matthew H. Porteus[2]

[1]Stem Cell Biology and Regenerative Medicine, Stanford University, Stanford, CA,[2]Pediatrics, Stanford University, Stanford, CA,[3]Biophysics, Stanford University, Stanford, CA

Autologous transplantation of CCR5 null hematopoietic stem and progenitor cells (HSPCs) is the only known cure for HIV-1 infection. However, this treatment is extremely limited due to the rarity of CCR5 null matched donors, the morbidities associated with allogeneic transplantation, and the prevalence of HIV-1 strains resistant to CCR5 knockout (KO) alone. Here, we propose a one-time therapy through autologous transplantation of HSPCs genetically engineered *ex vivo* to deliver both CCR5 null cells and long-term secretion of potent anti-HIV-1 antibodies. We employ highly efficient CRISPR-Cas9/AAV6 mediated genome editing techniques to simultaneously knock-out CCR5 and knock-in anti-HIV-1 antibody expression cassettes for multi-layered cell autonomous and cell non-autonomous HIV-1 resistance, respectively. We achieve over 90% knock-out efficiency and 25-35% knock-in frequency at the *CCR5* locus in primary HSPCs. We utilize a previously defined B cell specific promoter to drive expression of Ibalizumab and 10-1074, highly potent anti-HIV-1 antibodies used in combination to limit viral escape and provide broad resistance across viral strains. We engineer these antibodies for expression with a peptide linker physically pairing the light and heavy chains to prevent mispairing with endogenously produced antibodies. We demonstrated our engineered antibodies maintain their efficacy compared to their unmodified counterparts in an HIV-1 neutralization assay. Further, we achieved efficient targeted integration of our antibody expression cassettes in primary human B cells with frequencies up to 43% in the *CCR5* locus. We show that B cells edited to express 10-1074, Ibalizumab, or both antibodies secrete neutralizing levels of antibody in culture supernatant. After validating our system, we engineered HSPCs with CCR5 KO and integration of the 10-1074 antibody cassette for engraftment in sublethally irradiated NSG mice. Endpoint analysis at week 13 showed human chimerism up to 65%, and human cells containing our integrated antibody cassette were maintained, demonstrating persistence of our engineered cells *in vivo*. Importantly, serum taken from the engrafted mice generated highly efficient neutralization of HIV-1 pseudovirus when applied to an HIV-1 infection assay. Serum antibody concentrations estimated from the neutralization efficiency range from 40 μg/mL to 290 μg/mL, greatly surpassing the clinically relevant concentration of 10 μg/mL. Ongoing studies combine expression of multiple antibodies to deliver resistance to broad strains of HIV-1 and prevent the development of viral resistance. Here, we establish a highly efficient system to

simultaneously knock-out CCR5 and knock-in B cell specific antibody expression cassettes in HSPCs to engineer multilayered resistance to HIV-1. We believe this strategy has the potential to become a one-time therapy that leads to long-term control of HIV-1 infection, a disease that currently requires lifetime administration of anti-retroviral therapy to maintain viral suppression.



Hematologic and Immunologic Diseases

214 mRNA Delivery to Hematopoietic Stem Cells by Targeted Lipid Nanoparticles Allows *In Vivo* Genome Engineering and Control of Cell Fate

Laura Breda[1], Tyler E. Papp[2], Michael P. Triebwasser[3], Amir Yadegari[2], Megan Fedorky[1], Naoto Tanaka[1], Osheiza Abdulmalik[1], Giulia Pavani[1], Houping Ni[2], Drew Weissman[2], Stefano Rivella[1], Hamideh Parhiz[2]

[1]Children's Hospital of Philadelphia, Philadelphia, PA,[2]University of Pennsylvania, Philadelphia, PA,[3]University of Michigan, Ann Arbor, MI

Disorders of the blood, such as hemoglobinopathies and immunodeficiencies, can be cured by correcting or replacing diseased hematopoietic stem cells (HSC). Gene therapy (GT) for these non-malignant hematopoietic disorders (NMHD) is currently done with *ex vivo* lentiviral transduction of HSC or electroporation with genome editors. Myeloablative conditioning is required for HSC transplant (HSCT) of autologous gene-modified HSC. Conditioning is based on chemotherapy or radiation and has acute and chronic morbidity and mortality. We developed a novel CD117 (stem cell factor receptor) targeted lipid nanoparticle encapsulating modified mRNA to achieve *ex vivo* and *in vivo* genome engineering and control of cell fate. To evaluate LNP targeting, murine cre-responsive reporter models (Ai6, Ai9, Ai14) were utilized with LNP encapsulating Cre mRNA (LNP-Cre). Anti-CD117 targeted LNP-Cre (CD117/LNP-Cre) produced 95% genome editing in LSK cells after 6 hours treatment. To evaluate the multipotency of targeted cells, we transplanted C57BL/6 CD45.1 recipient mice with Ai14 BM cells treated *ex vivo* with increasing doses of CD117/LNP-Cre and Control IgG/LNP-Cre. 95% of long-term HSC (LT-HSC, $Lin^-Sca1^+cKit^+CD150^+CD48^-$) had been targeted at four months post-transplant (Fig. 1A), with all blood lineages showing edited cells (Fig. 1B) These HSC were found to be self-renewing utilizing secondary transplantation. We administered CD117/LNP encapsulating luciferase mRNA intravenously (IV) and observed activity in the bone marrow (Fig. 1C). IV administration of CD117/LNP-Cre (5μg) in Ai9 mice yielded 55% LT-HSC targeting at 4 months post-treatment, 2.9-fold higher than seen with Control IgG/LNP-Cre (Fig. 1D). Transplantation of BM from these animals phenocopied the donor bone marrow. Targeting of LNP to human CD117 (hCD117/LNP) encapsulating cas9-adenine base editor (NRCH-cas9-ABE8e) mRNA and gRNA converted 87% of alleles from the sickle hemoglobin mutation (Hbb^S) to the G-Makassar variant (Hbb^G) in erythroblasts derived from sickle cell disease affected $CD34^+$ cells *in vitro* (Fig. 1E). Hbb^G was 90% of β-like globins (Hbb^G+Hbb^S) in edited cells after erythroid differentiation (Fig. 1F). Hypoxia induced sickling in edited SCD erythroblasts was reduced by 96% compared to control cells (Fig. 1G and 1H). *In vivo* targeting of HSC offers the ability to modify HSC fate, potentially a therapeutic modality for NMHD. We tested the ability of pro-apoptotic mRNA as non-genotoxic conditioning for HSCT. mRNA expression in the liver was reduced by adding a miRNA binding site. CD117/LNP-PUMA induced HSC depletion *in vivo* and allowed for engraftment of GFP^+ donor BM. At the maximum tolerated dose, 3.7% of LSK cells were donor derived after four months, which is a therapeutic level of engraftment in some immunodeficiencies (Fig. 1I). These results show that LNP mRNA delivery can be controlled both by targeting and manipulation of the mRNA message. This may revolutionize the treatment of genetic diseases in two ways. First, the cure of NMHD disorders, such as sickle cell disease may be attainable with a simple infusion that corrects the causative molecular defect. Second, effecting cell-type specific state changes *in vivo* will allow previously impossible manipulations of physiology.

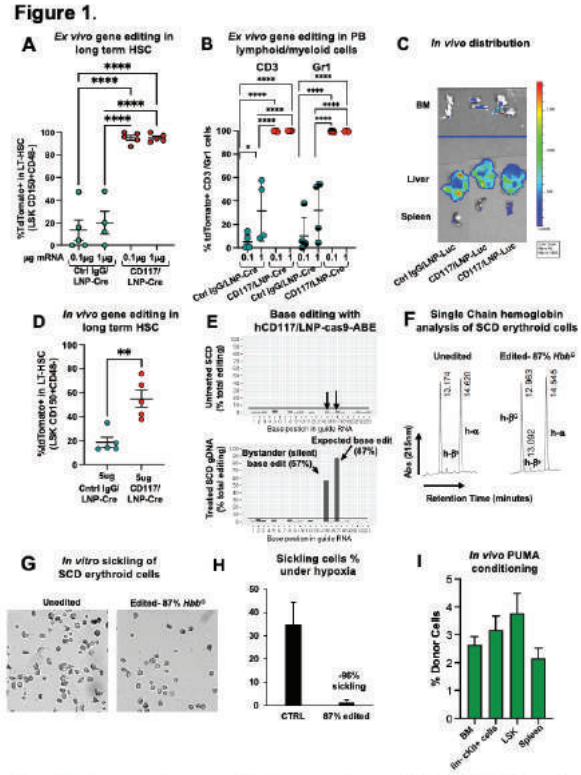


Figure 1. (A) Percentage of reporter positive bone marrow long-term HSC (LSK $CD150^+CD48^-$) and peripheral blood (PB) (B) CD3+ (lymphoid) and Gr1+ (myeloid) cells 4 months post-transplant in lethally irradiated congenic recipients engrafted with BM of Ai14 (tdTomato reporter) mice treated with IgG/LNP-cre or CD117/LNP-Cre *ex vivo* for 18 hours. (C) Luciferase activity in bone marrow, liver, and spleen after CD117/LNP-luciferase administered I.V. (D) *In vivo* editing in LT-HSC cells 4 months after I.V. injection of LNP-Cre. (E) Mutation analysis of sickle cell disease (SCD) erythroblasts after treatment with human (h) CD117 targeted LNP carrying cas9-adenine base editor (ABE) mRNA and separately hCD117/LNP carrying gRNA. (F) Reverse-phase HPLC analysis of single globin chains from unedited and hCD117/LNP-cas9-ABE + gRNA treated SCD erythroblasts. (G) Representative images from unedited and edited SCD erythroblasts exposed to hypoxic conditions and (H) quantification of the frequency of sickled cells by morphology (N=5 high powered fields per condition). (I) Engraftment analysis in bone marrow subsets after 4 months of mice receiving CD117/LNP-PUMA as conditioning and donor GFP^+ BM cells.

215 First Case of Leukaemia in Retroviral Gene Therapy for ADA-SCID

Daniela Cesana[1], Maria Pia Cicalese[1], Andrea Calabria[1], Pietro Merli[2], Roberta Caruso[2], Monica Volpin[1], Laura Rudilosso[1], Maddalena Migliavacca[1], Federica Barzaghi[1], Claudia Fossati[1], Francesco Gazzo[1], Simone Pizzi[2], Andrea Ciolfi[2], Alessandro Brusselles[3], Giulio Spinozzi[1], Giulia Pais[1], Fabrizio Benedicenti[1], Matteo Barcella[1], Ivan Merelli[1], Stefania Giannelli[1], Pierangela Gallina[1], Francesca Dionisio[1], Serena Scala[1], Miriam Casiraghi[1], Luisa Strocchio[2], Luciana Vinti[2], Lucia Pacillo[2], Eleonora Draghi[4], Marcella Cesana[5], Sara Riccardo[5], Chiara Colantuono[5], Emmanuelle Six[6], Marina Cavazzana[6], Filippo Carlucci[7], Manfred Schmidt[8], Caterina Cancrini[2], Fabio Ciceri[1], Luca Vago[4], Davide Cacchiarelli[5], Bernhard Gentner[1], Luigi Naldini[1], Marco Tartaglia[2], Eugenio Montini[1], Franco Locatelli[2], Alessandro Aiuti[1]

Hematopoietic stem cell (HSC) gene therapy (GT) using a γ-retroviral vector (γRV) is an effective treatment for Severe Combined Immunodeficiency due to Adenosine Deaminase deficiency (ADA-SCID). Here, we describe the first occurrence of drug-related T-cell acute lymphoblastic leukemia (T-ALL) that developed 4.7 years after GT. Routine follow-up until 3 months before the event onset did not reveal any immunological or clinical abnormalities. After diagnosis, the patient underwent chemotherapy and, after remission, HLA-haploidentical transplantation and is in molecular remission up to 20 months post-transplant. Blast cells contained a single vector activating insertion near the LMO2 proto-oncogene, confirmed by direct physical interaction, and showed low ADA activity resulting from methylation of viral promoter sequences. Mature T cells and other blood lineages harboring the insertion at the LMO2 locus were detected at stable levels years before T-ALL onset, suggesting that further mutagenic hits occurred at the level of a thymic progenitor. Indeed, a variety of known and novel somatic mutations including intragenic and structural rearrangements possibly contributed to orchestrate the development of the T-ALL. Interestingly, a clone with an activating insertion in the MECOM gene increased to 25% in myeloid cells during chemotherapy treatment for T-ALL and disappeared after allogeneic transplantation. It is possible that MECOM overexpression conferred a fitness advantage to this clone favoring its expansion and the development of clonal hematopoiesis during chemotherapy. Before T-ALL onset, the overall insertion profile and common insertion sites were similar to those of other γRV-treated ADA-SCID patients using the same vector, without the presence of prominent clones in proto-oncogenes. As compared to another ADA-SCID clinical trial based on γRV with a different viral promoter, the only major difference was the targeting frequency of MECOM which was significantly lower in our trial. The limited frequency of vector-related adverse events in γRV ADA-SCID GT, as compared to other immune deficiencies, suggests a predisposing role of disease and possible predisposing factors in this patient. While γRV GT for ADA-SCID maintains a positive benefit-risk ratio, the identified risk of insertional oncogenesis requires long-term safety monitoring of treated patients.

216 Lentiviral Vector Mediated *In Vivo* Gene Transfer into Hematopoietic Stem and Progenitor Cells

Michela Milani[1], Erika Zonari[1], Anna Fabiano[1], Raisa Jofra Hernandez[1], Monica Volpin[1], Fabio Russo[1], Mauro Biffi[1], Sofia Ottonello[1,2], Bernhard Rudolf Gentner[1], Eugenio Montini[1], Alessandro Aiuti[1,2], Alessio Cantore[1,2], Luigi M. Naldini[1,2]

[1]San Raffaele Telethon Institute for Gene Therapy, Milan, Italy,[2]Vita-Salute San Raffaele University, Milan, Italy

In the last decade, lentiviral vector (LV) mediated *ex vivo* gene therapy in hematopoietic stem and progenitor cells (HSPC) fulfilled the promise of a long-term treatment for a number of genetic diseases, including primary immunodeficiencies and hematological disorders. However, collection of high number of cells, their *ex vivo* manipulation and conditioning of the patient still pose challenges to broad access to HSPC gene therapy. To investigate the feasibility of *in vivo* LV-mediated gene transfer into HSPC, we systemically administered GFP-expressing LV to adult or newborn mice and found only in the latter stable GFP expression in 1% of all blood lineages up to 1-year. We observed comparable GFP marking in hematopoietic organs and in HSPC harvested from the bone marrow (BM), which were able to engraft long-term in busulfan-conditioned recipient mice. LV integration site analysis confirmed common origin of different hematopoietic lineages from multiple clones. These findings indicate successful *in vivo* gene transfer into *bona fide* HSC favored by some unique features of newborn hematopoiesis, such as access to hepatic hematopoietic niches persisting after birth, and HSC-trafficking to the BM. In order to evaluate newborn HSPC potential, we isolated hematopoietic cells from the liver or the BM of newborn mice and transplanted them in conditioned adult recipient mice. We observed similar engraftment and hematopoietic output in mice transplanted with cells isolated from the two sources and this was confirmed even upon secondary transplant. To increase gene transfer efficiency we exploited phagocytosis-shielded CD47-high LV and showed 3-fold higher gene marking in the blood and BM of treated mice. Sorted lineage-negative cells from the BM generated GFP-positive colonies *ex vivo*. Biodistribution studies showed transgene-positive cells in other relevant organs, such as the liver, the spleen, the brain, the lungs and the kidneys of newborn-treated mice, comprising hematopoietic, endothelial and in some cases parenchymal cells. While expression in non-hematopoietic cells could be avoided by tailored vector expression, it might be advantageous for treating systemic diseases. As a model for systemic disease correction, we administered LV expressing the adenosine deaminase (ADA) enzyme to ADA-SCID newborn mice and showed rescue from lethal phenotype and reconstitution of lymphocyte counts with selective advantage of LV-transduced cells. Twenty weeks after LV administration, we transplanted BM cells from ADA-SCID mice treated as newborns into NSG recipient mice and

showed long-term LV marking of around 5% in the BM and lymphoid organs of transplanted mice, in line with marking observed in donor mice treated as newborns. Our work shows *in vivo* gene transfer into HSPC in newborn mice and life-long maintenance of transgene expression, suggesting that special hematopoietic niches and higher HSPC accessibility in this window may be exploited to obtain disease correction, especially when a selective advantage of corrected cells is present. Further studies are ongoing to explore *in vivo* LV gene transfer into HSPC in other disease models.

217 Lentiviral-Mediated Gene Therapy for Fanconi Anemia [Group A]: Results from Global RP-L102 Clinical Trials

Agnieszka Czechowicz[1,2,3], Julián Sevilla[4], Claire Booth[5], Susana Navarro[6], Rajni Agarwal[1,2,3], Josune Zubicaray[4], Paula Río[6], Kritika Chetty[5], Gráinne O'Toole[5], Jinhua Xu-Bayford[5], Philip Ancliff[5], Elena Sebastián[4], Grace Choi[7], Miriam Zeini[7], Eileen Nicoletti[7], Cindy Eide[8], John E. Wagner[8], Gayatri Rao[7], Adrian J. Thrasher[5], Jonathan Schwartz[7], Maria-Grazia Roncarolo[1,2,3], Juan A. Bueren[6]

[1]Stanford School of Medicine, Palo Alto, CA,[2]Lucile Packard Children's Hospital, Palo Alto, CA,[3]Center for Definitive and Curative Medicine, Palo Alto, CA,[4]HIUNJ/CIBERER, Madrid, Spain,[5]UCL Great Ormond Street Institute of Child Health, London, United Kingdom,[6]CIEMAT/CIBERER/IIS-FJD, Madrid, Spain,[7]Rocket Pharmaceuticals, Inc., Cranbury, NJ,[8]University of Minnesota, Minneapolis, MN

Background: Fanconi anemia (FA) is an inherited deoxyribonucleic acid (DNA) repair disorder that results in progressive bone marrow failure (BMF) in 80% of patients within the first decade of life. Allogeneic hematopoietic stem cell transplant (alloHSCT) is potentially curative for FA-related BMF. Although survival exceeds 80% in experienced transplant centers, adverse effects including 100-day mortality and increased cancer risk present persistent limitations. The current studies utilize autologous FA-A CD34+ enriched hematopoietic stem and progenitor cells (HSPCs) and rely upon the proliferative advantage of gene-corrected FA HSPCs, enabling engraftment without conditioning. We report results from global RP-L102 studies. **Methods:** Patients with *FANCA* mutations, age ≥1 year with no HLA-matched sibling donor and ≥30 CD34+ cells/μL in bone marrow (BM) are eligible. Peripheral blood (PB) cells are collected via leukapheresis. Following CD34+ enrichment, HSPCs are transduced with a lentiviral vector carrying the *FANCA* gene, and infused without cryopreservation or conditioning. Patients are followed for 3 years for safety assessments (including insertion site analysis [ISA]) and for evidence of efficacy (increasing vector copy number [VCN], mitomycin-C [MMC] resistance in BM colony forming cells [CFCs]), and stabilization/correction of cytopenias). **Results:** As of October 2022, 12 patients age 2 to 6 years have received RP-L102. Sustained engraftment has been demonstrated in 7 of 10 evaluable patients with ≥12 months of follow up as indicated by peripheral blood mononuclear cell (PBMC) VCN (median: 0.53; range: 0.19-0.65 at 12-40 months). Six of these 7 patients have increasing BM CFC MMC resistance with concurrent hematologic stabilization (median: 85%; range: 22-94% at 12-40 months). One patient without genetic correction had progressive BMF and underwent successful alloHSCT. A transient serious Grade 2 RP-L102 infusion-related reaction was observed in one patient and resolved without sequelae. No patients have developed RCL. One patient developed T cell lymphoblastic lymphoma determined to be unrelated to gene therapy. There has been no evidence of RP-L102 related bone marrow dysplasia, clonal dominance or insertional mutagenesis. **Conclusions:** RP-L102 conferred phenotypic correction as demonstrated by sustained increase in BM CFC MMC resistance, genetic correction and hematologic stabilization in at least 6 patients with ≥1 year of follow up. Sustained engraftment, phenotypic correction, and hematologic stability was achieved in the absence of conditioning. RP-L102 represents a potentially curative therapy for FA-related BMF, which can be administered without transplant-conditioning related toxicities. Updated results for patients (n=12) with ≥ 1 year of follow-up will be presented.

218 Global Phase 1 Study Results of Lentiviral Mediated Gene Therapy for Severe Pyruvate Kinase Deficiency

Ami J. Shah[1,2,3], Jose Luis Lopez Lorenzo[4], Julián Sevilla[5], Susana Navarro[6], Lucía Llanos[4,7], Begoña Pérez de Camino Gaisse[4], Sol Sanchez[4], Josune Zubicaray[5], Bertil Glader[1,3], May Chien[1,3], Oscar Quintana Bustamante[6], Miriam Zeini[8], Grace Choi[8], Eileen Nicoletti[8], Gayatri Rao[8], Maria-Grazia Roncarolo[1,2,3], Juan A. Bueren[6], Jonathan Schwartz[8], Jose Carlos Segovia[6]

[1]Lucile Packard Children's Hospital, Palo Alto, CA,[2]Center for Definitive and Curative Medicine, Palo Alto, CA,[3]Stanford School of Medicine, Palo Alto, CA,[4]Hospital Universitario Fundación Jiménez Díaz, Madrid, Spain,[5]Hospital Infantil Universitario Niño Jesús, Madrid, Spain,[6]CIEMAT/CIBERER/IIS-FJD, Madrid, Spain,[7]Instituto de Investigación Sanitaria Fundación Jiménez Díaz (IIS-FJD), Madrid, Spain,[8]Rocket Pharmaceuticals, Inc., Cranbury, NJ

Background: Pyruvate kinase deficiency (PKD) is a rare inherited hemolytic anemia caused by *PKLR* gene mutations. Manifestations include anemia, splenomegaly and iron overload, which may be life-threatening. Currently available treatments are limited to a recently-approved enzyme activator or palliative therapies such as chronic blood transfusions, iron chelation therapy and splenectomy which are associated with significant side effects. A global Phase 1 clinical trial RP-L301-0119 (NCT04105166) is underway to evaluate lentiviral mediated hematopoietic stem and progenitor cell (HSPC)-targeted gene therapy for adults and children with severe PKD. **Methods:** Splenectomized patients with severe PKD (severe and/or transfusion-dependent anemia) are eligible. Following apheresis, HSPCs are transduced with lentiviral vector and cryopreserved. Myeloablative therapeutic drug monitoring-guided busulfan is administered and the gene therapy product (RP-L301) is thawed and infused. Patients are followed for safety assessments (including insertion site analysis [ISA]), and efficacy (genetic correction, decrease in transfusion requirements, significant improvement in anemia and reduction of hemolysis) for 2 years post-infusion. **Results:** As of October 2022, 2 patients (age 31 and 47 years at enrollment) with severe anemia have received RP-L301. Patient 1 received $3.9x10^6$ CD34+ cells/kg with mean vector copy number (VCN) of 2.73. Patient 2 received $2.4x10^6$ CD34+ cells/kg with mean VCN of 2.08. Despite baseline hemoglobin (Hb) levels in the 7.0-7.5 g/dL

range, at 24 months post-infusion both patients have normal-range hemoglobin (13.2 g/dL and 14.7 g/dL, respectively), and no red blood cell transfusion requirements post-engraftment. Other parameters of hemolysis and anemia (LDH, bilirubin, erythropoietin) are improved. Peripheral blood mononuclear cell (PBMC) vector copy numbers (VCNs) were 1.75 and 1.43 at 24-months. Both patients reported improved quality of life (QOL), also demonstrated by increases in both FACT-An and SF-36 scores, with marked improvement in SF-36 energy/fatigue, physical functioning, and general health components. No serious adverse events (SAEs) have been attributed to RP-L301. Hematopoietic reconstitution occurred within 2 weeks of administration. ISA in PB and BM for both patients up to 12 months following therapy indicate highly polyclonal patterns; longitudinal results delineating clonal diversity will be presented. **Conclusion:** Clinical efficacy and safety data indicate that RP-L301 is a potential treatment for patients with severe PKD, including those who did not derive benefit from available therapies. Robust and sustained efficacy in both patients at 24 months post-treatment was demonstrated by normalized hemoglobin, improved hemolysis parameters, and transfusion independence.

219 Unraveling the Effect of Proliferative Stress *In Vivo* in Hematopoietic Stem Cell Gene Therapy Mouse Study

Francesco Gazzo[1,2], Daniela Cesana[1], Pierangela Gallina[1], Laura Rudilosso[1], Giulio Spinozzi[1], Giulia Pais[1], Eugenio Montini[1], Andrea Calabria[1]

[1]San Raffaele Telethon Institute for GT (Sr-Tiget), IRCCS San Raffaele Scientific Institute, Milan, Italy,[2]Department of Electronics, Information and Bioengineering, Politecnico di Milano, Milan, Italy

The hematopoietic system of patients enrolled in hematopoietic stem cells (HSC) gene therapy (GT) treatments is fully reconstituted upon autologous transplantation of engineered stem cells. HSCs highly proliferate up to full restoration of homeostasis and compete for niche homing and engraftment. The impact of the proliferation stress in HSC on genetic instability remains an open question that cured patients advocate for characterizing long-term safety and efficacy. The accumulation of somatic mutations has been widely used as a sensor of proliferative stress. Vector integration site (IS) can be used as a molecular tool for clonal identity, inherited by all HSC progeny, to uncover lineage dynamics in vivo at single-cell level. Here we characterized at single-clone granularity the proliferative stress of HSCs and their progeny over time by measuring the accumulation of mutations from the DNA of each IS. To test the feasibility of the approach, we set-up an experimental framework that combines tumor-prone *Cdkn2a*$^{-/-}$ and wild type (WT) mouse models of HSC-GT and molecular analyses on different hematopoietic cell lineages after transplantation of HSCs transduced with genotoxic LV (LV.SF.LTR) or GT-like non-genotoxic LV (SIN.LV.PGK). The *Cdkn2a*$^{-/-}$ mouse model provided the experimental conditions to detect the accumulation of somatic mutations, since the absence of p16^{INK4A} and p19^{ARF} enhances the proliferative potential of cells that have acquired oncogenic mutations. As expected, mice transplanted with *Cdkn2a*$^{-/-}$ Lin^{-} cells marked with LV.SF.LTR (N=24) developed tumors significantly earlier compared to mock (N=20, $p<0.0001$), while mice treated with SIN.LV.PGK (N=23) did not. On the other side, mice that received WT Lin^{-} cells treated with LV.SF.LTR (N=25) or SIN.LV.PGK (N=24) vector have not developed tumors. Given this scenario, we expect that *Cdkn2a*$^{-/-}$ Lin^{-} cells transduced with LV.SF.LTR are associated with higher mutation rates compared to the SIN.LV.PGK group and wild type control mice. The composition of peripheral blood, lymphoid (B and T) and myeloid compartments was assessed by FACS on samples collected every 4 weeks and IS identification. More than 200,000 IS have been recovered. To identify the presence of somatic mutations, the genomic portions of sequencing reads flanking each different IS were analyzed with VarScan2. The accumulation rates of mutations have been evaluated by our new Mutation Index (MI) which normalizes the number of mutations by clones and coverage. Considering that a large portion of IS has been discarded since not covered by a minimum number of 5 unique reads (genomes), the remaining number of IS contained >90% of reads in each group. The MI increased over time in both LV.SF.LTR groups, with higher values for the *Cdkn2a*$^{-/-}$. On the other hand, treatment with SIN.LV.PGK resulted in lower MI in both groups compared to LV.SF.LTR groups, reflecting the higher clonal composition of the cells treated with the SIN.LV.PGK and the phenomenon of insertional mutagenesis in the LV.SF.LTR. Moreover, the higher MI values of the SIN.LV.PGK *Cdkn2a*$^{-/-}$ group compared with the WT group proved the induction of DNA fragility. Our results showed that the analysis of the accumulation of somatic mutations at single clone unraveled HSC proliferation stress in vivo, combining for the first time the analysis of acquired mutations with IS. We are now applying our model to different clinical trials, and studying HSCs subclonal trees by symmetric divisions, previously indistinguishable by IS only. Our study will open the doors to in vivo long-term non-invasive studies of HSC stability in patients.

220 Highly Efficient Correction of the Sickle Cell Disease Mutation in Patient HSC Using an RNA Gene Writing System, an RNA-Based, Nuclease-Free Approach to Genome Editing

Giulia Schiroli[1], Yaser Heshmati[1], Aamir Mir[1], Yu Cao[1], Shallu Kutlehria[1], Jicheng Duan[1], Lorenzo Tozzi[1], Rui Zhang[1], Felipe Gazos Lopez[1], William E. Salomon[1], James B. Rottman[1], Jane Wang[1], Anne Bothmer[2], Jean-Antoine Ribeil[3], John P. Manis[4], Cecilia Cotta-Ramusino[1], Michael C. Holmes[1]

[1]Tessera Therapeutics, Somerville, MA,[2]Tessera Therapeutics, Cambridge, MA,[3]Boston University, Boston, MA,[4]Boston Children's Hospital, Boston, MA

The ability to introduce new DNA sequences into the genome with high specificity and efficiency would provide a critical complement to existing gene editing approaches. Here, we developed Gene Writing systems, leveraging target-primed reverse transcription (TPRT) biochemistry evolved by non-LTR retrotransposon mobile genetic elements to edit genetic information at a specific genomic site without introducing DNA breaks in hematopoietic stem cells (HSC). Programmable TPRT requires the enzymatic steps of DNA nicking and reverse transcription. Using a large throughput screening, we developed synthetic Gene Writer enzymes that can catalyze a variety of editing reactions, such as the introduction of gene-length DNA sequence and substitutions, including the correction of *HBB* sickle mutation

to WT. These edits can be achieved with all-RNA delivery in primary cells and in vivo, eliminating the necessity for viral vectors and DNA template-based gene editing. Sickle cell disease (SCD) is caused by a point mutation in the *HBB* gene (E6V), affects erythroid lineage leading to severe anemia and significant multiorgan complications. Challenges of current gene therapy approaches for SCD include safety concerns due to insertional oncogenesis risk by viral vectors, DNA double-strand break induction by nucleases, and inadequate achievement of corrective levels of HSC modification. Using our Gene Writer system comprised of a reverse transcriptase fused to a synthetic RNA-guided Cas nickase and a modified template RNA, we first modeled the efficiency of *HBB* gene modification by introducing the *HBB* Makassar variant (E6A) in CD34+ human HSC from normal donors. Extensive studies optimizing the RNA template and delivery/expression of our Gene Writer system showed we could achieve up to 70% perfect allele modification. Similar editing efficiency was observed in quiescent HSC as compared to cytokine-stimulated cells, results that are consistent with our platform not requiring cell division or engagement by the HDR machinery. As compared to treatment with conventional nucleases, our Gene Writing system did not induce a detectable p53-related response. We then validated efficient editing of long-term repopulating HSC by demonstrating similar editing efficiencies in sorted CD90+ primitive cells and achieving ~70% perfect HBB modification in HSC and their multi-lineage progeny isolated from transplanted mice. No phenotypic or functional impairment was observed in edited HSCs as measured by colony forming assays, erythroid differentiation, or in vivo reconstitution studies up to 16 weeks post-transplant. Finally, we achieved efficient ex vivo editing of CD34+ cells from SCD patients, showing ~70% correction of sickle alleles to WT. Differentiation towards erythroid lineage showed gene modified cells exhibited improved enucleation and, importantly, restoration of normal adult hemoglobin levels by HPLC (98% HbA, 2% HbS) and LC-MS. Our editing strategy enabled phenotypical correction of virtually all differentiated erythrocytes, resulting in complete abrogation of cell sickling. Given that the all-RNA nature of our compositions potentially enables in vivo strategies for correcting SCD, we also showed we are able to efficiently deliver mRNA to HSC in animal models by LNP (>80% in humanized mice, >30% in NHP). These results highlight that our Gene Writing technology based on TPRT biochemistry is highly efficient at introducing precise edits in human HSC and provides a promising new therapeutic approach to SCD.

Cell Therapy Product Engineering and Development | Cancer

221 Allogeneic CAR T Cells with Regulated NEF Expression Display Immune Evasion and Optimized Signaling

Karlo Perica, Jorge Mansilla-Soto, Ivan Kotchetkov, Michel Sadelain

Center for Cell Engineering, Memorial Sloan Kettering Cancer Center, New York, NY

Allogeneic CAR T cells manufactured from healthy donor or pluripotent stem cells are a potential off-the-shelf alternative to current autologous therapies. Allogeneic products could reduce cost and allow rapid treatment, but are limited by host-versus-graft immune (HVGI) rejection. To study HGVI, we developed a leukemia xenograft model in immunodeficient mice engrafted with PBMC, and demonstrated that CD8 T cell responses limit allogeneic CAR T cell persistence and tumor control. To develop an allogeneic CAR T cell resistant to immune rejection, we used retroviral vectors to co-transduce CAR and a panel of viral immune evasion proteins, including US2 and US11 from hCMV, K5 from KSV, BNLF2a from EBV, and NEF from HIV1. All evasion proteins downregulated MHC-I surface expression to varying degrees, leading to resistance from CD8 T cell killing *in vitro*. However, variegated expression from a retroviral promoter led to variable and transient downmodulation of MHC levels *in vivo*. In contrast, site-specific genomic insertion from a constitutive promoter leads to stable expression, durable MHC downregulation, and longer in vivo persistence. We next utilized a tumor-only xenograft model to show that expression of HIV-1 NEF but not other evasion proteins intrinsically enhanced CAR T cell expansion and tumor control. Using phosphoproteomics, we demonstrated that that NEF attenuates CAR T cell signaling, including decreased CD3ζ and CD28 phosphorylation. We further demonstrated this function depends on the NEF SH3-binding domain that modulates T cell signaling through interactions with several proteins, including LCK. As a result, regulated NEF expression led to stable MHC downregulation, increased T cell expansion, and improved tumor clearance in a PBMC-engrafted NALM6 leukemia model and a CD19 expressing glioblastoma model. Thus, we achieve a clinically translational allogeneic CAR T cell platform by enhancing both intrinsic CAR T cell function and immune evasion.

222 Mechanistic Characterization of Afamitresgene Autoleucel (Afami-cel; Formerly ADP-A2M4)

Laura Hudson, Elizabeth Evans, Elizabeth A. Marchant, Gareth Betts, Alex Tipping, Alicia Soria, Natalie Bath, Alasdair Gunn, Chris Evans, Cheryl McAlpine

Adaptimmune, Abingdon, Oxfordshire, United Kingdom

Afami-cel is a T-cell receptor (TCR) T-cell therapy composed of autologous CD4+ and CD8+ T-cells genetically modified to express an engineered TCR targeting the cancer testis antigen MAGE-A4. Afami-cel demonstrated encouraging results and an acceptable benefit-to-risk profile in adults with relapsed/refractory metastatic

solid cancers, especially synovial sarcoma (SyS). In the Phase 1 trial of afami-cel (NCT03132922), there was an overall response rate (ORR) of 44%, a disease control rate of 94%, and a median duration of response of 6.4 months in patients with SyS.[1] Results from Cohort 1 of the Phase 2 trial of afami-cel (SPEARHEAD-1; NCT04044768) show an ORR of 38.6% and durable responses (median of 11.6 months) in SyS.[2] Ongoing translational analyses evaluate if there is optimal phenotypic composition of afami-cel manufactured product (MP), conferring better tumor killing response, proliferative capacity, and ability to survive in the tumor. Here we examine how afami-cel MP phenotypic composition translates to functional profile. MP was sampled before infusion into patients in SPEARHEAD-1. Samples were stimulated using magnetic particles labelled with MAGE-A4-specific peptide-HLA and anti-CD28 antibodies, with or without interleukin 2. Unstimulated and stimulated MP were phenotypically profiled by flow cytometry using multi-color staining panels for T-cell exhaustion and activation at Day 0 and after 24 h. Functional cytotoxicity and proliferation profiling was performed on unsorted and FACS-sorted T-cell subpopulations. Cytotoxicity assays using Incucyte imaging examined tumor derived cell line growth (A375nucGFP$^+$) in the presence or absence of MP. T-cell proliferation and death were measured simultaneously over 6 d using RealTime Glo MT cell viability and CellTox Green cytotoxicity assays. Mitochondrial metabolic state was determined by flow cytometry using MitoTracker Green FM and Red CMXRos to quantify mitochondrial mass and membrane potential at Day 0 and 24 h after stimulation. Preliminary mechanistic analyses were performed for three MP samples, which showed a variable range in manufactured dose (4.7-9.4 $\times 10^9$ cells), transduction efficiency (25-77% transduced cells), and CD4+ (32-52%) and CD8+ (44-66%) T-cell frequencies. Flow cytometry profiles showed differential stimulation-induced increases in (co-)expression levels of activation/exhaustion markers within sample subpopulations and between samples, related to functional responsiveness. Overall, the MP sample with the highest manufactured dose and percentage of transduced cells showed the greatest cytotoxic response and proliferative capacity, as indicated by faster kinetics and magnitude of CD4+/CD8+ T-cell proliferation in response to stimulation. The converse was noted for the MP sample with the lowest manufactured dose and percentage of transduced cells; the lower proliferative capacity was shown to not result from increased cell death. The MP with lowest proliferative and cytotoxic capacity showed a higher mitochondrial mass at baseline and a lack of mitochondrial response post stimulation. Initial data demonstrate proof-of-concept translation of afami-cel MP phenotype to in vitro function and indicate a relationship to manufacturing dose and transduction efficiency. To understand if the mechanistic capacity of MP indicates postinfusion clinical response, expanded MP datasets with SPEARHEAD-1 clinical correlatives will be presented.1. Hong, et al. Nat Med (2023). https://doi.org/10.1038/s41591-022-02128-z. 2. Van Tine, et al. Paper 61: CTOS 2022; Vancouver, Canada

223 Cytosine Base Editor Ameliorates the Safety Profile of (TCR) - Transgenic T Cells for the Adoptive Cell Therapy of Gastrointestinal Tumors

Martina Spiga[1], Alessia Potenza[1], Stefano Beretta[2], Martina Fiumara[2], Samuele Ferrari[2], Neda Mohammadi[1], Maria Pia Protti[1], Stefano Crippa[3], Massimo Falconi[3], Luigi M. Naldini[2], Eliana Ruggiero[1], Chiara Bonini[1]

[1]Experimental Hematology, San Raffaele Scientific Institute, Milan, Italy,[2]SR-TIGET, Milan, Italy,[3]Pancreas Center, Ospedale San Raffaele, Milan, Italy

Adoptive cell therapy (ACT) with T cell receptor (TCR) - transgenic T cells is a promising therapeutic strategy for advanced gastrointestinal cancers. However, the paucity of TCRs targeting relevant tumor antigens and the immunosuppressive tumor microenvironment (TME) limits ACT applicability. We combined the analysis of published datasets with a multidimensional investigation of CRC and PDAC samples collected and analyzed at Ospedale San Raffaele to select a set of tumor-associated antigens (TAAs) to be targeted by ACT. By clonal tracking of TCR repertoire of T cells stimulated with autologous APCs loaded with the selected antigens, we isolated 6 TCRs specific for different TAAs, including HER2 and mesothelin. TCR-transgenic T cells tested against PDAC cell lines and CRC patient-derived organoids showed anti-tumor efficacy toward HLA-matched cells while sparing HLA-unmatched controls. CRISPR/Cas9 is often selected as a tool to genetically manipulate T cells to redirect their specificity and endow them with the ability to counteract the immunosuppressive TME. However, CRISPR/Cas9 activity can produce important off-target events at the genomic level, affecting the safety profile of therapeutic cellular products. To overcome these limitations, we optimized the genome editing approach of T cells by relying on a cytosine base editor, BE4max. We generated $HER2_{369\text{-}377}$-specific T cells deprived of the endogenous TCR and TIGIT, a key immunosuppressive molecule, exploiting CRISPR/Cas9 and BE4max. Both editing procedures proved highly efficient in simultaneously disrupting *TRAC*, *TRBC1*, *TRBC2* and *TIGIT* (mean 96.6% and 96.3% of TRAC disruption, 81% and 73.6% of TRBC1 disruption, 75% and 67.3% of TRBC2 disruption and 89.3% and 90.7% of TIGIT disruption with CRISPR/Cas9 and BE4max, respectively) without impairing T cells' memory phenotype differentiation nor their expansion abilities. Remarkably, we only detected translocations between our four target loci in CRISPR/Cas9 treated cells (up to 0.44%). Moreover, by performing ultra-deep whole exome sequencing of base edited cells, we observed that BE4max efficiently mediated gene disruption without introducing biologically relevant off-target mutations. In functional assays, $TIGIT_{KO}HER2_{369\text{-}377}$-redirected T cells engineered with BE4max showed superior abilities, compared to TIGIT competent T cells, in eliminating PDAC cell lines (PANC1, T3M4 and BxPC3) and CRC patient-derived organoids. Our findings suggest that base editors can generate cellular products with a better safety profile and promising therapeutic efficacy in gastrointestinal tumors.

224 CD19/BCMA Dual-Targeting CAR-T Cells Generated by Co-Transduction for the Treatment of Non-Hodgkin Lymphoma

Mireia Bachiller[1], Nina Barcelo[1], Celia Dobaño-Lopez[1], Alba Rodriguez-Garcia[1], Joan Castellsague[1], Marta Gimenez-Alejandre[1], Leticia Alserawan[2], Julio Delgado[2], Marta Español-Rego[2], Mariona Pascal[2], Manel Juan[2], Patricia Perez-Galan[1], Alvaro Urbano-Ispizua[2], Sonia Guedan[1]

[1]Fundacio Clinic per la Recerca Biomedica, Barcelona, Spain,[2]Hospital Clinic de Barcelona, Barcelona, Spain

Introduction: A common mechanism of resistance to CD19 CAR-T cell therapy is the loss or downregulation of antigen expression. Simultaneous targeting of more than one antigen has been proposed as a strategy to overcome this challenge. However, lack of preclinical studies comparing side-by-side the approaches together with missing predictive assays challenge the development of optimized clinical candidates. Here, we propose the dual-targeting of CD19 and BCMA to treat B-cell non-Hodgkin lymphoma patients, as most B-NHL subtypes co-express both antigens. Our in-house developed CARs targeting CD19 (ARI0001) and BCMA (ARI0002) have proven safe and efficacious in the treatment of patients with B-cell malignancies and multiple myeloma, respectively. We hypothesized that the co-transduction of two lentiviral vectors (ARI0001 and ARI0002) is a feasible strategy to obtain CD19/BCMA dual-targeting CAR-T cells with potential for clinical translation. **Methods**: We developed the following dual-targeting approaches: 1) Co-transduction of both lentiviral vectors (named ARI0003), 2) Pooled single CAR-T cells, 3) Bicistronic CAR-T cells encoding both CARs on the same lentiviral vector separated by a T2A peptide and 4) Tandem and Loop-CARs composed of two scFvs in one CAR construct. All CAR constructs contain the intracellular domains of 4-1BB and CD3. To evaluate these strategies in models that mimic a potential lack of response or relapse due to CD19 low densities, we developed two different preclinical models. First, we generated a CD19low cell line of Burkitt lymphoma and second, we generated Patient-Derived Lymphoma Spheroids (PDLS) from B-NHL patients that relapsed after treatment with CD19 CAR-T cells. Finally, we compared these strategies in different *in vivo* settings, including a model of high disease burden and a model of secondary treatment after treatment failure with ARI0001. **Results**: First, we observed that bicistronic and tandem/loop CARs required four times more integrated DNA lentiviral vector copies than the rest of the strategies to obtain the same levels of CAR expression on the T cell membrane, raising potential safety concerns. In addition, tandem and loop CARs showed limited long-term *in vitro* killing and persistence, which might be due to complex conformations of its extracellular domain and steric impediment to antigen recognition, and therefore were not included in future characterizations. Long-term *in vitro* assays, coculture experiments with PDLS from patients who relapsed anti-CD19 therapy and conventional *in vivo* experiments revealed that the co-transduction and pool groups behaved very similarly, significantly outperforming ARI0001 and the bicistronic vector in terms of killing, proliferation and antitumor effects, especially in models of low CD19 densities. Importantly, ARI0003 preserved effective antitumor activity after treatment failure with ARI-0001 against a CD19low B-NHL xenograft and outperformed the pool in the control of disease recurrence. Based on these results, ARI0003 was finally selected as our clinical candidate. The production of five clinical-grade CAR-T cell products using CliniMACS Prodigy confirmed the feasibility and potential of translating this strategy to the clinic. **Conclusion**: In summary, we propose the co-transduction as an efficient strategy to obtain highly effective CD19/BCMA dual CAR-T cells. We are currently preparing the required documentation to get approval from the regulatory agencies to initiate clinical trials to treat NHL patients with this therapy.

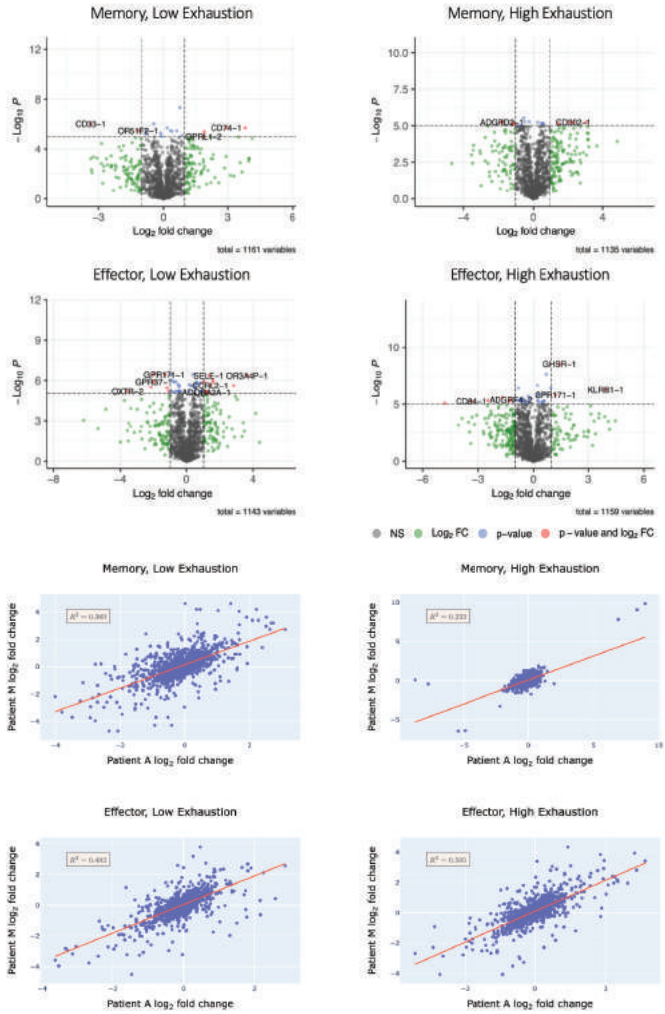
225 High-Throughput Screen of Chimeric Antigen Receptor (CAR) T Cells with Native and Non-Native Costimulatory Domains

Conor Kelly, Wenjun Zhu, Stephanie E. Sellers, Cynthia Dunbar, Stefan Cordes

National Institutes of Health (NIH), Bethesda, MD

Chimeric antigen receptor (CAR) T-cells have shown great promise in clinical studies. Their therapeutic utility can be limited by lack of durability of the CAR T-cells and therapy related toxicities including cytokine release syndrome and neurotoxicity. Efficacy, persistence, and toxicity are known to correlate with the distribution of T cell subsets in the infusion product. T cell activation requires two signals, one that is antigen-dependent and another that in natural T cells is provided through the binding of a costimulatory receptor to its cognate ligand. In second generation CAR T cells, both signals are delivered by the CAR. Different costimulatory signals result in skewing of T-cell subsets. A limited variety of costimulatory domains have been used clinically and there has been relatively little research into the effect of non-native costimulatory domains. In this study we performed high throughput *in vitro* screening of > 1,200 intracellular domains from receptors found in the innate and adaptive immune systems for their potential utility to CAR T-cell therapy. To design the pool, we queried the Uniprot database for the primary sequences of the intracellular portions of transmembrane immune signaling molecules. Most of the elements in this pool are not naturally expressed in T cells and include receptors involved in activation, regulation, development and cytokine signaling of innate and adaptive immune cells. The motifs in our pool include those previously studied such as ITAMs and many not yet studied such as TIR and SPRY/B30.2. We inserted codon-optimized versions of the candidate costimulatory signaling sequences into a backbone plasmid containing a second generation anti-CD20 CAR with a truncated EGFR marker. We lentivirally transduced the pool of CAR into T cells from healthy human donors and co-cultured with CD20-expressing Raji cells. After 5 days the CAR T cells were FACS sorted by memory or effector T cell immunotype and high versus low expression of peripheral tolerance markers. We extracted DNA from the sorted CAR T cells and sequenced to identified costimulatory domains enriched in each group. The results were statistically analyzed to identify the enrichment or depletion of costimulatory domains which promote desirable T cell subtype distributions. We found that CAR T-cells with cytosolic portions of CD33 were depleted in the low exhaustion memory immunophenotype. CAR T with the cytosolic domain of KLRB1, an important receptor that inhibits cytotoxicity in NK cells, were enriched in CAR T with the high exhaustion effector phenotype. We performed our experiment with T cells obtained from two healthy human donors and found no significant differences in

the enrichment and depletion profiles. High throughput screening is a useful tool for CAR T-cell design. As a next step, we plan to use data generated by these experiments to train a machine learning model to predict the probability that a CAR T-cell with novel costimulatory receptors will adopt a desired immunophenotype.



226 Epitope Editing in Hematopoietic Cells Enables Universal Blood Cancer Immune Therapy

Nils Wellhausen[1], Austin K. Rennels[1], Stefanie Lesch[1], Nils W. Engel[1], Regina M. Young[1], K. Christopher Garcia[2], Carl H. June[1], Saar I. Gill[1]

[1]Center for Cellular Immunotherapies, University of Pennsylvania, Philadelphia, PA,[2]2Department of Molecular and Cellular Physiology, Stanford University School of Medicine, Stanford, CA

Background: Targeted immunotherapies such as CAR-T cells are limited to several well-known lineage markers for which the on-target off-tumor toxicities are clinically tolerated. CAR-T cells have been developed individually for different hematologic malignancies based on the relevant lineage antigens (e.g. CD19 for B cell leukemias). By targeting a pan-hematologic antigen, a single "drug" could be used for all hematologic indications, thereby accelerating clinical research. CD45 is expressed on most hematologic malignancies and is, therefore, an attractive target for pan-hematologic cancer immunotherapy. However, targeting CD45 with CAR-T cells is limited by (i) on-target/off-tumor toxicities due to expression of CD45 on hematopoietic stem cells (HSC) and their progeny, and (ii) CAR-T cell fratricide. To protect HSCs and T cells from CART-45 mediated cytotoxicity we sought to modify the relevant CD45 epitope in T-cells and HSCs in such a way that it is unrecognized by the anti-CD45 CAR-T cells while preserving CD45's phosphatase activity, which is crucial for HSC and T-cell function. **Results:** We mapped the amino acid residues on the extracellular domain of human CD45 that are required for binding by anti-CD45 CAR-T cells (CART-45) by alanine mutagenesis and devised a CRISPR base editing approach to install a single mutation at the identified epitope. This allowed us to generate a CD45 molecule that is "invisible" to CART-45 cells. T-cells transduced with CART-45 show substantially impaired ex vivo expansion compared to CD19-directed CAR-T cells due to fratricide, as expected. However, CART-45 cells in which the targeted epitope was altered through adenine base editing (CART-45^{edited}) were resistant to fratricide, enabling their expansion comparable to that of CD45^{KO} or CAR19 control T cells. In contrast with CD45^{KO} CAR-T cells, CD45^{edited} cells retain CD45 phosphatase expression which we hypothesized to be crucial for CAR-T cell function in xenograft tumor models. In a B-ALL tumor xenograft model, CD45^{edited} CART-19 function was equivalent to CD45^{WT} CART-19, and superior to CD45^{KO} CART-19, indicating that CD45 is needed for the proper function of CAR-T cells. We then tested CART-45 in a patient-derived xenograft (PDX) model of human AML and found that CART-45 eliminated tumor cells with no detectable blasts in peripheral blood or bone marrow 4 weeks post CART-45 injection. To protect the hematopoietic system from CD45-directed on-target/off-tumor toxicity, we base-edited the targeted CD45 epitope in human HSCs, achieving the desired base conversion in 85% of human HSCs. CD45^{WT} and CD45^{edited} HSCs were engrafted into immunodeficient mice and treated with CART-45. Crucially, CD45^{edited} HSCs and their progeny persisted after CART-45 injection, whereas CD45^{WT} HSCs were readily eliminated, suggesting that CD45^{edited} hematopoiesis is protected from CART-45. We further show that CD45^{edited} HSCs transplanted into immunodeficient mice led to equivalent hematopoietic engraftment and differentiation when compared with CD45^{WT}cells, whereas CD45^{KO} hematopoiesis was lost over time. **Conclusions:** Here we developed a novel platform that combines pan-hematologic anti-CD45 CAR-T cells with an engineered hematopoietic stem cell transplant endowed with selective resistance to CD45-specific immunotherapy while maintaining CD45 expression and function. This platform creates a cancer-specific antigen in all residual host hematopoietic cells, enabling its use in most hematopoietic malignancies and perhaps other diseases requiring profound hematopoietic ablation.

227 Co-Expression of the IL15-IL15α Complex with a 41BB-Based Chimeric Antigen Receptor Promotes Superior Antitumor Activity in NKT Cells

Gabriel A. Barragan Bravo, Amy N. Courtney, Xin Xu, Gengwen Tian, Linjie Guo, Boning Yang, Leonid S. Metelitsa

Center for Advanced Innate Cell Therapy, Department of Pediatrics, Baylor College of Medicine, Houston, TX

Despite successes in hematologic malignancies, conventional T cells expressing chimeric antigen receptors (CARs) are largely ineffective against solid tumors. Invariant natural killer T cells (NKTs) are a subset of innate lymphocytes that have inherent antitumor properties and traffic to tumor sites. We have shown that CAR-NKTs targeting disialoganglioside GD2 expressed by neuroblastoma (NB) tumor cells mediate potent antitumor activity in a xenogeneic model of NB. This effect was further enhanced by co-expression of the NKT homeostatic cytokine, IL15. Previous research has shown that *trans*-presentation of IL15 by IL15 receptor α (15Rα) is the main physiological mechanism of action for this cytokine. Therefore, we hypothesized that co-expressing IL15 and 15Rα (15.15Rα) in GD2.CAR NKTs will enhance their antitumor activity. We generated GD2.CAR constructs encoding the CD28 or 41BB co-stimulatory domain and co-expressed 15.15Rα (28z.15.15Rα and BBz.15.15Rα), using constructs without cytokine co-expression or co-expressing IL15 only as controls. We found that all constructs mediated similar levels of GD2-specific *in vitro* cytotoxicity against NB cell lines. However, BBz.15.15Rα NKTs had the greatest fold expansion after serial tumor challenge and crucially demonstrated superior control of tumor growth in a mouse model of NB, significantly increasing animal survival beyond all other groups ($p<0.01$). Gene expression analysis after NB tumor cell challenge revealed that BBz.15.15Rα NKTs have a similar gene expression profile to naïve or central memory T cells while 28z.15.15Rα NKTs instead resemble exhausted T cells ($p<0.05$). Therefore, the BBz.15.15Rα construct has emerged as the leading candidate for the next-generation CAR-NKT cell therapy for NB.

Gene Targeting and Gene Correction: New Technologies

228 Shuttle Peptide Delivers Base Editor RNPs to Rhesus Monkey Airway Epithelial Cells *In Vivo*

Katarina Kulhankova[1], Soumba Traore[1], Xue Cheng[2], Hadrien Benk-Fortin[2], Stéphanie Hallée[2], Mario Harvey[2], Joannie Roberge[2], Frédéric Couture[3], Thomas Gross[4], Gregory A. Newby[5], David R. Liu[6], Alice F. Tarantal[7], David Guay[2], Paul B. McCray[1]

[1]Pediatrics, University of Iowa, Iowa City, IA,[2]Feldan Therapeutics, Québec, QC, Canada,[3]TransBIOtech, Lévis, QC, Canada,[4]Internal Medicine, University of Iowa, Iowa City, IA,[5]Broad Institute of MIT and Harvard, Cambridge, MA,[6]Harvard University and HHMI, Cambridge, MA,[7]University of California, Davis, Davis, CA

Gene editing strategies for cystic fibrosis are challenged by the complex barrier properties of airway epithelia. We previously reported that the amphiphilic S10 shuttle peptide non-covalently combined with CRISPR-associated (Cas) ribonucleoprotein (RNP) enabled editing of human and mouse airway epithelia. Here, to improve base editor RNP delivery, we optimized S10 to derive the S315 shuttle peptide with improved Cas9 RNP delivery properties. Following intratracheal aerosolization of a Cy5-labeled peptide cargo with a nuclear localization signal in young rhesus monkeys, we confirmed delivery throughout the respiratory tract. A nuclear Cy5 signal was observed in luminal ciliated cells (acetylated tubulin$^+$), secretory cells (SCGB1A1$^+$), sporadically in basal cells (CK5$^+$), and in alveolar type II (SP-C$^+$) cells in the parenchymal regions. The delivery efficiency ranged between 0.5% - 20.8% and 1% - 17.8% in the large and small airways, respectively. Subsequently, we targeted the rhesus *CCR5* locus with co-administration of ABE8e-Cas9 RNP and S315 peptide by intratracheal aerosol. We achieved editing efficiencies up to 5.3% in rhesus airway epithelia (range 0.2% - 5.3%). The magnitude of Cy5 delivery and *CCR5* editing efficiency correlated with the anatomical distribution of deposited aerosolized materials as assessed by analysis of chest CT scans taken pre- and post-delivery. To investigate the long-term persistence of gene edited airway epithelial cells *in vivo*, we used the Ai9 ROSA26 tdTomato reporter mouse model. Following delivery of MAD7 nuclease RNP with the S10 shuttle, we documented persistence of edited tdTomato positive epithelial cells for up to 12 months (duration of the experiment). Finally, we examined the utility of the peptide-mediated base editor delivery to correct the CFTR function in human airway epithelia. We delivered ABE8e-Cas9 RNP with the S315 peptide to cultured human airway epithelial cells with the R553X mutation. We achieved 4.9% A•T to G•C editing at the target locus and restored CFTR-mediated anion secretion as measured in Ussing chambers. In summary, a single shuttle-peptide mediated delivery of ABE8e-Cas9 RNPs to the airways of the young rhesus monkeys, and *in vitro* delivery of the editor to human airway epithelia with the R553X mutation yielded similar editing efficiencies. In human CF epithelia adenine base editing restored CFTR anion channel function. These results demonstrate the therapeutic potential of base editor delivery with S315 to functionally correct the *CFTR* R553X mutation in human respiratory epithelia.

229 A Novel Type V CRISPR System with Potent Editing Activity in Mice and Non-Human Primates

Alan R. Brooks, Luis Gamboa, Janet Mei, Kalya Stanten
Metagenomi, Emeryville, CA

CRISPR-Cas based genome editing systems are being used extensively to make specific changes to the genomes of mammalian cells with the eventual goal of treating a wide range of genetically driven diseases. The majority of gene editing tools are based on the spCas9 or saCas9 nucleases which are members of the type II family of CRISPR systems. The type V family of CRISPR systems are structurally and functionally distinct enzymes that utilize a short guide RNA and generate staggered cuts. Despite the observation that type V CRISPR systems can exhibit higher specificity than type II systems, there is limited experience applying them for in vivo gene editing. The relatively low potency of native Cas12a/cpf1 has limited it's utility, and engineering approaches have yet to adequately address this. We discovered a new type V system designated MG29-1 from a metagenomics sample taken from a deep sea vent that exhibits minimal sequence identity to Cas12a/cpf1. MG29-1 is a 1280 amino acid RNA programmable nuclease that recognizes the PAM KTTN. Optimization of the guide RNA structure and chemical modifications, together with sequence optimization of the mRNA for MG29-1, enabled saturating editing in the liver of mice after systemic administration of mRNA and guide RNA encapsulated in a LNP, without the need for engineering of the nuclease. Guides for an exemplary target gene were identified that resulted in potent protein reduction in mice following single administration of LNP demonstrating the potential of MG29-1 for therapeutic gene knockdown. Two potent human/NHP guide RNA spacers were each co-formulated with the MG29-1 mRNA in a hepatocyte targeted LNP and infused into cynomolgus macaques. On-target editing as high as 55% in the whole liver (estimated to be 75% of hepatocytes) was achieved without notable safety concerns. While a transient elevation of ALT and AST was observed that returned to baseline by 4 days post dose, there was no significant increase in inflammatory cytokines despite the fact that no anti-inflammatory medications were used. Preliminary analysis of the off-target profile of MG29-1 using several guides targeting different genes supports the high fidelity of this nuclease. These results support further development of MG29-1 for therapeutic gene knockdown.

230 An *In Vivo* CAST-Seq Workflow Identifies and Quantifies Off-Target Activity as Well as Chromosomal Translocations in Organs Edited *In Vivo* with CRISPR-Cas Nucleases or Nickases

Julia Klermund[1,2], Luisa Loiacono[3], Laura Torella[4], Kay Chmielewski[1,2], Geoffroy Andrieux[5], Melina El Gaz[1,2], Melanie Boerries[5,6], Roberto Nitsch[7], Gloria Gonzalez-Aseguinolaza[4], Toni Cathomen[1,2]

Genome editing-associated genotoxicity, such as off-target (OT) activity and chromosomal translocations, must be carefully assessed before clinical application of gene-edited products. Three methods have been employed to evaluate OT activity *in vivo*: VIVO based on *in vitro* identification of candidate OTs that must be validated *in vivo*, DISCOVER-Seq relying on ChIP to nominate OTs based on the recruitment of MRE11 to double-strand breaks, and GUIDE-tag requiring the co-delivery of a DNA donor to 'tag' DSBs for subsequent capture. We recently described CAST-Seq, a method to nominate OT activity by detecting CRISPR-Cas induced chromosomal aberrations. Here, we show that *in vivo* CAST-Seq can identify OT sites and chromosomal translocations in *in vivo* edited mouse livers with unprecedented sensitivity. CAST-Seq was performed on genomic DNA isolated from livers upon adenoviral or AAV-based delivery of different CRISPR-Cas nucleases or nickases, respectively. For instance, OT analyses of *Pcsk9*-edited livers confirmed that CAST-Seq can identify more OT effects than the other three methods both quantitatively and qualitatively. While VIVO discovered 19 OTs, DISCOVER-Seq 26, and GUIDE-tag 40, CAST-Seq nominated 87 confirmed OTs. Subsequent analysis by rhAmp-Seq verified mutagenesis at these OTs, allowed us to establish the frequencies of chromosomal translocations, and demonstrated that each OT translocated with at least one other OT site. In addition, for a highly specific *Pcsk9*-targeting CRISPR-Cas9 nuclease previously reported to have no off-target activity, 4 OT-mediated translocations could be identified, despite a very low percentage of indels at these OTs (0.1-0.23%). Importantly, on-target aberrations, such as large deletions or integrations of vector sequences, could be readily detected using *in vivo* CAST-Seq. In conclusion, CAST-Seq followed by rhAmp-Seq provides a workflow to identify and quantify genome editing-associated OT activity as well as gross chromosomal rearrangements *in vivo*, with a process that is applicable to any tissue at any time point after editing, including human biopsies during therapeutic *in vivo* genome editing.

231 Writing a Chimeric Antigen Receptor (CAR) into T Cell Genomes Using RNA-Based Gene Writing Systems

Alberto De Iaco, Mike Magee, Jason Rodriguez, James Rottman, Donghui Li, Darienne Myers, Giulia Schiroli, Pooja Sabhachandani, Yu Cao, Bill Querbes, Madhusudan V. Peshwa, Michael C. Holmes, Cecilia Cotta-Ramusino

Tessera Therapeutics, Somerville, MA

Chimeric Antigen Receptor (CAR)-T cell therapy is a revolutionary approach to cancer treatment where patient's autologous T cells are modified to express a CAR specific for a tumor antigen and kill the malignant cells. As of today, all approved CAR-T cell treatments use vectors of retroviral origin to deliver the CAR transgene. While these therapies have proven to be effective, the use of retroviruses poses several challenges. The complex manufacturing process reduces scalability with consequent limited access to this therapy. There are also safety concerns given the potential for formation of replication competent viruses, as well as the integration profile that is biased towards gene bodies. Our RNA Gene Writer technology leverages target-primed reverse transcription (TPRT) biochemistry evolved from non-LTR retrotransposon mobile genetic elements to modify the genetic information in cells without the introduction of DNA breaks. Using a large throughput screening approach, we developed multiple synthetic Gene Writer enzymes that can catalyze a variety of editing reactions, such as the introduction of gene-length DNA sequences, substitutions, insertions, and deletions. These edits can be achieved with all-RNA delivery in primary cells and *in vivo*, eliminating the necessity for viral vectors and DNA template-based gene editing. When using this novel class of gene editing enzymes, our Gene Writer technology can modify up to 40% of primary human T cells to express a transgene. This process was well-tolerated with little impact on cell viability, proliferation, and activation of p53 or interferon responses and is compatible with lipid nanoparticles (LNP) delivery. RNA Gene Writer enzymes delivered via electroporation can re-engineer T cells to express a functional CAR and kill tumor cells *in vitro* and *in vivo*, comparable to a lentivirus application. In addition, the modularity of our RNA Gene Writing technology allows multiplex editing to co-introduce multiple genetic changes including generation of universal and more potent CAR-T cells through the knock-out of B2M and TRAC without generating double strand breaks. Here we show that we can achieve both edits simultaneously in 80% of T cells while concurrently integrating a CAR transgene via another RNA Gene Writer enzyme. Furthermore, we will show successful LNP-based delivery of RNA to T cells *in vivo*, 80% reporter expression in a humanized mouse model and 45% in non-human primates (NHP) that may facilitate generation of CAR-T cells *in vivo*. As of today, our RNA Gene Writing technology is uniquely positioned for a one-time delivery of all-RNA components *to* achieve wide editing capabilities, from gene knock-out to gene integration. This technology will enable a simpler manufacturing process and a broader application for immunotherapies.

232 Cell Type-Programmable CRISPR-Cas9 Delivery for Human T Cell Engineering

Jennifer R. Hamilton[1,2], Evelyn Chen[1,2], Barbara S. Perez[1,2], Cindy R. Sandoval Espinoza[3], Jennifer A. Doudna[1,2,4,5,6]

[1]UC Berkeley, Berkeley, CA,[2]Innovative Genomics Institute, Berkeley, CA,[3]Stanford University, Palo Alto, CA,[4]Howard Hughes Medical Institute, Berkeley, CA,[5]Gladstone Institutes, San Francisco, CA,[6]Lawrence Berkeley National Laboratory, Berkeley, CA

The lack of approaches for delivering genome editors to specific cell types limits the therapeutic application of CRISPR-Cas9. Enveloped delivery vehicles (EDVs), such as virus-like particles, enable targeted genome editing by leveraging the cell binding specificity of viral glycoproteins for the transient delivery of CRISPR-Cas9 tools. However, the repertoire of naturally occurring viral glycoproteins with cell-specific tropisms (ex. HIV-1 envelope glycoprotein to target CD4+ T cells) is limited. Inspired by chimeric antigen receptors and their ability to link programmable targeting to cellular function, we hypothesized that displaying antibody fragments on Cas9-guide RNA complex-packaging enveloped delivery vehicles (Cas9-EDVs) would allow for the delivery of genome editors to specific cells. Working with engineered 293T cells, we found that antibody-targeted Cas9-EDVs direct genome editor delivery to cognate ligand-expressing cells, leaving bystander cells largely unmodified. We next screened a panel of antibody-based molecules for genome editing primary human T cells. We identified Cas9-EDV targeting molecules for specifically editing T cell subpopulations (anti-CD4) and T cells broadly (anti-CD3). CD3-targeted Cas9-EDVs mediate genome editing levels comparable to Cas9-EDVs pseudotyped with the broadly-transducing VSV-G viral glycoprotein. Additionally, this antibody-directed targeting approach can be applied to lentiviruses for precisely delivering transgenes to T cells, both ex vivo and in vivo. Retro-orbital administration of CD3-targeted lentiviral EDVs leads to the generation of chimeric antigen receptor (CAR) T cells in humanized mice, demonstrating targeted delivery in vivo. Together, antibody-targeted EDVs are a programmable approach for the transient, cell-selective delivery of transgenes and CRISPR-Cas9 genome editor complexes.

233 Efficient and Safe RNA Editing in Non-Human Primates Using AAV Delivered LEAPER Agents

Pengfei Yuan, Zexuan Yi, Yanxia Zhao, Gangbin Tang, Yongjian Zhang, Jun Hu

EdiGene Inc., Beijing, China

Programmable A to G editing could theoretically treat nearly half of the genetic diseases caused by single-nucleotide polymorphisms (SNPs), including those leading to premature stop codons or splicing site mutation. As an important post-transcriptional modification, adenosine deaminases acting on RNA (ADAR) mediated RNA editing occurs widely in eukaryotic cells. In this process, the adenosine undergoes deamination to become inosine, which is recognized as guanosine in subsequent splicing or translation mechanisms, thus enabling the rewriting of the genetic message. Several ADAR-dependent RNA base editing tools have been developed. Among them, LEAPER and its upgraded version, LEAPER 2.0, enables precise, efficient, and

long-lasting editing of RNA transcripts with engineered circular arRNAs (circ-arRNAs) and endogenous ADAR. However, it is unclear whether such an approach is realistic for therapeutics given that the expression of endogenous ADAR varies with organs and species, and the choice of delivery routes has not been thoroughly validated. Here we report that LEAPER 2.0 enables efficient and safe RNA editing in non-human primates (NHPs) delivered by AAV. Specifically, we tested three doses, 3×10^{12}, 1×10^{13}, and 3×10^{13} vg/kg to deliver circ-arRNA into NHPs and the overall editing efficiency reached ~50% in liver within 1-3-month post infection. The alanine aminotransferase (ALT) and aspartate aminotransferase (AST) activity levels, body weights and cytokine analysis in the experimental groups were all comparable to the control group, and the liver slices showed no liver injury throughout the experiment. To test whether circ-arRNA-mediated targeted RNA editing affects endogenous ADAR activity, we performed AEI (Alu editing index) assay in two 3×10^{13} vg/kg NHPs and the control group. The results showed no significant difference in AEI between them, indicating that the endogenous cellular ADAR editing was not affected. The specificity of endogenous ADAR-based RNA editing has been reported at the transcriptome-wide level in comparison with $ADAR2_{DD}$ (ADAR2 deaminase domain) overexpression-based RNA editing. We performed again such transcriptome-wide RNA sequencing analysis in NHP livers and detected only 18 potential off-target sites, and most of them either were located in the 3' UTR regions or caused synonymous mutations. The minimum free energy analysis suggested none of these off-target hits form a stable duplex with circ-arRNA. Therefore, it is unlikely that any of these sites were sequence-dependent off-targets. In summary, our results demonstrate that LEAPER 2.0 via AAV delivery enable efficient editing in non-human primates with potential long-term persistence, showing broad applicability for both therapeutics and biomedical research.

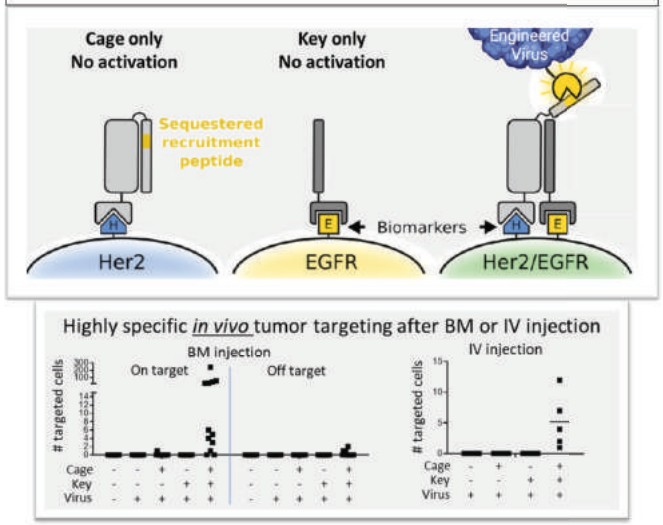
234 Co-LOCKR-Mediated, Highly Specific *In Vivo* Targeting without Off-Targets

Kurt Berckmueller[1], Ravishankar Madhu[1], Mohamad Abedi[2], Jilliane Bruffey[2], Peter Rupert[3], Roland Strong[3], David Baker[2], Hans-Peter Kiem[4], Stefan Radtke[1]

[1]Fred Hutchinson Cancer Research Center, Seattle, WA,[2]Department of Biochemistry, University of Washington, Seattle, WA,[3]Basic Sciences Division, Fred Hutchinson Cancer Research Center, Seattle, WA,[4]Fred Hutch, Seattle, WA

Gene therapy is currently performed *ex vivo*, which requires extensive medical infrastructure, limiting the availability. Moving to *in vivo* therapies would avoid infrastructure limitation and enhance feasibility, portability, and access. A key bottleneck for *in vivo* delivery is the target specificity to avoid unwanted off target effects. Agents recognizing only a single marker on target cells are often insufficient due to epitope sharing in between on- and off-target tissues. The Baker Lab previously designed a system of protein switches known as Co-LOCKR, which enable the specific recognition of two antigens simultaneously. Co-LOCKR targeted CAR T cells highly specifically killed tumor cells *in vitro* with virtually no off-target effects. Here, we designed and evaluated Co-LOCKR-targeted viral vectors for *ex vivo* as well as *in vivo* applicability and comprehensively tested the on-target specificity in a murine tumor model. We initially designed a modified lentiviral vector incorporating the BCL-2 peptide on the capsid to enable the recognition of the sequestered peptide Bim embedded in the Cage protein. We modified the VSVG fusion protein and knocked out its native ability to target low density lipoprotein ensuring the virus could only bind cells recognized by both components of the Co-LOCKR complex. Viral particles were quality controlled for size, concentration, and binding ability to Bim using in-house developed nanoparticle tracking analysis (NTA)-based read out. Specificity and functionality of viral particles was initially tested on cell lines ex vivo. Once this was confirmed, we moved to in vivo tumor targeting. Ex vivo, BCL-2 targeted vectors specifically transduced $EGFR^+HER2^+$expressing Raji cells in the presence of both the cage and key. No off-target was seen either in $EGFR^-Her2^-$ cells or in the absence of individual Co-LOCKR components. Next, we co-injected both cell types into femoral bones of irradiated NBSGW mice. Once the tumor was established, BCL-2 targeted vectors and Co-LOCKR proteins were injected into the tumor-infiltrated bone. Similar to the ex vivo experiments, we observe highly specific targeting of $EGFR^+HER2^+$ expressing Raji cells only in the presence of all Co-LOCKR components and virtually no off-target. Finally, we injected the virus and protein into the tail vein to evaluate the feasibility of our system for a systemic administration. Although the targeting efficiency decreased, highly specific on-target transduction in $EGFR^+HER2^+$ expressing Raji cells was seen. Here we show that Co-LOCKR proteins combined with engineered viral vectors can localize target cells ex vivo as well as in vivo with a remarkably high on-target specificity. Co-LOCKR proteins and Bcl2-targeted viral vectors are stable, resist serum inactivation, and can travel the full length of a murine circulatory system, enter the bone marrow, and successfully transduce cells even in hardly accessible tissues. Most importantly, Cage and Key targeting molecules can easily be exchanged for the targeting of hematopoietic stem cells or T cells. The ability to target bone marrow-resident cells highly specifically via an intravenous administration of this novel delivery system provides a new strategy to perform HSC gene therapy in vivo without the need of mobilization.

Figure: Diagram of Co-LOCKR system functionality. Co-LOCKR components and viruses injected either directly into the bone marrow compartment or through tail vein of mice specifically target cells of interest.



Pharmacology/Toxicology Studies: Bio Distribution

235 PK/PD Modeling to Inform Clinical Development of an Adeno-Associated Virus Gene Transfer Therapy for Duchenne Muscular Dystrophy

Lilly East, Rachael Potter, John Snedeker, Alex Haile, Chris Wier, Louise Rodino-Klapac
Sarepta Therapeutics, Cambridge, MA

Delandistrogene moxeparvovec (previously known as SRP-9001) is an investigational recombinant adeno-associated viral (rAAV) vector-based gene transfer therapy designed to compensate for missing dystrophin in Duchenne muscular dystrophy (DMD) by delivering the SRP-9001 dystrophin transgene, which encodes a shortened, engineered dystrophin protein that retains key functional domains of the wild-type protein. We evaluated vector biodistribution, expression, and clinical dose selection of delandistrogene moxeparvovec using a novel application of a pharmacokinetic (PK) and pharmacodynamic (PD) modeling approach applied to data collected from an animal model of DMD (DMD^{MDX} mice). We analyzed PK/PD relationships between dose, tissue vector genome exposure, micro-dystrophin protein expression (percentage dystrophin-positive fibers [PDPF] and western blot), and functional improvement (relative specific force from tibialis anterior and diaphragm). Linear kinetics with a dose-proportional increase in tissue drug exposure were demonstrated across the nearly 10-fold dose range (4.41x1013-4.01x1014 vg/kg), and in all tissues. The relationship between tissue vector exposure and PD endpoints (PDPF, motor function outcome) showed a saturable response across a wide range of vector exposures. The vector exposure at 1.33x1014 vg/kg (the clinical dose) approached the maximum treatment response. Relative specific force and PDPF were significantly correlated (P=4.43x10-6). However, the relationship appeared to be nonlinear, with increased PDPF expression approaching the maximal functional improvement. Relative specific force and western blot were not significantly correlated. For the first time, biodistribution, biomarker, and functional efficacy data were used to quantify and demonstrate PK/PD relationships for an adeno-associated virus (AAV)-based gene transfer therapy in a DMD animal model. The results continue to support the expected therapeutic benefit and clinical dose of delandistrogene moxeparvovec, an AAV-based gene transfer therapy. This study was funded by Sarepta Therapeutics, Inc.

236 Vector Shedding in Patients with DMD Treated with Delandistrogene Moxeparvovec and Seroconversion from Shed Vector in Naïve Mice

Elizabeth S. Smith, Jyoti Malhotra, Sarah Lewis, Xiaolan Zhang, Damon R. Asher, Shufang Wang, Lilly East, Rachael Potter, Louise Rodino-Klapac
Sarepta Therapeutics, Cambridge, MA

Delandistrogene moxeparvovec (previously known as SRP-9001) is an investigational gene transfer therapy designed to compensate for missing dystrophin in Duchenne muscular dystrophy (DMD) by delivering the SRP-9001 dystrophin transgene, which encodes a shortened, engineered dystrophin protein that retains key functional domains of the wild-type protein, packaged in an adeno-associated virus (AAV) vector. Due to the biological properties of viruses, vector shedding is expected following the administration of a virus-based gene therapy product. We evaluated the extent of vector shedding and clearance following a single administration of delandistrogene moxeparvovec (1.33×10^{14} vg/kg body weight) in ENDEAVOR (NCT04626674; Study 103; N=20), a Phase 1 study in patients with DMD. Delandistrogene moxeparvovec vector exposure in saliva, urine, and feces was quantified by droplet digital polymerase chain reaction. In a nonclinical study, we tested naïve mice to determine the risk of AAVrh74 seroconversion following mucosal vector exposure, with doses based on exposure levels (vector genome copies) demonstrated in nonclinical and clinical studies. Mice were exposed to AAVrh74.CMV.eGFP via optic exposure and intramuscularly. Antibody levels were measured by AAVrh74 ELISA at baseline and 4 weeks post-delivery. Following treatment in ENDEAVOR, the percentage decrease in amount of vector shed was >99% in saliva (n=12), urine (n=18), and feces (n=11) by Week 4. In mice, topical optical delivery of the AAVrh74 vector at relevant concentrations did not produce seropositivity or detectable vector genomes throughout tissues at doses based on clinical vector shedding levels. Clinical findings show that peak vector shedding occurs in the first few days after delandistrogene moxeparvovec administration and exponentially declines to insignificant levels by Week 4. In mice, seroconversion was not observed by relevant exposure route at relevant concentrations. Results suggest that the risk of seroconversion following exposure to vector shed by individuals treated with AAVrh74-based gene therapy may be very low. These conclusions conform with data and literature for other AAV-based gene therapy products currently approved or in development. This research was funded by Sarepta Therapeutics.

237 Development of an Immunosuppressed Murine Model for AAV Based Gene Therapy Biodistribution Studies

Mayuri Prasad[1], Hailey Appenzeller[1], Meera Manchanda[1], Isabelle Meehan[1], Allison Repic[1], Heather Flaherty[2], Alok Sharma[1], Sarah Wills[1], Alice Hedge[3], Brian McIntosh[1]

[1]Labcorp Drug Development, Madison, WI,[2]Labcorp Drug Development, Greenfield, IN,[3]Labcorp Early Development Laboratories, Harrogate, United Kingdom

In the past 6 years, 3 adeno-associated virus (AAV) based gene therapy products were approved by the United States Food and Drug Administration (USFDA), and it is anticipated that up to 20 products will be approved per year by 2025. This necessitates generating models more comparative to first in human administration scenarios, for which most preclinical studies conventionally use non-human primates (NHPs) in safety assessment. Due to the global shortage of captive-bred NHPs, the USFDA has provided a rich climate for considerations to alternate models via guidance, required for the success of gene therapy product development. In this work we describe our unique first-tiered approach to applying standard immunosuppression (IS) protocols used in NHPs to rate AAV gene therapy safety in a murine surrogate. These models represent alternatives to NHP models for general preclinical safety studies to continue to inform about risks in the advancement of new treatments. Many benefits exist in the development of an alternate IS murine model that may outweigh those of using NHPs. The murine model is competitively cost effective, rodents are easy to handle, require smaller housing facilities, and are readily available in large numbers. Additionally, murine models allow flexible experimental design, such as group numbers and increased number of endpoints, that are advantageous to discovery and preclinical therapeutic development. Further, the IS murine model reflects a real world scenario where immunocompetent patients require immunosuppression in order to limit uncontrolled inflammatory and cytotoxic responses from the immune system. For example, gene therapy patients who are administered Zolgensma or Luxterna receive systemic corticosteroids (Prednisolone) prior to AAV gene therapy product administration.In this 12-week study, we investigated the AAV2-mCherry and AAV9-mCherry vector biodistribution in C57BL/6J immunosuppressed murine model following an intravenous vector administration at a dose of $1x10^{14}$ genome copies/kg on Day 15 while the animals received Azathioprine or Prednisolone from Day 1 through Day 84 to assess the safety profile and tissue-specific transduction efficiency. The level of immunosuppression in the murine model was evaluated by $CD3e^{-}/CD19^{+}$ B Cell count in the peripheral blood once every 4 weeks, starting on 1st day of immunosuppressant dosing. The B Cell count demonstrated the dynamic nature of adaptive immune system, where the B cell population fluctuated or came in waves even when the dose of the immunosuppressant was stable throughout the regimen. In comparison, biodistribution models in immuno-incompetent models like NSG or SCID mice would not capture this dynamic immune response. We also evaluated the tissue-specific transduction efficiency by qPCR in the brain, lumbar dorsal root ganglia, heart, kidney, liver, lung, cervical, thoracic and lumbar spinal cord, spleen, thymus and ovary/testes of the female and male immunosuppressed animals. Vector transduction was the highest in the liver, followed by kidney and heart tissue in both the AAV2-mCherry and AAV9-mCherry administered immunosuppressed groups. Moderate level of transduction was seen in the brain and ovary/testes of AAV9-mCherry dosed animals, whereas low level of transduction was observed in the lumbar dorsal root ganglion of AAV2-mCherry and AAV9-mCherry animals.Taken together, our data demonstrates the feasibility of using IS murine models in AAV based toxicology and biodistribution studies. The development and communication of the IS murine model is a promising path forward in the safety assessment of gene therapies.

238 Assessment via Positron Emission Tomography of Adenovirus Capsid Biodistribution Following Intramuscular versus Intravenous Administration to Nonhuman Primates

Edward K. Fung[1], Jonathan B. Rosenberg[1], Dolan Sondhi[1], Stephen M. Kaminsky[2], Larisa Chakarian[1], Ronald G. Crystal[1], Douglas Ballon[1]

[1]Weill Cornell Medicine, New York, NY,[2]Weill Cornell Medical College, New York, NY

Adenovirus (Ad)-based vaccines are clinically approved for Ebola and COVID-19, and in various stages of development for a variety of other disorders. Despite the clinical use of these vaccines, there is little quantitative information available regarding adenovirus organ biodistribution following administration, especially in the event that an intended intramuscular Ad vaccine is inadvertently administered intravascularly. Using Ad serotype 5 (Ad5) covalently linked to the positron emitter iodine-124 (I-124, 4.2 day half-life) to enable positron emission tomography (PET), the goal of this study was to assess Ad biodistribution *in vivo*. As a first step, we assessed the distribution of Ad5 following intramuscular (IM) administration compared to the scenario of inadvertent intravenous (IV) administration. African Green nonhuman primates (NHP) were administered 0.37 - 2.96 MBq (10 - 80 μCi) of ^{124}I-Ad5, either intravenously in the right saphenous vein or intramuscularly in the deltoid muscle. The deltoid was chosen to mimic the most common site of human vaccination. Animals were imaged under anesthesia in an extended field of view (FOV = 4 ring, 22 cm) Siemens Biograph PET/CT immediately after injection and at 24, 48, and 72 h post-injection (p.i.). Coregistered CT's were acquired for attenuation correction and anatomical information. The reconstructed PET resolution was 2.0 x 2.0 x 5.0 mm^3. Regions of interest (ROI) were drawn over the heart, liver, spleen, brain, thyroid, PET-visible lymph nodes, deltoid muscle, kidneys, and whole body. Time-activity curves were fitted to a systemic biodistribution model to calculate the fractional biodistribution to ROI's and biological clearance times. The largest proportion of activity after IM administration was initially at the injection site as expected. In addition, two axillary lymph nodes nearest to the injection were clearly visible and exhibited high activity at all timepoints. Besides the injection site and associated lymph nodes, peak concentration values were in the gall bladder at 0.09% injected dose per gram (ID/g), and kidney at 0.04% ID/g, suggesting a renal route of Ad clearance. Tissue biodistribution patterns were markedly different with IV administration. Early systemic distribution was generally higher for all organs in the IV case by a factor of 2 or more at 0 h p.i. with the exception of kidney which was similar (1.4% ID/g

IM, 1.6% ID/g IV). Peak concentration values for IV administration were in the liver and spleen (0.24% ID/g and 0.17% ID/g respectively). Liver activity was exceptionally disparate, with peak activity occurring within 1 h p.i., and accounted for 37.7% of the total ID for IV administration, but only 1.8% ID following IM administration. Thyroid accumulation also increased, as expected, across all days for both IM and IV administration, peaking at similar values (5.3% ID/g *vs* 3.8% ID/g respectively at 72 h p.i). This is hypothesized to be the result of extraction from the bloodstream of free I-124 resulting from capsid processing. Although overall biodistribution patterns were very dissimilar, whole body clearance halftime was 18.2 h for IM and 17.0 h for IV. In summary, the biodistribution of Ad5 in NHP when administered via IM *vs* IV injection is significantly different across almost all organs as detected *in vivo* using radioiodinated capsids and PET. This methodology facilitates quantification of vector organ uptake and can be used to assess risk associated with different vaccine administration routes.

239 Neural Stem Cell Mediated Oncolytic Virotherapy for Ovarian Cancer

Ericka Yap[1], Hoi Wa Ngai[1], Rachael G. Mooney[1], Linda Flores[1], Marisa McDonald[1], Mohamed Hammad[1], Jacqueline Lara[1], Dae Hong Kim[1], Antonio Fernandez Santidrian[2], Duong Nguyen[2], Elaine Kang[3], Marcin Kortylewski[3], Thanh Dellinger[4], Karen S. Aboody[1]

[1]Developmental and Stem Cell Biology, Beckman Research Institute of the City of Hope, Duarte, CA,[2]Calidi Biotherapeutics, La Jolla, CA,[3]Immuno-Oncology, City of Hope Comprehensive Cancer Center, Duarte, CA,[4]Department of Surgery, City of Hope, Duarte, CA

Introduction. Oncolytic virotherapy is a promising cancer treatment that uses replication-competent viruses to induce cancer cell death. While clinical trials are underway for a variety of solid tumors; success has been hampered by rapid immune-mediated clearance/neutralization of the viral vectors, and poor viral distribution to tumor satellites dispersed throughout normal tissue. Neural stem cells (NSCs) are ideal cell carriers that could overcome viral delivery hurdles due to their intrinsic tumor-tropism and penetration capabilities. Our lab has established a well-characterized, non-immunogenic human NSC line that can selectively distribute to many different solid tumors. Most recently, we observed impressive selectivity and penetration of peritoneal ovarian cancer metastases after intraperitoneal NSC administration. We have engineered our NSCs to produce a conditionally replication-competent adenovirus, CRAd-Survivin-pk7 (CRAd-S-pk7 NSCs). This virus has two notable genetic modifications: (1) a polylysine fiber addition that enables high affinity binding to cell-surface proteoglycans, thus promoting viral entry into the target cell; and (2) a E1A transcriptional modification which prevents viral replication in the absence of the *survivin* promoter. 80% of ovarian tumors have elevated levels of survivin, which then drives viral replication. Clinical grade equivalent research banks of the CRAd-S-pk7 NSCs cells have demonstrated efficacy in orthotopic glioma models (IND 19532), and safety in a recent first-in-human trial (NCT 03072134) but have not yet been developed for treating metastatic ovarian cancer. We hypothesize that NSCs can selectively distribute this virus to ovarian metastases, provide protection from immune-mediated clearance, and achieve significant improvements in long-term survival. Our long-term goal is to demonstrate efficacy and safety of CRAd-S-pk7 NSCs for targeted selective tumor killing in patients suffering from stage III ovarian cancer. ***Methods***. Human Xenograft and immunocompetent syngeneic models of peritoneal ovarian cancer were treated with escalating doses of CRAd-S-pk7 NSCs. Treatment efficacy was determined by week 8 tumor burden and long-term survival. Pilot toxicology studies were conducted using the highest and lowest effective dose. Immunophenotyping was performed on treated tumors to assess possible mechanism-of-action. ***Results***. We demonstrate that CRAd-S-pk7 NSCs can improve long-term survival in mouse models of ovarian cancer. We identify the LOAEL dose, demonstrated negligible toxicity at this dose, and confirm CRAd-S-pk7 NSC treatment causes t-cell infiltration into the tumor micro-environment (improves CD8+/FoxP3 ratio). The LOAEL dose was converted to human equivalent levels, and Pre-IND package submitted.

240 A Novel Technique to Detect Peripheral Blood CAR+ T Cells Using RNAscope *In Situ* Hybridization (ISH) in Non-Human Primates and Mice

Sundeep Chandra

Sana Biotechnology, South San Francisco, CA

In clinical studies, CAR T cells are routinely detected in blood and/or tissues either by flow cytometry (using an anti-idiotype antibody) or by ddPCR. When preclinical studies are conducted in animal models, flow cytometry can be challenging due to limiting blood sample volumes or ability to obtain species specific reagents. We developed a novel method using HistoGel™ to facilitate the detection of either CD20-directed or CD19-directed CAR T cells in peripheral blood mononuclear cells (PBMCs) by *in situ* hybridization (ISH). HistoGel is an aqueous specimen-processing gel that suspends cytologic, i.e., cell culture or cytospin samples from body fluids, in a solidified medium amenable for histologic processing. HistoGel has the advantage that it also can be repeatedly sampled. Probes to detect woodchuck hepatitis post-transcriptional regulatory element (WPRE) mRNA were used to detect transcription of the WPRE element that is part of the polycistronic transcript that was used to encode each CAR. WPRE serves as a surrogate marker for engineered T cells expressing the CARs. We used CD8-targeted fusosomes to generate in vivo CAR T cells. These fusosomes are pseudotyped integrating viral vectors designed to specifically target CD8+ T cells and deliver a chimeric antigen receptor (CAR) transgene. Samples for evaluation were obtained from each of three studies. Studies 1 and 2: Nemestrina macques were intravenously administered a single dose of a CD8-targeted fusosome, carrying a CD20 CAR transgene and euthanized 8 days (Biodistribution Study) or 35 days (Safety and Pharmacology Study) after infusion. Following infusion, CD8+ enriched PBMCs were isolated on Days 2, 4 and 7, fixed in 10% formalin, centrifuged, and the resulting cell pellet was resuspended in HistoGel. The PBMC- HistoGel pellets were processed for paraffin embedding, sectioned, and stained by ISH. Study 3: NSG mice were engrafted with human PBMCs and 24-hrs later were administered a CD8-targeted fusosome carrying a CD19 CAR transgene as part of a pharmacology study. On Day 4, human PBMCs were isolated from 4 mice, pooled, and processed using the same HistoGelmethod. Bone marrow aspirates from a different set of NSG mice from the same study were harvested and processed in

HistoGel. ISH assay positive controls consisted of PBMC cell pellets from human and Nemestrina, that were transduced in vitro with the CD8-targeted CD19 CAR and CD20 CAR fusosomes, respectively. Expression of WPRE was observed in Nemestrina PBMCs as early as Study Day 2 as fine punctate to granular staining and also present in PBMCs on days 4 and 7. Similar to Nemestrina, WPRE expression was detected in human PBMCs isolated from NSG mouse samples on Day 7 and in bone marrow aspirates on Day 30. These data demonstrate for the first time the feasibility of using a HistoGelmethod for ISH on circulating and tissue derived PBMC and bone marrow aspirates to specifically detect CAR T cells. Although specificity or sensitivity of the HistoGelmethod was not compared to flow cytometry, the novel technique may have utility beyond preclinical research for application in the clinical laboratory setting where limiting cell samples or archival cell or tissue samples are available.

241 Nonclinical Pharmacology, Biodistribution, and Safety Studies Supporting the Clinical Development of DB-OTO (AAV1-Myo15-hOTOFv5) for Hearing Loss Due to Genetic Otoferlin Protein Deficiency

Christopher Thompson[1], Seth Koehler[1], Ning Pan[1], Lars Becker[1], Quynh-Anh Fucci[1], Xichun Zhang[1], Joseph Goodliffe[1], Tyler M. Gibson[1], Janet Chung[1], Peter Slade[1], Orion Keifer[1], Peter Weber[2], Eduardo Corrales[3], Kathy So[1], Yoojin Chung[1], Sarah Cancelarich[4], Danielle Velez[4], Leah Sabin[4], Meghan Drummond[4], Yamini Patel[4], Jonathan Weyne[4], Courtney Shanks[1], Joseph Burns[1], John Lee[1], Adam Palermo[1], Jonathon Whitton[1], Vassili Valayannopoulos[1]

[1]Decibel Therapeutics, Boston, MA,[2]Boston Medical Center, Boston, MA,[3]Brigham and Women's Hospital, Boston, MA,[4]Regeneron, Tarrytown, NY

Background Otoferlin is a calcium sensor protein expressed in the inner hair cells and is important for proper synaptic transmission between inner hair cells and the afferent fibers of the spiral ganglion. Biallelic loss of function mutations in the OTOF gene lead to congenital severe-to-profound sensorineural hearing loss in both humans and in mice. DB-OTO is an adeno-associated virus (AAV)-based dual-vector gene therapy designed to provide durable hearing to individuals with profound congenital hearing loss caused by mutations of the otoferlin gene. **Methods** Good Laboratory Practice (GLP) studies were performed to support the conduct of human clinical trials of DB-OTO. OTOF-deficient mice and wild type non-human primates (NHPs) were used to characterize the pharmacology, toxicity and biodistribution of DB-OTO after inner ear delivery. In the experiments involving NHPs, we modeled the surgical approach and delivery of DB-OTO that is being used in the first-in-human clinical trial. **Results** DB-OTO can instate hearing function in OTOF$^{Q828X/Q828X}$ mutant mice as measured by ABR and it can be successfully delivered to the NHP ear via RW injection with lateral semi-circular canal fenestration. Using qRT-PCR, we found that hOTOF mRNA transcript levels peaked 4 weeks after DB-OTO injection in mice and 6 weeks after DB-OTO injection in NHPs, plateauing thereafter. A similar time course was observed for ABR improvements post DB-OTO injection in the congenitally deaf OTOF$^{Q828X/Q828X}$ mutant mice. We followed OTOF$^{Q828X/Q828X}$ mice for 8 months post-administration of DB-OTO and observed stability of the instated ABR throughout that period at clinically relevant doses. In GLP studies, there were no adverse DB-OTO-related findings in otic or non-otic tissues across any evaluation in OTOF$^{Q828X/Q828X}$ mice (5-7-week-old and post-natal day 14-16) or healthy NHPs. We assessed the distribution of vector genomes outside of the ear following DB-OTO injection in NHPs. Vector shedding and levels of systemic escape into tissues in NHPs were limited. The proposed volumetric dose scaling was directly proportional to the total cochlea perilymph volumes of mouse, NHP, and humans. Comparable vector genome DNA and hOTOF mRNA levels in mouse and monkey GLP studies confirmed the validity of this volumetric scaling approach for dose adjustments of DB-OTO between species. The presence of pre-existing neutralizing antibodies were not associated with transgene expression in the ear or safety post DB-OTO injection, suggesting that there may be limited impact of systemic pre-existing neutralizing antibodies on local administration of AAV gene therapies to the inner ear. **Conclusions** Together, these data supported the initiation of a Phase 1/2 clinical trial of DB-OTO in pediatric patients with congenital hearing loss due to an otoferlin deficiency.

Emerging Preclinical Gene and Cell Therapy Approaches for Neurological Disorders

242 Transplantation of Wild-Type Hematopoietic Stem and Progenitor Cells Rescue Alzheimer's Disease in a Mouse Model and Highlights the Central Role of Microglia in Disease Pathogenesis

Priyanka Mishra[1], Alexander Silva[1], Jay Sharma[1], Jacqueline Nguyen[1], Donald Pizzo[1], Denise Hinz[2], Debashis Sahoo[1], Stephanie Cherqui[1]

[1]University of California, San Diego, La Jolla, CA,[2]La Jolla Institute for Immunology, San Diego, CA

Alzheimer's disease (AD) is the most prevalent cause of dementia, but still no effective treatment exists. The major hallmark of AD is significant neuronal degradation, inflammation, progressive memory loss, behavioral decline and an accumulation of extracellular β-amyloid (Aβ) plaque in the brain. Microglia have been implicated in AD pathogenesis, but their role is still matter of debate. Sustained microglia inflammation has been identified as a contributor to AD pathogenesis, as the release of inflammatory cytokines and chemokines increase Aβ production.Because hematopoietic stem and progenitor cells (HSPCs) differentiate into microglia-like cells, we believe that the WT HSPC transplantation will shed further information on the significance of microglia in familial AD pathogenesis and could potentially be used to as a therapy. We used 5xFAD mouse model of AD, which expresses mutant human APP and PSEN1 transgenes, and transplanted them with Sca1^{+} HSPCs isolated from WT GFP transgenic mice after lethal irradiation (5xFAD/WT HSPC). As a control we analyzed WT, lethally

irradiated WT transplanted with WT HSPCs, non-treated 5xFAD, lethally irradiated 5xFAD mice transplanted with 5xFAD HSPCs (5xFAD/5xFAD HSPC). At 4-month post-transplant, behavioral testing demonstrated that transplantation of WT HSPCs in 5xFAD mice led to the preservation of their memory, perception of risks, anxiety level, and locomotor activity as opposed to 5xFAD and 5xFAD/5xFAD HSPC mice. Amyloid beta (Aβ) deposition was also reduced in the hippocampus and cortex of 5xFAD/WT HSPC mice compared to controls. We then characterized the engraftment and differentiation of WT HSPCs in the brain of mice and found substantial engraftment of GFP$^+$ HSPC-derived cells. These GFP$^+$ cells were immunoreactive with Iba1, characterizing these cells as microglia-like cells. We also observed that transplanting WT HSPCs led to the significant reduction in microgliosis and inflammatory state of the brain by immunohistochemistry, qPCR and Elisa. Transcriptomic analysis also revealed significant decrease in gene expression related to "disease-associated microglia" in the cortex, and "neurodegeneration-associated endothelial cells" in the hippocampus of the WT HSPC-transplanted 5xFAD mice compared to diseased controls. Altogether, these data suggest that microglia-associated neuroinflammation in AD is an important feature of neurodegeneration and preventing microgliosis was sufficient to prevent the neurocognitive impairments in the 5xFAD mice. This work also shows that HSPC transplant represents a promising therapeutic avenue for familial AD.

243 Intracerebroventricular Delivery of SLC6A8 by Self Complimentary AAV9 Restores Brain Creatine and Reduces Hyperactivity in a Mouse Model of SLC6A8 Deficiency

Troy B. Webster[1], Robyn T. Binsfeld[1], Ilona Tkachyova[2], Andreas Schulze[2], Jagdeep S. Walia[3], Steven Gray[4]

[1]Center for Neuroscience, Queen's University, Kingston, ON, Canada,[2]The Hospital for Sick Children, Toronto, ON, Canada,[3]Pediatrics, Queen's University, Kingston, ON, Canada,[4]Department of Pediatrics, University of Texas Southwestern (UTSW) Medical Center, Dallas, TX

Solute Carrier Family 6 Member 8 (SLC6A8, creatine transporter) is an active Na+Cl- dependent transporter responsible for cellular uptake of creatine. SLC6A8 deficiency is an X-linked genetic disorder induced by loss of function mutations in SLC6A8 resulting in the inability of cellular creatine uptake and a severely depleted or absence of creatine in the central nervous system. Creatine plays a role in many cellular functions, most notably as a phosphate buffer for ATP and is critical in proper regulation of energetics and metabolism in the brain. Disease manifestation includes a wide range of symptoms including developmental delay, intellectual disability, motor function impairment, seizures, hyperactivity, and autism-like behavior. Murine models share some of these symptoms such as hyperactivity, memory deficits, and decreased creatine and creatinine in the central nervous system. Additionally, knockout (KO) mice have reduced body weight and muscle mass. The frequency of SLC6A8 deficiency is not well known but thought to be between 1-2% of all X-linked intellectual disability cases. Due to the minimal passive transport of creatine, supplementation has a minimal effect leaving clinicians with a lack of therapeutic options. Here we present both in vitro and in vivo data on the delivery of SLC6A8 as a potential gene therapy treatment for SLC6A8 deficiency. In vitro transfection of a codon optimized SLC6A8 plasmid carrying the scAAV9-SLC6A8 construct restored cellular creatine levels. Intracerebroventricular (ICV) injections allow for direct delivery of viral vector to the brain on postnatal day 0. An ICV dose of 2.5e10 vector genomes of scAAV9-SLC6A8 in KO mice resulted in significant increases in body mass (by 25 %) and a significant decrease in night-time activity (by 50%) relative to untreated KO mice 24 weeks post injection approaching the activity of wildtype (WT) mice. Both mid and caudal sections of the brain showed a 5-fold increase in creatine and creatinine concentration with the midsection of the brain approaching WT creatine levels (Figure1. A, C). This data shows great potential for AAV delivery of SLC6A8 as a treatment for SLC6A8 deficiency. Further studies are ongoing to determine optimal dose and time of administration. Our study forms a foundation for a potential gene therapy of this so far untreatable condition.

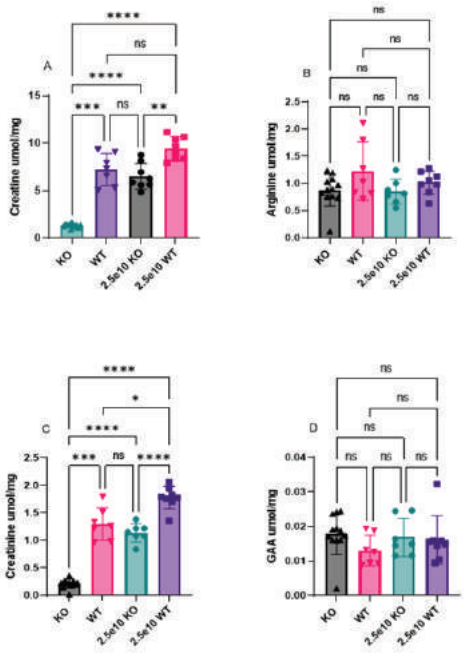


Figure 1. Postnatal day-0 intracerebroventricular delivery of 2.5e10 vg of *scAAV9SLC6A8* restores creatine concentration to KO mice in the midsection of the brain. Mice were euthanized 24 weeks after delivery and brain creatine, arginine, creatinine and Guanidinoacetate (GAA) were determined using liquid chromatography mass spectrometry and normalized to tissue mass. Both creatine and creatinine were significantly elevated in treated KO mice relative to KO counterparts (Dunnett T3 MC test * P<0.05, **P<0.01, *** P<0.001 ****P<0.0001). There were no statistical differences detected in either GAA or arginine concentration.

244 AAV9-Mediated Expression of Secreted Klotho Reduced Several Aging-Associated Phenotypes and Increased Longevity

Joan Roig-Soriano[1], Ángel Edo[1], Sergi Verdés[1], Cristina Sánchez-de-Diego[2], Cristian Griñán[3], Mercé Pallàs[3], Bryen A. Jordan[4], Francesc Ventura[2], Carmela R. Abraham[5], Assumpció Bosch[1,6,7], Pura Muñoz[8,9], Miguel Chillón[1,6,9,10]

[1]Institut de Neurociències (INc), Universitat Autònoma de Barcelona, Bellaterra, Spain,[2]IDIBELL, Universitat de Barcelona, Barcelona, Spain,[3]Faculty of Pharmacy and Food Sciences, Universitat de Barcelona, Barcelona, Spain,[4]Dominick P. Purpura Department of Neuroscience, Albert Einstein College of Medicine, New York, NY,[5]Department of Pharmacology and Experimental Therapeutics, Boston University School of Medicine, Boston, MA,[6]Vall d'Hebron Institut de Recerca (VHIR), Barcelona, Spain,[7]Ciberned, Instituto de Salud Carlos III, Madrid, Spain,[8]Department of Medicine and Life Sciences, Pompeu Fabra University, Barcelona, Spain,[9]ICREA, Barcelona, Spain,[10]Unitat de Producció de Vectors (UPV), Universitat Autònoma de Barcelona, Barcelona, Spain

Advances in health care and quality of life in modern societies have led to an increase in the percentage of the population reaching advanced ages, with a projected 25 % of U.S. citizens being over the age of 65 by 2060. Aging is one of the main risk factors for a wide range of pathologies, including osteoporosis, sarcopenia, and cognitive degeneration. These conditions are accompanied by suffering, disability, and elevated economic and social costs, thus new therapies are needed to achieve healthy aging. The protein Klotho (KL) has been identified as a promising anti-aging molecule due to its pleiotropic actions, with pro-longevity effects on pathways such as insulin/insulin-like growth factor and Wnt signaling, and inflammatory and oxidative stress modulation. Here, we explored the anti-aging potential of the secreted isoform of this protein in the SAMP8 and C57BL mice, models for accelerated and non-pathological aging, respectively. Systemic and intracerebroventricular delivery of AAV9 efficiently increased concentration of s-KL protein in serum, improving the aging phenotype in different organs analyzed. KL treatment improved fitness in behavioral tests, associated with reduced muscular fibrosis and increased muscle regeneration. Cortical and trabecular microstructural parameters in the aged bones, measured by MicroCT analysis, were also improved in treated animals. Cognitive capacities of aged animals were improved, which was accompanied by increased markers of adult neurogenesis (Ki67 and DCX), and normalization of cellular markers in the hippocampus like Iba1$^+$ and GFAP$^+$ cells populations, supported by histological and transcriptional analysis. Remarkably, long-term AAV-mediated expression of s-KL lead to a 20% increase in total longevity of C57BL mice. These results show for the first time, the potential of exogenous increase in s-KL protein to treat several age-associated deficits, increasing both health and life span of wild type animals. Due to the safer pharmacological profile of s-KL compared to other KL isoforms, and being a naturally secreted protein, gene therapies increasing s-KL levels represent a promising approach to reduce the impact of the age-associated degeneration in multiple organs.

245 A System for Whole-Body Gene Delivery Rescues Wolfram Syndrome II

Michael Florea

Harvard, Cambridge, MA

Progerias result from mutations that cause accelerated onset of aging-like features in one or more of the body's organ systems. Wolfram Syndrome II is a rare human and mouse progeria characterized by sensorineural, metabolic and hormonal defects and caused by genetic disruption of the *Cisd2* gene. *Cisd2* is of considerable interest in the geroscience community, because its loss or reduction of expression leads to premature aging and has been associated with several prevalent human diseases, while its overexpression protects against age-related diseases and increases lifespan in mice. Gene therapies hold promise for treating progerias, but their application has been hampered by the fact that there are no known gene delivery vectors that can deliver DNA sufficiently broadly across the body. Here, we have engineered an adeno-associated virus (AAV) based system that enables efficient and tunable gene expression across multiple organs simultaneously. This system (called DAEUS) combines multiple engineered AAV serotypes and gene regulatory elements with model guided dosing. DAEUS can drive gene delivery to all tested organs, across more than 80% of the body mass overall. We used DAEUS to engineer a whole-body gene delivery to Wolfram Syndrome II. In Wolfram Syndrome II mice, DAEUS-*Cisd2* gene therapy restores near wild-type *Cisd2* expression across major tissues of the body and protects against development of disease in all cohorts tested. Specifically, mice treated as neonates or young adults, DAEUS-*Cisd2* therapy prevents the development of frailty, loss of activity, loss of vision and extends post-treatment lifespan by 75% to 140%. Surprisingly, in mice with advanced progeria, DAEUS-*Cisd2* gene therapy reverts disease pathology in multiple tissues, in addition to extending lifespan and protecting against further progression of the disease. These data indicate that DAEUS holds promise as a platform for treatment of multi-organ genetic diseases and that restoration of *Cisd2* expression may provide therapeutic benefit to Wolfram Syndrome II patients at any treatment age. This work was supported by the NIH DP1 AG063419 and Glenn Foundation

246 A Gene Therapy Approach to Treat PMLD1

Elena Georgiou[1], Styliani Theophanous[1], Christina Tryfonos[2], Jan Richter[2], Christina Christodoulou[2], Kleopas A. Kleopa[1]

[1]Neuroscience Department, The Cyprus Institute of Neurology & Genetics, Nicosia, Cyprus,[2]Molecular Virology Department, The Cyprus Institute of Neurology & Genetics, Nicosia, Cyprus

Pelizaeus-Merzbacher-like disease (PMLD1)/ hypomyelinating leukodystrophy type 2 (HLD2) is an autosomal recessive hypomyelinating leukodystrophy, which is characterized by early-onset nystagmus by 7 weeks of age, impaired motor development and ataxia, spasticity, dysarthria, dystonia, seizures, optic atrophy, and diffuse hypomyelination in MRI. PMLD1/ HLD2 is caused by loss-of-function mutations in the *GJC2/Cx47* gene encoding the gap junction (GJ) protein connexin47 (Cx47). Cx47 is expressed specifically in all oligodendrocytes throughout the CNS and is crucial for their gap junctional communication and homeostasis forming most GJs with

other oligodendrocytes and astrocytes. The aim of this study was to develop an optimal gene replacement therapy comparing lumbar intrathecal and intravenous delivery of two leading AAV serotypes, AAV9 and AAVrh10, that are currently used in most clinical trials for other neurological disorders. The 1.9kb myelin basic protein (Mbp) promoter was used to drive expression of the reporter gene EGFP or of the human *GJC2/Cx47* gene specifically in oligodendrocytes. To directly compare serotypes and routes of delivery, AAV9-*Mbp.GJC2*, AAVrh10-*Mbp.GJC2*, and the corresponding reporter gene vectors (titers of at least 1x10^13 vg/ml) were injected into P10 wild type mice (EGFP vectors) or into Cx47 knockout mice (GJC2 vectors) either by L5-6 lumbar intrathecal injection (total of 2x10^11 vg in 20 µl) or by tail vein intravenous injection (4x10^11 vg in a 30µl volume) at a slow rate of 5µl/min. We examined EGFP and Cx47 expression 4 weeks after vector delivery by double immunostaining with relevant cell markers and by immunoblot analysis. We found that expression with both serotypes was restricted to oligodendrocytes, and was not detected in neurons, astrocytes or microglia. AAV9 provided overall higher expression rates in oligodendrocytes compared to AAVrh10 vectors. Moreover, intravenous delivery resulted in a more widespread biodistribution and gene expression in the CNS while lumbar injection mainly targeted the spinal cord. After confirming the higher efficacy of intravenously delivered AAV9-*Mbp.GJC2* to replace Cx47 in oligodendrocytes, we proceeded with a therapeutic treatment trial in groups of Cx32/Cx47 double KO (dKO) mice, an authentic model of PMLD1, with severe early onset demyelination. Mice (n=10 per group) were treated at P10 either with the AAV9-*Mbp.GJC2* therapeutic vector or with the AAV9-*Mbp.EGFP* (mock vector) and outcomes including motor behavior and CNS pathological changes were compared at P30. We found significant improvements in motor performance measured by the foot slip test, rotarod test, and foot print test in treated compared to mock-treated dKO mice. Analysis of myelination in corpus callosum, internal capsule, anterior and posterior spinal cord white matter confirmed improved myelin density and reduced vacuolation in treated mice. Furthermore, analysis of inflammatory glia responses showed improvement in astrogliosis and microglia activation in the CNS of treated mice. Finally, survival was significantly prolonged in treated compared to mock-treated dKO animals. This project provides a proof of principle for a gene replacement approach to treat PMLD1, as well as potentially other leukodystrophy forms resulting from mutations in structural genes expressed by oligodendrocytes.

247 Gene Therapy for Mucolipidosis IV Using Novel CNS-Targeted AAV Capsid

Yulia Grishchuk[1], Madison Sangster[1], Martha Bishop[1], Maxwell Miller[2], Anil K. Chekuri[2], Yizheng Yao[3], Fengfeng Bei[3]

[1]Center for Genomic Medicine and Department of Neurology, MGH, Boston, MA,[2]Grousbeck Gene Therapy Center, Schepens Eye Research Institute and Massachusetts Eye and Ear Infirmary, Boston, MA,[3]Department of Neurosurgery, Brigham and Women's Hospital, Harvard Medical School, Boston, MA

Mucolipidosis IV (MLIV) is a lysosomal disease resulting in severe psychomotor deficits and vision loss. It is caused by loss-of-function variants of *MCOLN1* gene that encodes the lysosomal transient receptor potential channel mucolipin1, or TRPML1. With no existing therapy, the unmet need in this disease is extremely high. Recently we showed that AAV-mediated CNS-targeted gene transfer of the human MCOLN1 rescued motor function and alleviated brain pathology in the MLIV mouse model. We found that intracerebroventricular administration of AAV9-MCOLN1 in neonatal MLIV mice significantly improved motor function, myelination and reduced lysosomal storage load. Despite being currently a vector of choice for CNS-directed applications, AAV9 has biodistribution limitations such as low transduction of brain and retina from either systemic or CSF-directed routes of administration and toxicity concerns such as dorsal root ganglion (DRG) degeneration with intra-thecal administration. To achieve optimal therapeutic outcomes in MLIV, broad brain biodistribution is required. Here we report preclinical efficacy in MLIV mouse model using systemic administration of a novel AAV9-derived vector with enhanced CNS tropism expressing human *MCOLN1*. Compared to AAV9, this vector demonstrates 5-50-fold enhancement in transduction of the CNS and retina in both mice and non-human primates and is therefore of high advantage to efficiently rescue both CNS dysfunction and vision loss in MLIV. Intravenous delivery of this vector expressing human MCOLN1 in symptomatic *Mcoln1*$^{-/-}$ mice resulted in broad peripheral and CNS biodistribution, showed dose-dependent improvement of motor function and significantly delayed time to paralysis as compared with vehicle-treated group. Evaluation of brain pathology showed significant reduction of microgliosis (CD68) and astrocytosis (GFAP) in the brains of vector-treated *Mcoln1*$^{-/-}$ animals. Evaluation of lysosomal pathology and myelination is currently ongoing. These data suggest a new systemic gene replacement therapy for patients with MLIV mediated by a highly translatable novel AAV vector.

248 Development of an *Ex Vivo* Gene Therapy for Frontotemporal Dementia (FTD)

Yuri Ciervo, Silvia Spadini, Massimo Accardo, Rita Milazzo, Alessandra Biffi

The University of Padua, Padova, Italy

Frontotemporal Dementia (FTD, OMIM:607485) is a severe and fatal adult neurodegenerative condition devoid of any cure or specific approved treatment. About 20% of familial FTD cases are caused by pathogenic loss-of-function mutations in the progranulin gene (GRN). GRN is a secreted lysosomal protein that functions as neurotrophic factor and regulator of neuroinflammation. Raising GRN levels in the brain of FTD patients, and in particular in microglia, may result in therapeutic benefit. Hematopoietic Stem Cell - Gene Therapy (HSC-GT) based on the use of lentiviral vectors (LVV) for gene transfer offers the potential benefit of long-lasting delivery of robust GRN levels in the central nervous system (CNS) of FTD patients, potentially restoring physiological microglia function, modulating neuroinflammation and attenuating neuronal damage. We developed and tested therapeutic LVVs with novel inducible synthetic promoters able to safely deliver multiple copies of the human *GRN* cDNA in GRN knock-out (ko) cell models. Upon cell transduction we observed over-expression of the therapeutic protein which was then secreted and token up by target GRN ko cells. The most promising among these constructs have been tested *in vivo* at different transgene doses (vector copy number [VCN] of drug products ranging from 1 to 8 copies) in optimized transplant conditions enabling CNS-specific and selective engraftment of the transplanted cells and of their progeny. In particular, cohorts

of young myeloablated GRN-ko mice were intracerebroventricularly transplanted with HSCs derived from GRN-ko previously transduced with LVV expressing the GRN under control of a strong constitutive promoter or myeloid/specific inducible promoters. With our approach we showed that GRN-transduced murine HSCs retain their proliferative and clonogenic capacity, they are able to engraft and repopulate the brain myeloid compartment of FTD mice, and to locally deliver GRN already at 6 weeks from the transplant. Moreover, the delivery of GRN into the brain of recipient mice is proportional to the degree of brain engraftment, to the transgene dose and can be controlled in a regulated fashion reflecting the nature of the promoter that drives transgene expression. We are currently monitoring cohorts of transplanted GRN-ko mice to evaluate the safety, feasibility, and long-term efficacy of the therapeutic strategy by comparing two different promoters (strong constitutive vs inducible) and transplantation routes (intra-CNS vs systemic). The efficacy of this potential therapeutic approach is being evaluated both at the behavioral and pathological level.

AAV Vector Genome Biology and Engineering II

249 Mechanistic Evaluation of Liver-Specific Transgene Repression from AAV Vectors in Non-Human Primates and Minipigs

Zhuo Wang, Jason Yang, Randolph Qian, Chunping Qiao, Ting Chen, Ryan Clarke, William Marcus Henry, Trang Nguyen, Samantha Yost, Ye Liu, Olivier F. Danos, Joseph T. Bruder, Subha Karumuthil-Melethil

Research & Early Development, REGENXBIO Inc., Rockville, MD

The recent FDA approval of Hemgenix for treating hemophilia B has shown that adeno-associated viral (AAV) vector mediated, liver-directed Factor IX expression can provide therapeutic benefits for patients. Circulating Factor IX in serum necessary to prevent bleeding is in the nanograms per milliliter range, relatively low compared to what is required for other indications. Significant reduction of mRNA levels in liver of non-human primates (NHP) when compared to mouse liver following AAV delivery has been reported by us and others. Liver-directed expression of an anti-plasma Kallikrein antibody (anti-pKal Ab) packaged in an AAV8 vector was evaluated in mice and NHPs where we observed equivalent copies of vector DNA delivered to the liver, but a 1000 to 3000-fold reduction in transgene mRNA levels in the liver of NHP versus mouse. Here we further discuss our findings in NHPs as well as evaluation of minipigs as an alternate animal model to study liver-specific expression from AAV vectors. To evaluate the effect of different AAV capsids (AAV8, AAV9 and AAV6), promoters (ApoEhAAT, TBG, CAG, LMTP6, LMTP24), routes of administration [Intravenous and Intra-muscular (one or multiple dose sites)], and different antibody formats (IgG vs scFv-Fc) on the expression of anti-pKal antibody in the serum as well as the mRNA expression from the liver, we conducted additional NHP studies. None of the modifications we explored significantly improved the protein and mRNA expression from the NHP liver. Minipigs were evaluated for liver-specific expression of anti-pKal Ab. AAV8-ApoEhAAT-Anti-pKal-Ab vector was injected intravenously into 2-month-old minipigs and monitored for 4 weeks. The serum levels of the secreted anti-pKal Ab were measured at 14- and 28-days post AAV delivery. At the same vector dose per kilogram bodyweight, minipigs and NHPs had similar serum anti-pKal Ab levels at time points examined, which were a 1000-fold lower than the levels in mouse serum for the same vector and dose. A similar trend was observed in the liver transgene mRNA levels between the 3 species with equivalent number of vector copies in the liver of all three species. RNAscope evaluation of liver sections from these studies correlated with the PCR analysis showing no or limited mRNA detected in NHP and minipig hepatocytes in the presence of AAV vector DNA in the nucleus. Thus, minipig recapitulated the liver-specific mRNA repression we observed in NHP and can be used for further evaluation of AAV vector mediated expression from liver. To gain understanding of the possible mechanism(s) underlying this significant difference in transgene expression in the liver of different species, we applied single cell multiome ATAC plus gene expression sequencing on liver tissue from different species treated with AAV vector. This technique enabled simultaneous analysis of transgene expression, differential gene expression pattern and AAV genome accessibility. The molecular structure and complexity of episomal AAV DNA were evaluated for mouse and NHP liver treated with AAV vector. Plasmid-Safe ATP-Dependent DNase and a single cutter restriction enzyme digestion followed by ddPCR quantification was used to investigate the average number of AAV genomes per concatemer: 1-2 in NHP liver vs 2-3 in mouse liver. When put together, we expect all these studies to help us understand factors contributing to the repression of mRNA levels in the liver of NHPs and minipigs.

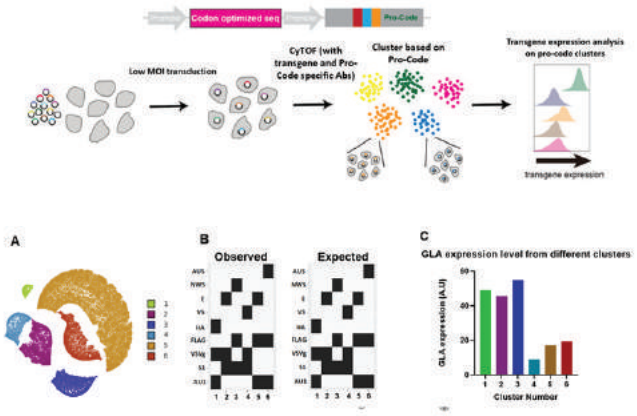
250 HICOS: High-Throughput Screening of Codon Optimized Sequences Using Protein Barcoding

Jang Hwan Cho, Perry Evans, Mitul Patel, Pichai Raman, Federico Mingozzi, Sean M. Armour, Daniel M. Cohen

Spark Therapeutics, Philadelphia, PA

Introduction: Gene therapy using recombinant AAV (rAAV) vectors is a promising approach to treat many different genetic diseases. Despite its promise, one unmet challenge in gene therapy is the development of optimized transgene encoding sequences to achieve high levels of expression, while reducing vector immunogenicity. Higher vector doses have been associated with enhanced immune responses and, in some cases, systemic toxicities. Similarly, high content of CpG motifs, cryptic splice variants, and other sequence features can contribute to immunogenicity of AAV vectors. Codon optimization is a common approach to enhance expression levels while modulating vector genome-driven immunogenicity. However, a rate limiting step in the screening for top performing codon optimized cDNAs is the inability to screen large numbers of variants for protein expression *in vitro*. Here, we developed a protein barcoding system for high throughput codon-optimized screening (HICOS) to enable high-throughput screening of cDNAs (Figure 1). **Method:** Genetic barcodes detectable as proteins (Pro-Codes) are a cell barcoding system operating at protein level in which a fusion protein composed of different combinations of epitope tags (e.g., HA, V5, and FLAG) and dNGFR, a truncated receptor without an intracellular domain (Wroblewska *et al., Cell*

2018). Combinations of antibody-detectable epitopes form a higher order set of barcodes and Pro-Code expressing cells can be analyzed by time-of-flight mass cytometry (CyTOF). HICOS pairs Pro-Code and codon optimized cDNA to allow protein-level phenotyping in genetic screens. **Results: Figure 1.** Schematic of HICOS method. (Top) Dual promoter constructs were utilized to enable tandem expression of transgene and a unique protein barcode (Pro-Code) (Bottom) Cells are transduced with Pro-Code library using lentivirus at low MOIs (multiplicity of infection) such that each cell receives a single HICOS element. Following selection, a population of pooled transduced cells are stained with heavy metal conjugated antibodies and detected by CyTOF. Cells are clustered based on Pro-Code identity and linked to a quantitative measure of transgene expression. **Figure 2.** Stratification of codon-optimized GLA variants by HICOS. (A) HICOS assay comprised of 6 different CpG-depleted, codon-optimized GLA (alpha galactosidase A) variants (numbered 1 through 6) was conducted in Huh7 cells. Pro-Code clustering is based on epitope expression pattern and each cluster represents single CpG-depleted, codon-optimized GLA. (B) Unique combinatorial epitopes (Pro-Codes) mapped per cluster (C) Stratification of cDNAs into high-expressors (clusters 1-3) vs. low expressors (clusters 4-6). **Conclusion:** HICOS is a novel platform for efficient screening of codon optimized cDNAs. Our proof-of-principle study successfully identified the best performing variants in a set of codon-optimized cDNAs encoding the GLA protein. The HICOS approach may enable rapid identification of lead cDNAs encoding therapeutic transgenes.



251 Tissue Regeneration Enhancer Elements Enable Injury Responsive AAV Gene Expression

David Wolfson[1], Alan Rosales[2], Roza Ogurlu[2], Thomas Dvergsten[1], Aravind Asokan[1], Kenneth Poss[1]

[1]Duke University School of Medicine, Durham, NC,[2]Duke University, Durham, NC

Clinical translation of gene therapies for tissue regeneration will require precise spatiotemporal control of transgene expression to mitigate off-target effects, tissue overgrowth, and oncogenesis. Epigenetic profiling in regenerating tissues of zebrafish have revealed genetic enhancers that gain open chromatin marks after injury and during regeneration, thus termed tissue regeneration enhancer elements (TREEs). Recently, we reported these zebrafish TREEs can be modulated to drive gene expression in mammalian injury sites, both in mice and pigs. Here, we characterize TREE-driven AAV transgene expression in various mouse models of injury to map spatial and temporal dynamics. Specifically, we administered AAV vectors harboring TREEs upstream of an *Hsp68* minimal promoter and a firefly luciferase reporter transgene, intravenously to adult mice prior to injury induction. Injury models included cardiac ischemia-reperfusion, barium chloride muscle injury, and digit amputation. Injected mice were imaged with IVIS imaging in a longitudinal manner to track TREE-driven expression before and after injury. At the end of the imaging period, luciferase assays as well as biodistribution assays to quantify viral genomes in healthy and injured tissues were carried out. Taken together these results highlight on-target and off-target aspects of the transient and injury-site specific nature of TREE-driven expression in mice. Zebrafish TREEs are a promising new platform for inducing focal and transient gene expression at injury sites with potential clinical implications.

252 Strong Compact Neuron Specific Promoters for AAV Gene Transfer

Xiupeng Chen, Phillip WL Tai, Guangping Gao, Jun Xie

UMass Chan Medical School, Worcester, MA

Recombinant adeno-associated viral (rAAV) vectors are currently considered the leading platform for *in vivo* gene therapy. However, the packaging capacity of AAV is limited to <5 kb, which excludes larger therapeutic genes from conventional vector designs. Many efforts have been developed to overcome this limitation, such as split rAAVs and fragmented rAAV strategies. A compact and efficient promoter will be beneficial for packaging and expressing larger transgenes. Here, we identified three compact promoters derived from the human survival motor neuron (*SMN1*) gene with lengths of 61 bp, 155 bp, and 303 bp. We constructed *EGFP* reporter plasmids harboring these three promoters and evaluated their activities in HEK293 and Neuro2a cells by plasmid transfection. All three promoters can drive efficient transgene expression in both cell lines, where the 155 bp promoter is the most efficient and the 61 bp promoter is the least. We then packaged these reporter constructs into self-complementary AAV9 (scAAV9) vectors and injected them into neonatal C57BL/6 mice at P1 at a dose of 4E11 vg/mouse by facial vein administration. An scAAV9 vector with the cytomegalovirus enhancer/chicken β-actin (*CMVen/CB)* promoter driving an EGFP reporter (scAAV-*CB/CMV-EGFP*) was injected side-by-side for comparison. After three weeks, we sacrificed the mice and examined GFP expression in brain, spinal cord, heart, muscle, and pancreas. We found that the 61-bp promoter exhibited neuron specific expression in the brain and spinal cord. However, no expression was detected in heart, muscle, or pancreas, suggesting that the 61-bp promoter is active in neurons of the central nervous system (CNS). Compared to the 61-bp promoter, both the 155-bp and 303-bp promoters showed stronger activities that were close to those achieved by *CB/CMV* promoter in the brain and spinal cord. Interestingly, the 155-bp and 303-bp promoters also showed heart activity that were comparable to those achieved by *CB/CMV*, but they lacked activity in skeletal muscle and pancreas. Further characterization of these promoters in adult mice is ongoing. In conclusion, our study has identified a small 61-bp promoter that is active in the neuron, and

two additional small promoters with lengths of 155 bp and 303 bp with activities in the neuron and cardiac cell.* **G.G., and J.X are co-corresponding authors**

253 Capsid Mediated Control of Adeno-Associated Viral Genome Transcription

Ezra Loeb[1], Lawrence P. Havlik[2], Aravind Asokan[2]

[1]Department of Biomedical Engineering, Duke University, Durham, NC,[2]Duke University, Durham, NC

The host range and tissue tropism of Adeno-associated virus (AAV) is generally attributed to capsid-receptor interactions. While examining mammalian host cell permissivity to an Avian AAV isolate, we discover that AAV genome transcription is inhibited in a capsid-dependent manner. However, by swapping the VP1 N-terminus of primate-derived AAVs onto Avian AAV, we unlocked robust transduction. To determine why Avian AAV transcription is silenced in mammalian cells, we conducted a chromatin accessibility assay. While primate-derived AAV and an Avian/primate AAV chimera displayed chromatin accessibility resembling a euchromatin control locus, Avian AAV chromatin accessibility mirrored a heterochromatin control. To further interrogate whether epigenetic modification may play a role in Avian AAV genome silencing, we carried out a CUT&RUN assay to profile histone methylation. Specifically, we targeted H3K4me3, a marker for active transcription, and H3K9me3, a marker for transcriptional repression. H3K4me3 and H3K9me3 modifications were found on both Avian AAV and Avian/primate chimeric AAV genomes; however, their respective profiles were significantly altered. Moreover, significantly less H3K4 modifications and H3K9 modifications were found across the Avian AAV genome compared to the Avian/primate AAV chimera. Based on these results, we conducted a proximity ligation based, BioID spatial interactome analysis to identify host factors that interact differentially with Avian and Primate AAV capsids, specifically their respective VP1 N-terminal domains. Gene ontology analysis of primate AAV N-terminal interactors yielded a number of significantly enriched terms related to transcription and RNA processing. Our results corroborate the notion that the VP1 N-terminus of primate AAVs have evolved to recruit host factors that exert influence on AAV genome transcription. Knockdown experiments of several candidates within this interactome significantly reduced primate AAV transduction. Thus, mammalian host factors, including those linked to innate immune pathways, interact with the VP1 N-terminus in a capsid-specific manner to modulate the epigenetic status and transcriptional silencing of AAV genomes. Taken together, we identify a minimal structural component of primate-derived AAVs that regulates vector genome transcription in mammalian cells. We further postulate a mechanistic basis for how AAV capsids restrict host range independent of receptor interactions.

254 DNA Damage Repair Pathways Have Opposing Effects on Concatenation and Expression from rAAV Vectors

Anna C. Maurer[1,2,3], Brian Benyamini[1,3], Matthew D. Weitzman[4], Robert T. Tjian[1,2,3]

[1]Department of Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA,[2]California Institute for Regenerative Medicine Center of Excellence, Berkeley, CA,[3]Howard Hughes Medical Institute, Berkeley, CA,[4]University of Pennsylvania Perelman School of Medicine and the Children's Hospital of Philadelphia, Philadelphia, PA

Recombinant adeno-associated viral vectors (rAAVs) deliver DNA to a wide range of tissue types, but safe application to a broad spectrum of diseases is limited by vector genome (VG) capacity and requirements for large doses. Overcoming these limitations requires an understanding of how VGs are processed and regulated in recipient cells. rAAV VGs concatenate in host nuclei and can form episomes which stably express transgenes, but the mechanisms governing these central processes in gene therapy are unclear. To identify host factors involved in VG processing and potential druggable targets for increasing transduction efficiency, we performed a genome-wide CRISPR knockout screen for negative regulators of split transgene reconstitution, which relies on concatenation to express a trans-splicing dual vector. Genes are highly enriched in chromatin architecture and a specific subset of DNA Damage Repair (DDR) pathways, including several genes not previously studied in the context of AAV biology. Here, we focus on cellular proteins involved in double-strand break (DSB) repair. Using a split *lacZ* dual vector reporter system, we observe a 4-fold increase in split *lacZ* expression in cells depleted of BRCA1, which is involved in Homology Directed Repair (HDR). Pharmacological inhibition of other HDR factors, such as Rad51, induce a 10-fold increase in split *lacZ* expression. Conversely, inhibition of Non-Homologous End Joining (NHEJ) enzymes decrease split *lacZ* transduction by 10-fold.To examine the mechanisms underlying these effects at individual VG resolution, we [HT1] generated VGs that include 64 *lacO* repeats, a minimal CMV promoter, and 24 MS2 stem loops. Transducing cell lines that express LacI-mNeonGreen and MCP-mCherry enables visualization of rAAV VGs (mNeonGreen foci) and their nascent transcription (mCherry foci) *in-situ*. In addition to super-resolution imaging, we perform high content imaging to quantitatively assess VGs, expression, and colocalizing host factors in tens of thousands of cells per experiment. Compared to control cells, BRCA1 depletion or Rad51 inhibition increases the number and size of VG foci per cell in addition to the proportion of transcriptionally active VGs. Conversely, inhibition of NHEJ enzymes has the opposite effect. Immunostaining for cellular DDR factors reveals competitive occupancy of HDR and NHEJ factors on VG foci, with one dominating when the other is inhibited. We also observe colocalization of VGs with phosphorylated Histone 2 variant H2AX (γH2AX), the marker of chromosomal DSBs, as early as 2 hours post-transduction. Furthermore, inhibition of ATM kinase, which orchestrates DSB repair via γH2AX phosphorylation, drastically reduces the proportion of cells with VG foci, number of foci per cell, and average size of VG foci. Taken together, our observations suggest a model wherein VGs uncoat, quickly associate with histones, and are recognized in a similar manner to chromosomal DSBs most robustly by HDR factors. However, NHEJ may function more efficiently in concatenation and processing that

leads to transgene expression. Ongoing animal studies are testing the effects of HDR inhibition on dual vector transduction *in vivo*. Our novel findings provide insights into rAAV genome processing mechanisms and highlight how host factors can be manipulated to increase rAAV transduction, particularly for trans-splicing dual vectors that can express large transgenes for therapeutic applications.

255 Should You Judge an AAV by Its Cover? The Role the AAV Capsid Plays in Setting up the Vector Epigenome

Eirini Vamva[1], Adriana Gonzalez-Sandoval[1], Mark A. Kay[2]

[1]Pediatrics and Genetics, Stanford University, Palo Alto, CA,[2]Stanford University School of Medicine, Stanford, CA

Adeno-associated viral vector (AAV) is the most commonly used vector for *in vivo* based gene therapeutics. However, the unpredictable discordance in vector mediated transduction between species poses a major challenge to selecting the optimal vectors for human clinical trials. Recombinant AAV-LK03, a capsid currently evaluated in several clinical trials was shown to robustly transduce human but not mouse hepatocytes in a humanized mouse model. To our surprise, a single-amino acid insertion, 266iG named AM, into the AAV-LK03 capsid managed to enable efficient transduction in mice while further enhancing transduction efficiency in human cells compared to AAV-LK03. Using Cut and Tag methods, we demonstrated that the limitation to transduction in mouse was unrelated to cell entry and nuclear transport but rather due to depleted histone H3 epigenetic modifications related to active transcription, namely H3K4me3 and H3K27ac, on the vector itself. We recently found that insertion of the 266G amino acid into a second primate selective capsid, AAV-NP59 increased transduction measured by transgene expression by ~30 fold in mouse cells. To identify which of the VP proteins is responsible for the dual tropism phenotype of AM, we created AAV-AM/LK03 VP hybrids as well as AAV-AM- and LK03- VP3 only virions. Our preliminary data suggest the 266iG in VP3 is primarily responsible for the observed dual tropism of the AM vector. Overall, these results suggest that the capsid proteins uncoat and the viral genome in the nucleus directly interact with host proteins to affect the epigenetic state of the viral episomal genome and that these interactions differ between species. To identify host factors that interact with the capsid and/or vector genome and are involved in this process, we performed anti-A20 immunoprecipitation and mass spectometry, followed by evaluation of candidate proteins on LK03 and AM transduction efficiency with siRNA silencing. Of note, our siRNA screen identified 3 novel proteins as host restriction factors critical for AAV transduction and we are establishing if and how these proteins might participate in setting up the vector epigenome. In addition, we are currently performing intranuclear AAV injections and fluorescence imaging to study potential spatial differences in nuclear localization between AAV-AM and AAV-LK03 delivered genomes and their effect on transgene expression. Unraveling the mechanism behind the observed differences in capsid-mediated vector epigenome dependence based on species will not only improve our understanding of basic AAV biology but also improve our ability to correlate outcomes in humans based on preclinical testing in animals.

Genome & Epigenome Editing Technologies I

256 A Metagenomics-Derived Gene-Editing Toolbox Enables Efficient Genome Engineering with Nucleases and Base-Editors in Primary Cells and *In Vivo*

Rebecca C. Lamothe, Lisa Alexander, Daniela S. A. Goltsman, Sarah M. Laperriere, Liliana Gonzalez-Osorio, Jennifer Oki, Audra Devoto, Ben Freeman, Jyun-Liang Lin, Jin Wen Tan, Cindy Castelle, Ashley Quintana, Ashcon Khoubyari, Ashley Graham, Andre Nguyen, Ed Tuan, Ansley Tanoto, Kartik Rallapalli, Kristen Hershey Darrell, Sara Wegner, Whitney Krey, Margaret Hackney, Diego Espinosa, Mike MacKillop, Caitlin Ethridge, Kia Aliakbar, Rodrigo Fregoso Ocampo, Morayma Temoche-Diaz, Christine A. Romano, Steven J. Flammer, Keirstinne Turcios, Ming Gao, Bokyoung Son, Allison Quach, Luis Alfonso Gamboa, Alan R. Brooks, Cristina N. Butterfield, Christopher T. Brown, Brian C. Thomas, Gregory J. Cost

Metagenomi, Emeryville, CA

Gene-editing technology has revolutionized molecular therapeutics, enabling engineering-based approaches to treat disease. Despite this, development of medicines using gene editing has been hampered by technological, immunological, and legal limitations. We described previously the discovery of two novel gene-editing systems from metagenomic data, the characterization of these systems in vitro, and a demonstration of their activity. Here, we add multiple additional nucleases from metagenomic sampling so as to create a genome-editing platform capable of targeting almost every base pair in the human genome. The platform is composed of a "menu" of both type II and type V nucleases, capturing the PAM diversity of the former and the increased specificity of the latter. Our metagenomic approach discovers entire families of editing systems rather than isolated enzymes. We take opportunistic advantage of the structural conservation and PAM diversity across these families to perform PAM-interacting domain (PID) swaps between family members, substituting PIDs from less-active members into the backbone of a more-highly active nuclease. Such chimeric enzymes rapidly and significantly increase the targeting density of the platform. Further, we engineer one of our nucleases into an adenine base editor (ABE), sourcing the adenine deaminase from our metagenomic database. We achieve up to 95% A-to-G conversion in cultured cells. The ABE was engineered in the context of one of our chimeric nucleases, allowing our base-editing platform to share the high targetability conferred by our PAM library. Finally, as our gene-editing systems are sourced from microbes found in environmental samples and from the non-pathogenic human microbiome, we expected that pre-existing immunity to our nucleases would be quite rare. We demonstrate this is indeed the case, as there is no detectable pre-existing antibody immunity in a panel of serum samples from forty-eight randomly selected donors. In all, we show

that these new gene-editing systems have the activity, specificity, and translatability necessary for broad use in genetic medicine development.

257 Programmable A-to-Y Base Editing by Fusing an Adenine Base Editor with an N-methylpurine DNA Glycosylase

Huawei Tong[1], Xuchen Wang[2,3], Yuanhua Liu[2], Nana Liu[1], Yun Li[1], Jiamin Luo[1], Qian Ma[1], Danni Wu[1], Jiyong Li[1], Chunlong Xu[4], Hui Yang[1,2]

[1]HuidaGene Therapeutics Co., Ltd., Shanghai, China,[2]Center for Excellence in Brain Science and Intelligence Technology, Chinese Academy of Sciences, Shanghai, China,[3]College of Life Sciences, University of Chinese Academy of Sciences, Beijing, China,[4]Lingang Laboratory, Shanghai, China

Background: Base editors are promising tools for precise base-editing in basic research and therapeutic applications. For years, adenine base-editors (ABEs), cytosine base-editors (CBEs), and C-to-G base-editors (CGBEs) have been developed and widely used. However, base editor enabling A-to-T and A-to-C transversions remains to be achieved to repair large number of point mutations, accounting for up to 27% genetic diseases. **Methods**: To induce A-to-T and A-to-C transversion editing, we hypothesized that excision of ABE-induced deoxyinosine might enable more versatile base-editing outcomes by triggering the base-excision-repair (BER) pathway in cells. We developed three prototype versions of adenine transversion base-editor (AYBE, Y = C or T base) by fusing ABE8e to wild-type human N-methylpurine DNA glycosylase protein (MPG), which could excise hypoxanthine in damaged DNA at different orientations with respect to nCas9. An intron-split EGFP reporter system with an inactive splicing acceptor signal was engineered to evaluate the transversion activity of AYBE by introducing disruptive point mutations into the intron boundary. Only A-to-T or A-to-C transversion could correct the mutation for proper splicing of EGFP-coding sequence, thus activating EGFP expression. To improve AYBE activity, we performed rational mutagenesis of MPG and generated hundreds of AYBE variants for screening (Fig. 1A). A proof-of-concept study using a stable HEK293T cell line generated via lentiviral transduction was performed to investigate the therapeutic potential of AYBE variants for correcting disease-related transversion mutations. Finally, we further increase the efficiency and purity of A-to-T editing outcomes by engineering ATBE. **Results**: We detected 56.6% and 7.32% of EGFP$^+$ cells using AYBEv0.1 (with wild-type MPG fused at the C-terminus) with A-to-T and A-to-C reporter, respectively. After rounds of mutagenesis screening, we found synergistic enhancement of transversion editing activity by 4.78-fold for AYBEv3 variant in comparison with AYBEv0.1 (Fig. 1B). AYBEv3 also exhibited efficient A-to-Y transversion editing activity when replaced nCas9(D10A) with dCas9 or dCas12. Furthermore, the engineered AYBEv3 variant could enable targeted editing with high transversion editing activity (up to 72% for A-to-C or A-to-T editing). We also found approximately 36% and 44% correction frequencies of A-to-C edits at *DMD* and *SLC26A4* nonsense mutation sites and approximately 11% and 20% correction frequencies of A-to-T edits at *ATM* and *TTN* splicing acceptor site mutations in the stable lentivirus-transduced HEK293T cells, respectively. The engineered ATBE could mediate A-to-T transversion efficiency up to 52% and the purity up to 79% (Fig. 1C). **Conclusions**: Our findings with engineering a novel AYBE for effective A-to-T and A-to-C editing provide the complementary toolkit (Fig. 1D) to the current base-editor repertoire for modeling and treating disease-causing transversion mutations in humans. A more accurate ATBE would enhance the therapeutic potential of the base-editor platform.

Fold changes are calculated relative to the wild-type MPG group. **(C)** A-to-T editing outcomes for the introduction of Polη. **(D)** Diagram showing types of achievable point mutations with the available base editors. n = 3, all values are presented as mean ± s.e.m.

258 Multiplexed Epigenome Editing to Induce Sustained Silencing of Immune Checkpoints' Expression in CAR T Cells

Maria Silvia Roman Azcona, Toni Cathomen, Claudio Mussolino

Institute for Transfusion Medicine and Gene Therapy, Medical Center - University of Freiburg, Freiburg, Germany

The development of an exhausted phenotype is one of the major obstacles to the success of chimeric antigen receptor (CAR) T cell therapy. Amongst the hallmarks of T cell exhaustion, one of the best characterized is the overexpression of immune checkpoint receptors, such as PD-1, CTLA-4, LAG-3, TIM-3 and others. When these receptors encounter their respective ligands, expressed from either tumor cells or other components of the tumor microenvironment, activation of inhibitory intracellular pathways impairs T cell functions. Therefore, interrupting such interaction became an attractive strategy to protect T cells from exhaustion. Immune checkpoint blockers have shown promising results in this regard, reinvigorating the immune response against tumors. Moreover, combined blockage of multiple immune checkpoints elicits synergistic effects. However, the occurrence of severe immune-related side effects due to the systemic activity of the blockers, and the adaptation of the tumor microenvironment that can eventually lead to resistance, are still unresolved. We have devised a strategy to render CAR T cells devoid of two major immune checkpoints via hit-and-run epigenome editing. Designer epigenome modifiers (DEMs) targeting *PDCD1* or *LAG3* were delivered by electroporation, in the form of in vitro transcribed mRNA in activated T cells expressing a 2nd generation CAR capable of specifically recognize the prostate-specific membrane antigen (PSMA), an antigen highly expressed on prostate cancer cells. This one-time intervention led to the deposition of de novo

cytosine methylation in their respective promoters, sustainably and simultaneously inducing silencing of the two genes in the targeted cell population. The epigenetically induced silencing was persistent throughout repetitive CAR T cell activation through direct contact with PSMA-positive target cells. Furthermore, the epigenetically edited CAR T cells were fully functional and indistinguishable from their parental unmodified cells in an array of in vitro assays including cytotoxic capacity, cytokines release, differentiation towards effector phenotype and proliferative ability, thus, demonstrating the safety of DEM-mediated epigenome editing in CAR T cells. The specificity of these DEMs to target *PDCD1* and *LAG3* is currently being assessed. However, DEMs targeting other loci have shown remarkable conserved specificity, encouraging the anticipation of favorable outcome. Our results propose this technology as a novel approach to modulate diverse T cells inhibitory pathways needless of DNA sequence modification, in a simultaneous and targeted manner employing a protocol compatible with the current clinical application of CAR T cell therapy.

259 Novel Cas9 Orthologs Expand the Genome Editing Toolbox for CRISPR-Based Therapeutics

Laura Pezzè[1], Matteo Ciciani[2], Sally Bertolini[1], Kalina Badowska[1], Eleonora Pedrazzoli[2], Elisabetta Visentin[2], Michele Demozzi[2], Nicola Segata[2], Anna Cereseto[2], Antonio Casini[1]

Genome editing holds great promise for therapeutic applications, however its full potential is hindered by the current limitations of the genome editing toolbox, such as delivery, safety and PAM requirements. One way to overcome these limitations is to expand the toolbox by identifying novel Cas9 proteins with unique properties. In this work, we interrogated a massively expanded microbiome dataset (above 1 million bacterial genomes, >90000 Cas9 loci) to identify novel Cas9 proteins characterized by desirable features, including reduced molecular size (<1100 aa), variegated phylogenetic distribution, low homology to previously characterized nucleases, and diverse PAM specificities, as determined by *in silico* prediction. Among the Cas9 orthologs carefully selected for validation, most of them were shown to be active in mammalian cells. Notably, we identified 4 candidates showing comparable editing activity to the widely used SpCas9, reaching more than 90% EGFP knock-out in reporter cells. The activity of these nucleases was further compared to other widely used Cas9 proteins, showing comparable editing levels on endogenous loci and improved specificity, as determined by GUIDE-seq. Furthermore, given their reduced molecular size, these newly identified Cas9 proteins, as opposed to SpCas9, could be packaged with their sgRNA within a single all-in-one AAV vector, either as active nucleases (>40% editing) or nickases fused to an adenine-base editor (>60% A-to-G conversion). Finally, we also explored their potential for the development of *in-vivo* AAV-based gene editing approaches for the treatment of inherited retinal diseases and *ex-vivo* applications. The identification of these novel Cas9 proteins, with their small size, high activity and diverse PAM recognition sequences expands the genome editing toolbox and provides new avenues for the development of safe and effective therapies for a broad range of diseases.

260 Multiplexed Editing without Chromosomal Rearrangements Using Epigenetic Editors

The ability to simultaneously alter the expression of multiple genes is desirable for many genome editing applications, such as optimizing CAR T cell function. However, conventional genome editing technologies that rely on double stranded DNA breaks (DSBs) have the potential for undesirable consequences beyond the generation of insertions and deletions (indels) at the target DSB sites, such as large deletions, translocations, and even chromothripsis. Genome editing many target genes leads to more DSBs thereby increasing the potential for such events. Epigenetic editing, in contrast, enables durable modulation of gene expression without cutting, nicking, adding to, deleting, or altering the DNA sequence. This makes epigenetic editing extremely well-suited for simultaneous targeting of multiple genes. In this study, we performed simultaneous silencing of three target genes in primary human healthy donor derived T cells using CRISPR-Off, a dCas9-based epigenetic editor. We compared CRISPR-Off silenced cells to cells edited at the same genes using Cas9 and evaluated chromosomal rearrangements using: (1) a quantitative sequencing-based assay that measures both small indels and structural rearrangements at guide RNA target sites; and (2) a fluorescence-based technique with single-cell resolution that can visualize structural rearrangements at the target sites. As expected, indels, which result from error prone repair of DSBs were only observed in the Cas9-treated cells and not in the CRISPR-Off treated cells. In addition, and in agreement with published literature, cells that had undergone multiplexed gene editing using Cas9 also displayed genomic rearrangements including translocations and truncations. In contrast, the rates of indels, translocations, and other chromosomal rearrangements in CRISPR-Off treated cells were similar to the background levels in untreated controls, while achieving knockdown of expression of all three genes. These data therefore reveal an important advantage of epigenetic editing compared to Cas9 genome editing in allowing genotoxicity-free multiplexed gene editing.

261 Metagenomic Mining and Engineering of Single-Strand Annealing Proteins for Cleavage-Free Genomic Knock-In of Long Sequence in Mouse Hepatocytes via dCas9 Targeting

Chengkun Wang, Hong Xiang, Xiaotong Wang, Guangxue Xu, William Johnson, Le Cong

Stanford University, Stanford, CA

INTRODUCTION The ability to edit long sequences with high accuracy and minimal errors is a highly sought-after technology in gene-editing. Such a tool has potential for diverse research areas and applications, from generating knock-in models, to engineering

therapeutic transgene for gene and cell therapy. New waves of editors have facilitated genome modifications at different scales, but the efficient, precise insertion of long sequences (kilobase-scale knock-in) in primary, post-mitotic cells is still challenging. RESULTS Here, building on our prior demonstration of knock-in editing with dCas9 coupled to phage single-strand annealing protein (SSAP), we performed a metagenomic mining and genomic knock-in screening of SSAP editors in human cells. We identified several high-activity candidate SSAPs with close to ~3-fold improved editing efficiencies compared with our previous SSAP benchmarks. Top candidate achieves over 40% knock-in efficiency without any selection. We show that the newly engineered cleavage-free SSAP editor efficiently inserts kilobase-scale sequences at endogenous Albumin locus in primary mouse hepatocytes. To achieve this, we integrated our engineered metagenomic SSAP (metaSSAP) editors with AAV-based delivery. Importantly, thanks to the compact size (200-300 amino acids) of metaSSAPs, we could fit the entire SSAP editor and the transgene cargo within a single AAV vector. Further, longitudinal expression assay and insertion mapping demonstrate the genomic insertion of transgene by SSAP is durable and accurate in primary hepatocytes. CONCLUSION We developed a next-generation dCas9-SSAP editor using novel metagenomic SSAPs. This editor has high knock-in efficiency and accuracy in challenging primary hepatocytes settings. Thus, this showed that the SSAP recombination approach can mediate gene insertion in post-mitotic cells. Our work leads to a new option for large knock-in for in vivo scientific discovery and therapeutic development via recombination-mediated gene-editing. FIGURE 1: Mining and development of metagenomic SSAP for recombination-based genomic insertion of long sequences in hepatocytes.

262 Comprehensive Engineering of CasX Holoenzyme to Create an X-Editor with High Activity, Specificity and Deliverability

The use of RNA-guided endonucleases from CRISPR-Cas systems has revolutionized the cell and gene therapy field. The need for Cas enzymes with reduced size, increased specificity, or distinct editing profiles or PAM preferences has motivated the identification and characterization of diverse novel Cas effectors. However, many of these naturally occurring effectors have poor activity in mammalian cells. Here, we present our efforts to engineer the CasX (Cas12e) holoenzyme for improved activity. CasX, like Cas9 or Cas12a, is a Class 2 Cas effector enzyme that binds and cuts dsDNA substrates when loaded with a matching guide RNA. Unlike the most active Cas9 and Cas12a variants, however, CasX is small enough (<1000 amino acids) to fit in an AAV vector with multiple guides or complex regulatory elements, generates distinct deletion patterns, and has less tolerance for mismatches between the guide RNA and dsDNA substrate. By building comprehensive and holistic libraries containing tens of thousands of distinct CasX molecules and screening them in both bacterial and human cell systems, we were able to identify mutations that increase the stability, DNA-binding ability, and cleavage activity of the protein. We then applied deep mutational scanning and selection methods to generate protein variants with broadened or respecified PAM preferences, thereby expanding genome targetability. A combination of high-throughput pooled screening and rational design was applied to the CasX sgRNA to yield a guide with significantly improved performance in both transcription-based and fully in vitro systems. The resulting improved "X-Editor" (XE) ribonucleoprotein (RNP) exhibits editing activity orders of magnitude higher than wild-type CasX molecules. We characterized XE editing efficiency compared to other engineered small Cas systems across dozens of loci in human cells, and further show that XE can achieve knock-out rates of immuno-oncology targets equal to or better than SpyCas9 when delivered as RNP to primary human immune cells. We demonstrate that XE is a potent and flexible platform for gene editing, with high activity, small size, and a range of accessible PAMs allowing it to be used across different delivery modalities and targets.

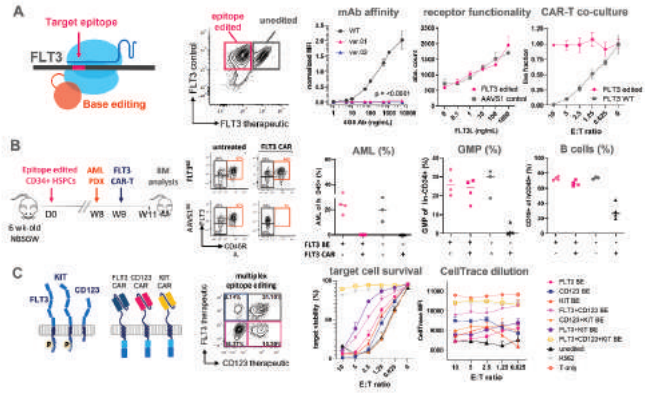
CAR Immunotherapy

263 Epitope Engineered Hematopoietic Stem and Progenitor Cells to Enable Multi-Specificity CAR-T Cell Immunotherapy for Acute Myeloid Leukemia

Gabriele Casirati[1], Andrea Cosentino[1], Adele Mucci[2], Mohammed S. Mahmoud[3], Denise Klatt[4], Christian Brendel[5], Jerome Ritz[1], Scott A. Armstrong[1], Pietro Genovese[6]

[1]Dana Farber Cancer Institute, Boston, MA,[2]Boston Children's Hospital, Boston, MA,[3]Fayoum University, Fayoum, Egypt,[4]Dana Farber Cancer Institute, Brookline, MA,[5]Boston Children's Hospital/Dana-Farber Cancer Institute, Boston, MA,[6]Pediatric Oncology, Dana-Farber Cancer Institute, Boston, MA

Despite treatment advances and the use of allogeneic hematopoietic stem/progenitor (HSPC) cell transplantation (HSCT), acute myeloid leukemia (AML) is associated with an unfavorable outcome for >50% of patients. While immunotherapies have proved compelling efficacy when targeting a dispensable lineage antigen (Ag), such as CD19 in B-ALL, their application for AML is hampered by the absence of actionable leukemia-restricted targets. Suitable targets are shared with healthy progenitor or mature myeloid cells, leading to on-target off-tumor toxicity. For these reasons, AML immunotherapies are typically restricted to a narrow time window before HSCT, reducing the chances of AML eradication. We found that specific epitopes on essential tumor-associated genes can be base-edited in healthy HSPCs to avoid the recognition by therapeutic Abs while preserving physiologic protein expression, regulation, and function. Precise epitope engineering allows targeting genes required for leukemia survival regardless of functional role in HSPC, minimizing the risk of immune escape. To this end, we selected the cytokine receptors *FLT3*, KIT and CD123, which are found in >85% of AML cases and whose mutation or overexpression is associated with poor prognosis. We identified single amino acid substitutions in FLT3, KIT and CD123 extracellular-domains that abrogate recognition by a therapeutic mAb while preserving physiologic surface expression, ligand-binding, kinase activation and signal transduction. These variants were resistant to CAR killing and did not induce CAR activation during in vitro co-culture (FIG.A). We identified a set of gRNAs that enable introduction of these mutations by adenine base editors (BE) without the need for dsDNA breaks. Electroporation of ABE8e mRNA and gRNAs into CD34+ HSPCs achieved up to 90%, 85% and 75% editing efficiency on FLT3, KIT and CD123 genes, respectively, either as single or multiplex. To assess if CAR-T cells can effectively eliminate AML while sparing the edited hematopoiesis, we sequentially engrafted NBSGW mice with edited HSPCs, human patient derived AML xenografts (PDX) and FLT3 or CD123 CAR T cells. FLT3 and CD123 edited HSPC sustained long-term multilineage hematopoiesis indicating successful editing of HSCs. Upon treatment with CAR-T, we observed eradication of AML PDX cells while sparing healthy hematopoiesis (B cells, GMP, LMPP and CD34+38- HSPCs for FLT3-CAR; dendritic cells and myeloid lineages for CD123-CAR) in mice engrafted with edited HSPCs but not in AAVS1^{BE} controls (FIG.B). Epitope editing can be multiplexed to enable multi-specific CAR-T cells, with combinations of FLT3, KIT and CD123 providing superior protection when challenged with triple-specific CAR-T in vitro (FIG.C). This enabled multi-target immunotherapies that could eradicate PDX that were resistant to FLT3 CAR monotherapy in vivo. In conclusion, transplantation of epitope engineered HSPCs endowed with selective resistance to CAR-T or Abs is a novel approach that can be rapidly implemented in currently used HSCT protocols to enable more effective and safer immunotherapies for high-risk AML patients.



264 IL-12 Reprograms CAR-Expressing NKT Cells to Long-Lived Th1-Polarized Antitumor Effector Cells

Elisa Landoni[1], Mark Woodcock[1], Gabriele Casirati[2], Simone Stucchi[1], Gabriel Barragan[3], Giulia Casorati[4], Paolo Dellabona[4], Pietro Genovese[5], Leonid S. Metelitsa[6], Barbara Savoldo[7], Gianpietro Dotti[1]

[1]UNC Lineberger Cancer Center, Chapel Hill, NC,[2]Dana Farber Cancer Institute, Brighton, MA,[3]Texas Children's Cancer Center, Houston, TX,[4]Fondazione San Raffaele Del Monte Tabor, Milan, Italy,[5]Harvard Medical School, Boston, MA,[6]Baylor College of Medicine, Sugar Land, TX,[7]UNC Lineberger Comprehensive Cancer Center, Chapel Hill, NC

Natural Killer T cells (NKTs) are characterized by the expression of an invariant TCR (iTCR) that recognizes glycolipids, presented in the monomorphic CD1d molecule. The advantages of NKTs are the lower alloreactive potential, easier generation as off-the-shelf product, and ability to infiltrate solid tumors. Heczey A. et al. in 2014 showed the potential of GD2 CAR NKT cells in eliminating neuroblastoma (NB) tumor cells, although the tumor would eventually relapse. We propose to further engineer GD2.CAR NKTs to produce Interleukin 12 (IL-12). IL-12 is a heterodimeric cytokine composed of p35 and p40 chains with proinflammatory and immunoregulatory properties. The transduction efficiency of the NKTs evaluated by measuring the expression of GFP or CAR was superior to 70%. IL-12 was produced by IL12(I)GFP and GD2.CAR(I)IL2 NKTs and was detected in the supernatant (3564±236 pg/ml and 1661±1439 pg/ml respectively). To validate IL-12 pro-inflammatory effects, we analyzed the production of IFNγand IL-4 by NKTs upon stimulation through the iTCR. IL12(I) GFP and GD2.CAR(I)IL12 NKTs showed superior release of IFNγ and reduced release of IL-4 compared to control NKTs (7785±1661 pg/ml, 8807±3328 pg/ml and 7785±2477 pg/ml of IFNγ respectively and 238±117 pg/ml, 46±28 pg/ml, 587±213 pg/ml of IL-4 respectively). IL12(I)GFP NKTs showed increased proliferative capacity upon

activation through the iTCR and higher expression of CD62L compared to GFP NKTs (82±11% vs 39±11% respectively), which is consistent with our previous observation that CD62L expression in human NKTs identifies a cell subset with a high proliferative capacity. IL12(I)GFP NKTs showed superior expansion and persistence in vivo in peripheral blood (P<0.0001), spleen (P=0.0059), and liver (P=0.0023) of NSG mice up to day 30, and more than 50% of NKTs maintained CD62L expression. At day 30, IL12(I)GFP NKTs were selected from the spleen and injected in new non-tumor-bearing NSG mice to mimic a serial transplant. IL12(I)GFP NKTs showed consistent engraftment in the serial transplant and maintained CD62L expression. Importantly, mice infused with IL12(I)GFP NKTs did not show signs of graft versus host disease. To measure the antitumor activity of GD2.CAR(I)IL12 NKTs, we used NSG mice engrafted with the NB cell line CHLA-255. By day 63 all mice treated with GD2.CAR NKTs developed tumor, while mice treated with GD2.CAR(I)IL12 NKTs remained tumor-free. GD2.CAR(I)IL12 NKTs continued to protect the mice from tumor growth after tumor rechallenge and promoted prolonged tumor-free survival (P=0.0004). Only GD2.CAR(I)IL12 NKTs were detectable in the peripheral blood and in the liver and spleen at the time of euthanasia while maintaining CD62L expression.The advantages of IL-12 in NKTs, were also validated in combination with anti-CD19 CAR in leukemia and lymphoma, and anti-CSPG4.CAR in melanoma and osteosarcoma in vitro models.Overall, these data show the advantages of engineering NKTs to co-express a CAR and IL-12. Transgenic IL-12 initiates a transcriptional program in NKTs that leads to the generation of NKTs characterized by a high potential for in vivo expansion, persistence, and superior anti-tumor activity which can have a significant impact for adoptive NKT cell-based therapies.

265 Knocking-Down Expression of BTG1, a Key Driver of NKT Cell Exhaustion, Promotes Durable Tumor Control by CAR-NKTs in a Xenogeneic Neuroblastoma Model

Andras Heczey[1], Xin Xu[1], Amy N. Courtney[1], Gengwen Tian[1], Gabriel Barragan[1], Linjie Guo[1], Claudia Martinez Amador[1], Nisha Ghatwai[1], Purva Rathi[1], Michael Wood[1], Yanchuan Li[1], Chunchao Zhang[1], Erica Di Pierro[1], Antonino Montalbano[1], Meena Subramaniam[2], Chenling Lu[2], Chirag Sachar[2], Daniel Wells[2], Leonid S. Metelitsa[1]

[1]Baylor College of Medicine, Houston, TX,[2]Immunai, New York, NY

After infusion into cancer patients, T and NKT cells expressing tumor-specific chimeric antigen receptors (CAR) often become hyporesponsive or exhausted, limiting their antitumor potential. However, the mechanisms underlying this hyporesponsiveness remain poorly defined. As part of our ongoing phase 1 evaluation of autologous NKTs co-expressing a GD2-specific CAR with interleukin (IL)15 (GD2-CAR.15) in children with neuroblastoma (NB)(NCT03294954), we performed single-cell RNA sequencing of both infusion products and infused NKTs derived from the peripheral blood of 12 patients at 2-3 weeks post-infusion. We identified B cell translocation gene 1 (*BTG1*) as a top upregulated gene in GD2-CAR.15 NKTs isolated from patient peripheral blood (**Fig 1A**). Consistent with the known role of BTG1 in maintaining murine naïve T cell quiescence, we found that unstimulated human NKTs and freshly isolated naïve T cells downregulate BTG1 expression shortly after TCR activation. However, continuous TCR stimulation led to re-expression and sustained upregulation of *BTG1* in NKTs and T cells. In gain-of-function studies, NKTs transduced with a BTG1 construct (OE) showed a decrease in global RNA content (**Fig 1B**) as well as decreased expression of genes associated with the TCR, cytokine signaling, and AP1 transcription factor activity. Functionally, NKTs overexpressing *BTG1* demonstrated an inhibited response to TCR stimulation ($p < 0.001$) due to increased cell death and markedly reduced proliferation compared to control NKTs (**Fig 1C-F**). To determine whether *BTG1* knockdown (KD) improves the efficacy of CAR-NKT immunotherapy, we generated a set of novel constructs that encode the GD2-CAR only or the GD2-CAR with IL15 (used in our clinical trial), each with and without an artificial microRNA targeting *BTG1* (CAR.15.amiR-BTG1) or a scrambled microRNA control (CAR.15.amiR-SCR). Compared to CAR.15.amiR-SCR NKTs, we found that CAR.15.amiR-BTG1 NKTs are enriched for CD62L+ central memory-like cells, express lower levels of PD1, mediate enhanced short- and long-term cytolytic activity, and undergo a greater degree of expansion throughout a serial tumor challenge assay (**Fig 2A-F**). Additionally, compared to control groups, CAR.15.amiR-BTG1 NKTs mediated durable antitumor activity in an aggressive model of metastatic neuroblastoma, inducing complete tumor regression in all treated animals (**Fig 2G-I**). These results establish BTG1 as a novel mediator of hyporesponsiveness in human NKT and non-naïve T cells and suggest that BTG1 silencing may broadly benefit the development of cancer immunotherapy.

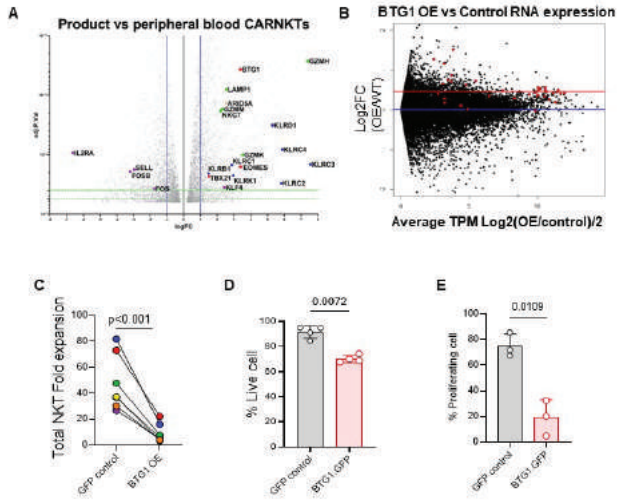


Figure 1. BTG1 expression is associated with CAR-NKT hyporesponsiveness. A. Volcano plot showing differentially expressed genes in pre-infusion product versus peripheral blood CAR-NKTs in patients treated with GD2-CAR NKTs. **B.** Total RNAseq reads from BTG1-overexpressing (OE) and GFP control NKTs. Red and blue lines indicate fold change from nuclear or mitochondrial transcripts, respectively. **C.** Fold expansion of BTG1-OE vs control NKTs after transduction. **D, E.** Survival of NKTs stimulated with aCD3/CD28 monoclonal antibodies and evaluated with annexin-V and fixable viability dye e780 on day 3, (**D**) and CellTrace Violet dilution measured on day 5 (**E**.).

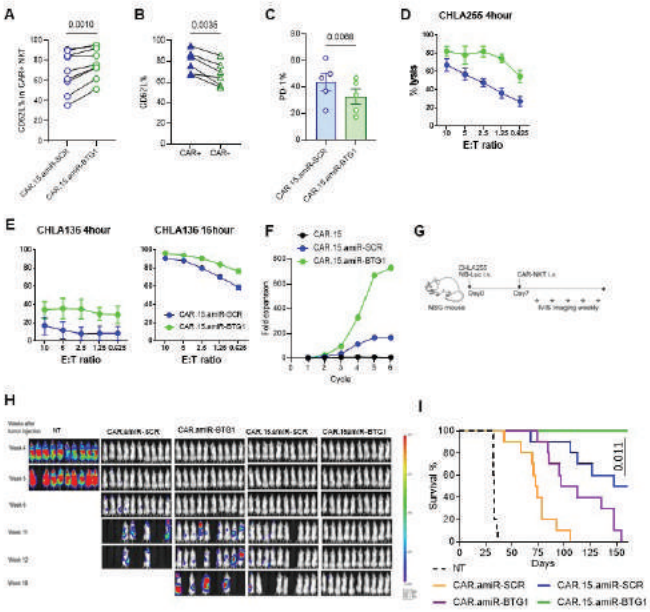

Figure 2. BTG1 knockdown (KD) enhances GD2-CAR.15 NKT antitumor activity. 266 Elucidating the Role of PD-1/PD-L1 Axis in Solid Tumour CAR-T Cell Therapy

Irene Andreu Saumell, Alba Rodriguez Garcia, Marta Gimenez-Alejandre, Joan Castellsagué, Berta Marzal, Marta Soria Castellano, Fara Brasó Maristany, Aleix Prat, Alvaro Urbano Ispizua, Sonia Guedan

Oncology and Haematology, Hospital Clínic, Barcelona, Spain

Introduction Dysfunction of therapeutic T cells can be a major challenge for CAR-T cell therapy against solid tumors. One possible strategy to overcome this situation is the inhibition of the PD-1/PD-L1 axis by genetic engineering. However, there is still controversy over whether chronic PD-1 inhibition can prevent or accelerate CAR-T cell exhaustion. Here, we explore the effects of PD-1 deletion on CAR-T cell function by testing different CAR constructs in a tumor model expressing varying PD-L1 levels. **Methodology** To generate a tumor model of PD-L1 expression, we eliminated *CD274* from ovarian cancer cells (SKOV3) by CRISPR-Cas9. PD-L1 negative cells were then sorted and transduced with lentiviral vectors encoding PD-L1 under the control of constitutive promoters of low (PGK100), medium (PGK300) or high (EF1α) intensity. We confirmed that PD-L1 expression levels after IFNγ or CAR-T cell exposure were similar to commercial cancer cell lines by flow cytometry. For CAR-T cell generation, T cells were genetically engineered to express CARs targeting HER2 either with low (LA-HER2) or high affinity (HA-HER2) or mesothelin (Meso) and containing the CD28 intracellular domain in tandem with CD3z. *PDCD1* was knocked out on CAR-T cells by using CRISPR-Cas9. The frequency of *PDCD1* ablation was between 50-90% in all normal donors, as determined by Sanger sequencing. T cell polyfunctionality was analyzed using IsoCode Single-Cell Adaptive Immune from Isoplexis and gene expression was analyzed using the CAR-T cell characterization panel, from Nanostring. **Results** LA-HER2 CAR-T cells were highly sensitive to the PD1-PDL1 axis inhibition, even when PD-L1 was expressed at low densities. In this setting, knocking out PD-1 restored cytokine secretion and increased T cell polyfunctionality. Transcriptomic analyses following antigen recognition revealed significant differences in the gene expression pattern of PD-1 KO CAR-T cells as compared to CAR-T cells, including an upregulation of signatures related to T-cell activation and Th1 polarization. *In vivo*, LA-HER2 CAR-T cells were able to induce complete responses (CR) in 87% of mice bearing tumors in the absence of PD-L1 expression (SKOV3 PD-L1 KO), while the percentages of CR in animals with PD-L1-expressing tumours (SKOV3 PD-L1 low, high or wild-type) were below 25%, with most of the animals showing progressive disease. By contrast, genetic *PDCD1* ablation strikingly enhanced tumour clearance by CAR-T cells, with more than 87% of animals with PD-L1-expressing tumours undergoing CR after treatment. We also confirmed a beneficial role of PD-1 inhibition in LA-HER2 CAR-T cells against other cancer types expressing HER2, as well as in meso-28z CAR-T cells both *in vitro* and *in vivo*. Surprisingly, in CAR-T cells expressing HA-HER2, *PDCD1* ablation led to milder increases in cytokine release, and no differentially expressed genes were detected between PD-1 KO CAR-T cells and CAR-T cells. Also, we did not observe an increase in antitumor efficacy after PD-1 deletion in any of the *in vivo* models tested, including tumors with high PD-L1 densities, in striking contrast to what we had observed in LA-HER2 CAR-T cells. **Conclusions** In summary, our results show that knocking out PD-1 improves the efficacy of CD28-based CAR-T cells (LA-HER2 and meso) both *in vitro* and *in vivo*. In contrast, this advantage was mitigated when using HA-HER2 CAR-T cells, suggesting that CAR affinity may be an important factor modulating the sensitivity to PD-1-PD-L1 axis inhibition in CAR-T cell therapy. We are currently investigating the mechanisms behind these differences. Importantly, knocking out PD-1 was not detrimental in any of the CAR constructs used, even when their sensitivities to PD-1-PD-L1 inhibition diverged.

267 Non-Virally Engineered Polyclonal γδ T Cells Exhibit Potent Anti-Tumor Activity *In Vivo*

Jacob Bridge, Patricia Claudio-Vazquez, Sophia Wenthe, Joshua Krueger, Branden S. Moriarity, Beau Webber

University of Minnesota, Minneapolis, MN

Introduction: γδ T cells are a subset of lymphocytes that recognize non-peptide antigens via canonical γδ T cell receptors (TCRs). Due to their diverse functionality and MHC-independent cytolytic activity, γδ T cells have garnered enthusiasm as a potential allogeneic immunotherapy. However, their heterogeneity and infrequency within peripheral blood, combined with inefficient genetic engineering and expansion of populations bearing polyclonal γδ TCR repertoires, has limited their clinical application. Here we implement a novel procedure for the large-scale production of polyclonal, non-virally engineered CAR-γδ T cells possessing potent anti-cancer activity. *In vivo* tracking of CAR-γδ T cells reveals selective persistence of specific

γδ T cell subsets correlating with therapeutic efficacy, providing opportunities to further refine the composition of γδ T cell products. **Methods:** Primary human γδ T cells were isolated from peripheral blood via immunomagnetic separation, then stimulated using plate-bound pan-γδ TCR and soluble CD28 antibodies (Fig. 1A). Non-viral transposon-based integration of a CD19 chimeric antigen receptor (CAR) construct was employed to direct intrinsic cytolytic activity against target cancer cells *in vitro* and *in vivo*. Candidate genes linked to γδ T cell inhibition, including *CISH*, *PD1*, and *Fas*, were inactivated at the genetic level using highly efficient Cas9 adenosine base editor (ABE). Cytotoxicity against tumor lines was first confirmed through *in vitro* serial killing assays, then evaluated *in vivo* using NSG mice challenged with Burkitt's Lymphoma. **Results:** Antibody-stimulated γδ T cell populations yielded >10,000 fold expansion by day 22, and maintained greater TCR diversity than populations derived from zoledronate-based expansion methods (Fig. 1B). γδ T cells were also amenable to highly efficient ABE-mediated triple gene knockout (>90%) without negatively impacting concurrent transposon-mediated CAR integration (>45%). CAR-γδ T cells exhibited potent *in vitro* anti-cancer activity in serial killing assays, and significantly extended mouse survival relative to PBS controls *in vivo* (22±1 vs 47±11 days; $p < 0.0001$; Fig. 1C). Peripheral Vδ1+ γδ T cells were enriched over time in treated mice (Fig. 1D), and exhibited increased persistence when engineered to secrete IL15 (Fig. 1E). Vδ1+ γδ T cell persistence also significantly correlated with survival in IL15-expressing groups (Fig. 1F). Strikingly, a distinct population of αβ TCR-Vδ1-Vδ2- cells representing <7% of injected γδ T cells predominated at endpoint in non-IL15-expressing groups (Fig. 1G). **Conclusions:** High cytolytic activity, potent effector function, and lack of alloreactivity make γδ T cells a prime candidate for use as an off-the-shelf cancer therapeutic. We developed a scalable, clinically-relevant method to expand non-virally engineered human γδ T cells with enhanced cytolytic activity. γδ T cell populations generated using this method achieved >10,000-fold expansion across a 22 day manufacturing process, and, when engineered with a CD19 CAR, displayed highly-efficient killing against tumor lines *in vitro* and *in vivo*. Our polyclonal approach supports improved characterization of discrete γδ T cell populations *in vivo*, informing the development of targeted immunotherapies against diverse subsets of cancer. Ongoing experiments are being conducted to screen for γδ TCRs with the highest reactivity *in vivo*, and to investigate the αβ TCR-Vδ1-Vδ2- cells identified at endpoint.

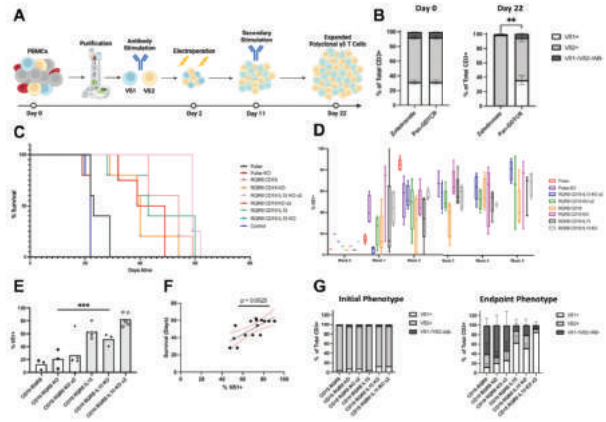

Figure 1. Discrete CAR-γδ T Cell Subsets Mediate Distinct Anti-Tumor Responses *In Vivo*. (**A**) Procedure for large-scale expansion of engineered γδ T cells. Purified γδ T cells were stimulated with pan-γδ TCR antibody and soluble anti-CD28, engineered after 48 hours, re-stimulated on day 11, and harvested at day 22. (**B**) γδ T cells stimulated with pan-γδ TCR possess higher TCR diversity than those produced from zoledronate. (**C**) Survival curve for NSG mice seeded with 10^6 Raji-Luc cells on day -4, then injected with 5 x 10^6 CAR-γδ T cells on day 0. N = 5 mice per condition. (**D**) Ratio of Vδ1+ to Vδ2+ cells through the first five five weeks of treatment. (**E**) CAR constructs containing IL15 yield greater Vd1 outgrowth at endpoint. IL15 production was confirmed via ELISA. (**F**) Endpoint Vd1 expression correlates with improved survival in mice receiving IL15-secreting CAR-γδ T cells. (**G**) Vδ1/Vδ2 expression of T cells at end point. Vδ1-Vδ2- cells also stained negative for αβ TCR. *P* ** > 0.01%, *** > 0.001.

268 Combining Anti-CD33 Chimeric Antigen-Receptor T Cells with the Hypomethylating Agent Decitabine to Treat Acute Myeloid Leukemia

Kenneth K.H. Ng, Marissa M. Del Real, Jonas Jian Wu, Tongyuan Xue, Emanuela Marcucci, Yate-Ching Yuan, Guido Marcucci, Stephen J. Forman, David Horne, Lihua E. Budde

City of Hope, Duarte, CA

Acute myeloid leukemia (AML) is the most common acute leukemia in adults, causing >10,000 deaths per year in the United States. Current therapies for AML, including hypomethylating agents such as decitabine (DAC), confer an overall long-term survival rate of only 35%, which decreases with patient age. Thus, novel and more effective therapies for patients with relapsed or refractory (r/r) AML remain an urgent unmet need. Targeted, immune-based strategies, including bispecific antibodies and chimeric antigen receptor (CAR) T cells, represent a promising new modality for the treatment of AML. CD33 is a cell surface glycoprotein restricted to early myeloid progenitors and expressed on more than 85% of AML cells, making CD33 an attractive immunotherapeutic target. Several ongoing clinical trials testing CD33-targeted bispecific antibodies and CAR T cells have validated CD33 as a target in AML and have shown favorable safety profiles. However, the clinical outcomes of these trials can be improved upon. Here we present a new CD33-targeted CAR (CD33 CAR) design and our preclinical combination of CD33 CAR T cells with DAC for the treatment of AML. Our platform to generate CD33 CAR T cells uses human CD4/CD8-selected T cells manufactured to express a CD33-CAR with a 4-1BB costimulatory domain. As a single agent, our CD33 CAR T cell induced potent antileukemia responses in vitro against primary AML blasts and tumor cell lines, as well as extended mouse survival compared to mock in our MOLM-14 NSG mouse model of AML. Importantly, our CD33 CAR T cells did not impair normal

hematopoiesis upon co-culture with hematopoietic stem/progenitor cells (HSPCs) cells in a colony forming-unit assay (n=3 HSPC donors), suggesting that our CD33 CAR T cells are unlikely to cause severe hematopoietic toxicity upon infusion in patients. When we tested the combination of CD33 CAR T cells with DAC, we observed enhanced antileukemia activity in vitro when we pretreated tumor cells with 200nM DAC for 3 days prior to coculture with CD33 CAR T cells. Similarly, we found that the in vivo combination of DAC (administered every 24 hrs for 5 days pre CAR T injection) and CD33 CAR T cells extended the median survival of mice to >120 days versus 70 days in mice receiving CD33 CAR T cells alone. To investigate the mechanism underlying the enhanced activity of CD33 CAR T cells following DAC pretreatment, we performed RNAseq analysis on the AML tumor line KG-1a with and without DAC treatment. Although we are currently identifying potential mechanisms, we have detected decreased mRNA transcript levels of DNA methylation machinery (DNMT1 and DNMT3B) and increased DNMT3A upon DAC treatment. Moreover, DAC treatment resulted in downregulation of DNA repair pathways, β-Catenin, and Notch signaling pathways.Taken together, we found that the antileukemia activity of CD33 CAR T cells was enhanced by pretreatment of leukemia cells with DAC. This combination represents a clinically relevant therapy for the treatment of patients with r/r AML.

269 Removal of Endogenous T Cell Receptor (TCR) May Inadvertently Compromise Allogeneic CAR T Cell Function

Hongjing Xia, Liaomin Peng, Boris Engels, Xiaobing Xie, Sujata Sharma, Ning Guo, Akash Kamalakar Sohoni, Carla Guimaraes, Jennifer Brogdon, Glenn Dranoff, Yi Yang

Novartis Institute of Biochemical Research, Cambridge, MA

Autologous chimeric antigen receptor (CAR) T cell therapy has been a paradigm shift in treating B cell malignancies. Despite its tremendous success in the past decade, the current individualized CAR T manufacture process is complex and has made broader patient accessibility challenging. Allogeneic CAR T cells have attracted huge investments from biotech startups and pharmaceutical industries for their potential as "off-the-shelf" products but until now, these cells have only showed limited persistence comparing to autologous CAR T cells in clinical trials. Generation of allogeneic CAR T cells usually involves ablating the endogenous T Cell Receptor (TCR), via gene editing, to prevent Graft-versus-Host Disease (GvHD). However, whether an intact TCR contributes to optimal CAR functions and persistence has not been thoroughly investigated. In this study, we disrupted the endogenous TCR by two approaches: 1, inserting the CAR-encoding sequence in the TRAC locus via CRISPR-Cas9mediated homologous recombination, using adeno-associated viruses (AAV) as donor templates; 2, directly knocking out TRAC via CRISPR-Cas9 in CAR T cells generated using lentivirus. We demonstrated that inserting the CAR in the TRAC locus under the control of the endogenous TRAC promoter led to reduced antigen-dependent proliferation *in vitro* and decreased tumor killing capacity or persistence in xenograft tumor models, likely due to impaired IL-2 production. This defect was observed with both the 2nd generation CAR tested, anti-CD19 and anti-BCMA CARs, comprising 4-1BB as the co-stimulatory domain. Providing exogenous IL-2 in culture media fully restored the antigen-induced proliferation capacity of the TCR-ablated CAR T cells to the level of TCR intact CAR T cells, generated by lentiviral transduction. We explored strategies to overcome this defect, including inserting CAR at different sites within the TRAC locus, changing the orientation of the CAR expression cassette relative to TRAC transcription, employing either the endogenous TRAC promoter or an exogenous EF1-α promoter to drive CAR expression, replacing 4-1BB with CD28 co-stimulatory domain, and deleting two ITAM domains in the CD3 zeta chain in the CAR construct. Taken together, our data substantiates an earlier report that endogenous TCR promotes *in vivo* persistence of CD19-CAR-T cells (Dana Stenger et.al., DOI: 10.1182/blood.2020005185). We propose that further characterization of the crosstalk between TCR and CAR will guide the design of the next generation of allogeneic CAR T cells, that are as robust as the clinically approved autologous products.

AAV Vectors - Preclinical and Proof-of-Concept In vivo Studies II

270 Adeno-Associated Virus Serotype 5 is a Suitable Vector for S100A1-Based Gene Therapy of Post-Ischemic Chronic Cardiac Dysfunction

Dorothea Kehr[1], Janek Salatzki[2], Florian Andre[2], Andreas Jungmann[1], Martin Busch[1], Patrick Most[1]

[1]Molecular and Translational Cardiology, Heidelberg University Hospital, Heidelberg, Germany,[2]Cardiology, Heidelberg University Hospital, Heidelberg, Germany

Introduction: Toxicity by recombinant adeno-associated viruses (rAAV) in clinical gene therapy trials (e.g., rAAV9-mediated fatal liver failure) can significantly impair the translatability of preclinical rAAV-based cardiac gene therapy programs employing such vectors. In contrast, rAAV5, which continues to demonstrate a beneficial long-term clinical safety profile and scalable producibility has never been systematically evaluated for cardiac-targeted gene therapy.

Hypothesis: We therefore hypothesized that rAAV5 may be a suitable vector for cardiac gene delivery and therapy, respectively, in a large animal heart failure (HF) model that closely approximates human size and cardiovascular pathophysiology. **Approach:** Using rAAV5 and a cardiomyocyte-biased promoter both with a luciferase (luc) reporter for a comparative biodistribution study against rAAV6 and rAAV9 and the human S100A1 gene - as previously validated therapeutic transgene for cardiac gene therapy in various HF models - for a subsequent intervention study, respectively, we determined the suitability of rAAV5 by catheter-based cardiac-targeted administration for sufficient myocardial gene delivery and therapeutic efficacy in normal and post-myocardial infarction (post-MI) HF pigs. **Results:** In a comparative study of rAAV5-luc, rAAV6- and rAAV9-luc in healthy farm pigs (n=5 each group; $1x10^{13}$ vgc per vector per pig), AAV5 achieved a homogeneous cardiac apical-basal transduction pattern that was significantly higher than rAAV9 while rAAV6 resulted in inhomogeneous cardiac transduction, as assessed by luc expression. Relative off-target transduction was significantly higher for rAAV6 and rAAV9 than rAAV5. In a subsequent clinically relevant study that used serial cardiac magnetic resonance imaging (cMRI), we the favorable cardiac transduction pattern of rAAV5 translated in a significant improvement of left ventricular ejection fraction (LVEF) by +19 ± 5 % three months after catheter-based retrograde AAV5-S100A1 gene delivery compared to AAV5-luc in infarcted pigs (n=4 each; $1x10^{13}$ vgc/pig). Moreover, S100A1-treated pigs showed significantly less infarct extension by late gadolinium enhancement (LGE) than controls (-0.5 ± 0.3 g S100A1 vs. +5 ± 1.3 g luc) measured by cardiac MRI. There were no unfavorable alterations in blood counts, clinical chemistry or ECG and S100A1 expression was predominantly contained to the heart. A weighted gene network correlation analysis of myocardial transcriptome data sets from treated pigs unveiled a significant correlation between the improved LVEF and a suppression of inflammatory and immunological pathways ($r=0.96$, $p < 0.01$) and between the absent infarct extension (LGE) and enhanced activity of cardioprotective signaling ($r=-0.82$, $p < 0.05$) by rAAV-S100A1. With injections of 2×10^{11} vgc of AAV5-S100A1 or AAV5-gfp (n=4 each) into the remote myocardium of a post-MI mouse model, we confirmed a significant improvement in echocardiographic LV fractional shortening (+43.8 ± 8.8 %, vs. gfp) and strong suppression of inflammatory gene expression including, i.e., IL1b or TNFa as a novel effect for S100A1 by RT-PCR. **Conclusion:** We conclude that AAV5 is a suitable vector for cardiac-targeted gene therapy and in combination with S100A1 proves effective in treating post-MI cardiac dysfunction in a human sized model. Given the clinical safety profile of rAAV5 and the rather low rAAV5-S100A1 dosage to achieve a lasting therapeutic effect with a clinically applicable route of administration, this vector-transgene combination may be a promising ensemble for a clinical HF gene therapy medicinal product program.

271 Expression and Function of Guanidinoacetate Methyltransferase (GAMT) is Effectively Restored in Cellular and Murine Models of GAMT Creatine Deficiency Following Treatment with *scAAV9.hGAMT*

Robyn T. Binsfeld[1], Troy B. Webster[1], Ilona Tkachyova[2,3], Michael Tropak[2,3], Melissa Mitchell[4], Andreas Schulze[2,3,5], Jagdeep S. Walia[4,6]

[1]Centre for Neuroscience Studies, Queen's University, Kingston, ON, Canada,[2]The Hospital for Sick Children, Toronto, ON, Canada,[3]Peter Gilgan Centre for Research and Learning, Toronto, ON, Canada,[4]Department of Paediatrics, Queen's University, Kingston, ON, Canada,[5]Departments of Pediatrics and Biochemistry, University of Toronto, Toronto, ON, Canada,[6]Kingston Health Sciences Centre, Kingston, ON, Canada

Guanidinoacetate methyltransferase (GAMT) is an essential enzyme in the biosynthesis of creatine, a small molecule that plays an important role in energy metabolism. Creatine deficiency disorders are inborn errors of metabolism resulting in several neurological manifestations including developmental delay, intellectual disability, and epilepsy, emphasizing the importance of creatine's role in the brain. Creatine is obtained exogenously and synthesized through the enzymatic function of arginine:glycine amidinotransferase (AGAT) to form guanidinoacetate (GAA) which is then converted to creatine by GAMT. GAMT-deficiency (GAMT-D) is an autosomal recessive disorder resulting in low creatine levels and accumulation of the neurotoxic intermediate, GAA. Current treatment for GAMT-D focuses on restoring creatine levels through oral creatine supplementation and on reducing GAA accumulation through ornithine supplementation to inhibit AGAT function. However, this does not restore creatine or GAA levels in the brain, leaving many of the symptoms unattended. We present a proof-of concept study testing the first central nervous system (CNS)-directed, AAV9-based gene therapy for the treatment of GAMT-D. *In* vitro studies showed that protein and mRNA expression of GAMT were restored resulting in increased intracellular creatine content and reduced GAA accumulation in cellular models of GAMT-D following transfection with the codon-optimized GAMT construct. In a murine model of GAMT-D, treatment with *scAAV9.hGAMT* delivered intrathecally, resulted in increased creatine content as well as significant decreases in GAA accumulation throughout the entire body, including the CNS (Figure 1). Serum collections taken at multiple time-points prior to the short-term endpoint of 13 weeks, showed a marked increase in creatine over time as well as a decrease in GAA accumulation compared to untreated knockouts. GAMT protein expression was restored in the livers of treated animals. This study represents proof-of-principle results for an effective GAA reduction and creatine increase in the CNS using an AAV9 based gene therapy. This therapeutic is currently under further investigation in mouse models to explore its impacts on behaviour and to determine an appropriate therapeutic window for efficacy and safety to allow for translation into human patients.

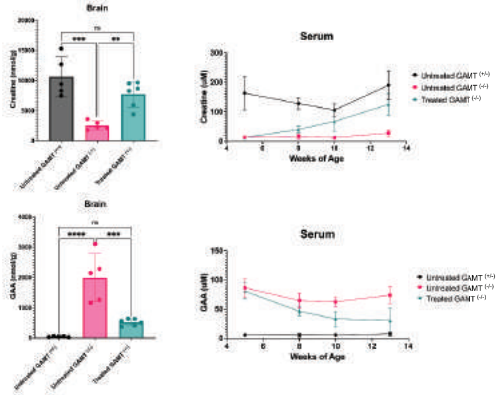

Figure 1. Creatine and GAA levels are corrected following treatment of GAMT knockout mice with *scAAV9.hGAMT* in the brain and serum. Mice were treated with $2.5e^{11}$vg/mouse of *scAAV9.hGAMT* at 6 weeks of age and sacrificed at 13 weeks of age. Proteins extracted from the tissue were analyzed by liquid chromatography tandem mass spectrometry for the presence of creatine and GAA. Significant increases in creatine and decreases in GAA were observed in the brain compared to untreated mice (** $p < 0.006$, *** $p < 0.0002$). Serum was collected at a baseline of 5 weeks of age, every two weeks following injections and at endpoint. Increases in creatine and decreases in GAA were observed over time with significance observed at 10 weeks and endpoint compared to untreated knockouts ($p < 0.002$).

272 Comparative Transcriptomic Analysis Identifies Rescue of Dysregulated Signatures by ATXN1 Knockdown and ATXN1L Overexpression in a Mouse Model of SCA1

Ashley Robbins[1,2], Ellie Carrell[2], Megan S. Keiser[2], Beverly L. Davidson[2,3]

[1]Neuroscience Graduate Group, University of Pennsylvania, Philadelphia, PA,[2]Raymond G. Perelman Center for Cellular and Molecular Therapeutics, Children's Hospital of Philadelphia, Philadelphia, PA,[3]Department of Pathology & Laboratory Medicine, University of Pennsylvania, Philadelphia, PA

Background: Spinocerebellar Ataxia Type 1 (SCA1) is an adult-onset neurodegenerative disease caused by a (CAG) expansion in the coding region of the ATXN1 gene. The resulting polyglutamine-expanded protein has both toxic gain of function properties, as well as loss of normal ATXN1 activity. We recently demonstrated reversal of disease phenotypes in SCA1 transgenic mice mouse model by overexpression of an ATXN1 paralog, ATXN1-like (ATXN1L), alone or in combination with miRNA-mediated knockdown of hATXN1, delivered by recombinant adeno-associated virus (rAAV) directly to the deep cerebellar nuclei (DCN). In the initial study, two dual expression transgenes were tested, differing in their use of RNA pol II or III driven expression of a hATXN1-targeting microRNA (miS1) and AAV serotype. Despite similar behavioral rescue, we found discordant effects on disease-specific transcriptional signatures between two different dual therapy transgenes and hypothesized that this reflected a difference in packaging capsid and resultant tissue tropism.**Methods:** Here we performed a direct comparison between the two dual SCA1 therapeutic strategies, that combined ATXN1L and simultaneous hATXN1 knockdown by either a mature miS1 arising from RNA pol III transcripts or an RNA pol II transcript intron. Transgenes were packaged into rAAV2/1 and delivered by direct injection into the DCN of B05 mice following onset of motor symptoms. Rescue of motor coordination and gene dysregulation were assessed by behavioral assays and whole transcriptome sequencing of the cerebellum. **Results:** While all strategies led to significant improvements in motor function, expression of human ATXN1L (hATXN1L) alone was not sufficient to normalize dysregulated gene expression signatures in symptomatic B05 mice. This agreed with our previous study, where we also determined that ATXN1 knockdown was necessary for gene normalization. When ATXN1L overexpression was combined with miS1, motor improvements were complemented by robust normalization of disease allele-induced changes in gene expression, regardless of RNA pol II or III usage. Further comparative analysis revealed subtle but significant glial activation and immune gene signatures in the cerebella of mice treated with vectors expressing miS1 under a pol III promoter. No such gene signatures were identified in mice expressing miS1 as an RNA pol II transcript intron. **Conclusion:** In summary, transcriptomic analysis of gene rescue by two dual ATXN1 knockdown strategies suggests that previous contrasting results were due to differing tropism of the AAV capsids. Our data continues to support the combination of both gene therapy strategies into a single rAAV for efficient delivery of a vector capable of overcoming both loss- and gain-of-function mechanisms of disease in SCA1. In addition, we demonstrate the utility of next-generation sequencing to confirm treatment efficacy and inform the development of therapeutic constructs.

273 Optimizing Base Editing Strategies in a Mouse Model of Zellweger Syndrome

Cathleen Lutz[1], Daniel Gao[2], Maximiliano F. Presa[3], Aamir Zuberi[3], Samagya Banskota[2], Joseph G. Hacia[4], David R. Liu[5]

[1]Rare Disease Translational Center, The Jackson Laboratory, Bar Harbor, ME,[2]Broad Institute, Cambridge, MA,[3]The Jackson Laboratory, Bar Harbor, ME,[4]University of Southern California, Los Angeles, CA,[5]Harvard University and HHMI, Cambridge, MA

Zellweger Syndrome is a rare disease associated with impaired peroxisome biogenesis and dysfunction caused by mutations in one of 13 genes responsible for peroxisome assembly. Peroxisomes play an important role in a number of cellular functions, including fatty acid metabolism, the catabolism of amino acids, and lipid biosynthesis. The spectrum of Zellweger disorder ranges from mild to severe, affecting a range of organ and tissue function. Patients typically present in early infancy with an incidence of 1 in 50,000 live births in the United States. Symptoms typically includes hypotonia, seizures, vision and hearing loss, as well as life threatening deficits in major organs. Mutations in the gene *PEX1* account for the majority of Zellweger patients and the G843D mutation is one of the most common pathogenic variants. Mouse models have been engineered for a number of Zellweger causative genetic mutations including loss of function alleles and the murine equivalent of the G843D allele in the Pex1 gene. This mouse model displays many of the key features of Zellweger syndrome, including the accumulation of long chain fatty acids. Precision gene editing methods such as base editing and prime editing are promising technologies for the treatment of genetic diseases. Establishing methods for the *in vivo* delivery of new adenine base editors (ABEs) in animal models of human disease is a critical first step before assessing its therapeutic potential. The Liu group has developed therapeutically relevant delivery strategies for base editors *in vivo*, including single-AAV and dual-AAV approaches. Our preliminary data using adenine base editor ABE7.10max (ABEmax) suggest that the dual AAV system can correct *Pex1* G844D mutation *in vivo*. To obtain higher correction levels, we applied recently evolved ABE8e

and ABE8e-V106W, which are more active than ABEmax. These high-activity base editors resulted in a high degree of genome correction with few detected off-target affects. Preclinical efficacy testing in our mouse model resulted in a significant reduction in the levels of very long-chain fatty acid accumulation as well as lipid levels in the liver. These data demonstrate a promising approach for therapeutic base editing as a potential treatment for Zellweger Syndrome.

274 Therapeutic Effect of Linker Protein-Mediated Gene Therapy in a Mouse Model for LAMA2-Related Muscular Dystrophy

Judith R. Reinhard[1], Shuo Lin[1], Dirk Grimm[2], Markus A. Rüegg[1]

[1]Biozentrum, University of Basel, Basel, Switzerland,[2]University of Heidelberg, Heidelberg, Germany

LAMA2-related muscular dystrophy (LAMA2 MD or MDC1A) is the most frequent form of congenital muscular dystrophies. It is caused by mutations in *LAMA2*, the gene encoding laminin-α2, one chain of the heterotrimeric extracellular matrix protein laminin-211 (α2β1γ1). Most patients lack laminin-α2 due to bi-allelic loss-of-function mutations in *LAMA2*. The large size of the coding sequence for laminin-α2 (~ 9.4kb) and the heterotrimeric structure of laminin-211 present a challenge for AAV-mediated gene replacement or gene editing strategies. Here, we describe the development of an AAV-based gene therapy to functionally replace laminin-211 by two small linker proteins. Prior work in transgenic mice has demonstrated that this Simultaneous Expression of Artificial Linkers (SEAL) in skeletal muscle of LAMA2 MD mice has a tremendous ameliorative effect on disease progression (Reinhard et al., 2017. *Sci Transl Med*. 9). As both linkers, mini-agrin (mag) and αLNNd, are small enough to be efficiently packed into AAV, we intravenously co-injected mag- and αLNNd-expressing AAV9 or AAVMYO vectors into LAMA2 MD mice. Both linkers were highly expressed in skeletal muscle and led to a strong improvement of disease phenotypes, including an increase in body- and muscle weights, grip strength, myofiber size and the reduction of fibrosis. Using AAVMYO as a capsid, the same improvement was seen at a ten-fold lower dose than with AAV9. These studies thus establish that systemic delivery of AAVs expressing the two linkers (SEAL technology) might be a possible strategy to treat LAMA2 MD patients. As the linkers are designed from proteins (agrin, nidogen-1 and laminin-α1) that are all expressed in LAMA2 MD patients, this treatment is expected to be well tolerated. Moreover, the fact that the linkers are secreted and act in the extracellular matrix where they also accumulate, suggests that this treatment might be efficacious over a wide dose range of AAV.

275 AAV-Mediated Monoclonal Antibody Expression for the Prevention and Treatment of *Pseudomonas aeruginosa* Infections

Jordyn A. Lopes, Nicole Garnier, Yanlong Pei, Jacob G. E. Yates, Brenna Stevens, Elena S. B. Campbell, Melanie M. Goens, Madison E. Hughes, Amira D. Rghei, Leonardo Susta, Cezar M. Khursigara, Sarah K. Wootton

University of Guelph, Guelph, ON, Canada

Vector-mediated monoclonal antibody (mAb) expression utilizing adeno-associated virus (AAV) has been shown to provide robust mAb expression from a single intramuscular (IM) dose. Our novel triple mutant capsid, AAV6.2FF, has been shown to provide long-term therapeutic mAb expression against infectious pathogens in numerous animal models. AAV6.2FF is capable of effectively transducing the lungs, therefore we aimed to target *Pseudomonas aeruginosa* - a nosocomial pathogen of global concern, that is particularly prevalent in patients suffering from cystic fibrosis (CF). Roughly 40% of patients with CF have chronic *P. aeruginosa* infections when reaching adulthood, which is associated with worsening lung function and increased mortality. Antibiotic treatment is the first line of defense when *P. aeruginosa* is first detected, although successful eradication is variable and not sustained due to the intrinsic and acquired resistance of *P. aeruginosa* towards multiple classes of antibiotics. To date, there are no licensed vaccines for this pathogen, prompting the urgent need for novel treatment approaches to interfere with *P. aeruginosa* infection and persistence. A highly protective mAb targeting exopolysaccharide Psl has been shown to mediate serotype-independent opsonophagocytic killing of *P. aeruginosa.* Psl is abundantly expressed in both mucoid and non-mucoid isolates, and is suggested to be involved in host attachment, immune evasion and biofilm formation. The PcrV protein located at the apex of the type-III secretion system injectosome is integral for the translocation of effector molecules into the host cell cytoplasm, and has also been shown to be a highly potent mAb target. Given the critical role of Psl and PcrV in the establishment of *P. aeruginosa* infections, it was rationalized that a combination of both anti-Psl and anti-PcrV mAbs engineered into a single bispecific mAb would enhance strain coverage and reduce bacterial burden. Bispecific hIgG antibody (MEDI3902) which combines single-chain variable fragments of both anti-Psl and anti-PcrV mAbs has been found to provide protection in prevention and treatment of *P. aeruginosa* infections *in vivo* and was evaluated in a Phase II clinical trial (NCT02696902). Here we have validated the AAV6.2FF platform as a strategy to generate long-term antibody expression beyond 12 weeks post-vector administration. Our three vectors of interest, AAV6.2FF-PcrV, AAV6.2FF-Psl and AAV6.2FF-MEDI3902 provided significant protection in a lethal challenge model against *P. aeruginosa* strains PA01 and PA14. BALB/c mice IM injected with $1x10^{11}$ vector genomes (vg) of AAV6.2FF-PcrV provided 100% protection from a lethal intranasal challenge of $4.47x10^{7}$CFU PA01. AAV6.2FF-mediated expression of these antibodies dramatically reduced bacterial burden *P. aeruginosa* dissemination to other organs in a lethal PA01 challenge model. All vectors provided significant protection, although notably the bispecific vector provided significantly greater protection against bacterial dissemination to the liver, lung, spleen, and blood compared to the monospecific vectors. Together, these results support further investigation of utilizing AAV-mediated

mAb expression for the prevention and treatment of *P. aeruginosa* infections and other bacterial pathogens of public health concern, in which current treatment strategies are limited.

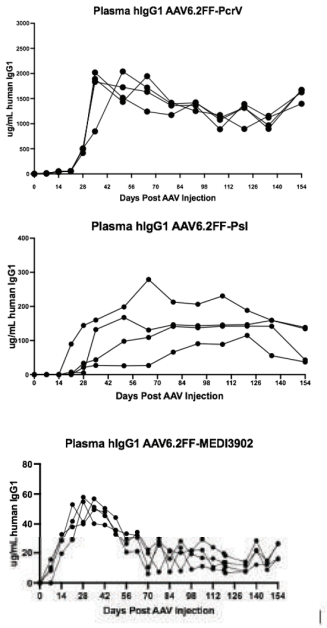

Figure 1: Serum antibody expression levels after intramuscular administration of 1x10^{11} vg of AAV6.2FF-PcrV, AAV6.2FF-PsI or AAV6.2FF-MEDI3902. BALB/c mice (n=4) were IM administered 1x10^{11} vg of AAV6.2FF-PcrV (A), AAV6.2FF-PsI (B), or AAV6.2FF-MEDI3902 (C), and their serum human IgG levels were monitored for 22 weeks.

276 AAV9-Delivered Artificial miRNA Gene Therapy Rescues the PS19 Mouse Model of Tauopathy

Huei-Bin Wang, Irvin T. Garza, Katherine M. Pearce, Sydni Holmes, Krishanna Knight, Rachel M. Bailey

Center for Alzheimer's and Neurodegenerative Diseases, University of Texas Southwestern Medical Center, Dallas, TX

Tau protein is expressed by the microtubule-associated protein tau (*MAPT*) gene and plays an essential role in the central nervous system. Aging, environmental stress, and *MAPT* mutations can alter Tau expression and its post-translational modifications, leading to abnormal accumulation of tau proteins and CNS dysfunctions (characterized as tauopathies). Tauopathies are presented in a spectrum of neurodegenerative diseases (e.g. Alzheimer's disease and frontotemporal dementia), and have been associated with cognitive decline in both clinical studies and animal models. Based on WHO surveys, more than 55.2 million people worldwide suffer from dementia, with a predicted increase to 139 million in 2050, suggesting an urgent need for treating tauopathies. To treat tauopathies, we propose a tau-reduction therapy, which is the use of adeno-associated viral (AAV)-mediated gene silencing therapy. To reduce tau levels, we developed panels of artificial, tau-specific microRNA (miRNA) shuttles that were designed to target mRNA for all isoforms of tau found in the human or mouse brain. We previously selected lead candidates based on tau reduction at both mRNA and protein levels and packaged them into AAV9 vectors. The therapeutic effects of AAV9-hTaui were tested in a commonly used mouse model of tauopathy, PS19 mice, which carry the 1N4R isoform of human MAPT with the P301S disease-associated mutation. PS19 mice express human MAPT at a 7 times higher level than the endogenous mouse Mapt, and they exhibit significant tau pathology, neurodegeneration, loss of body weight and progressive hind-limb paralysis around 9-12M of age. We tested efficacy of our treatment by delivering AAV9-hTaui to PS19 mice at 3M, 6M and 9M of age. Treatment groups included WT littermates treated with vehicle or AAV-Scr and PS19 mice treated with vehicle, AAV-Scr or AAV9-hTaui. Survival rate, functional tests, and BW changes were evaluated 3M after the intra-cisterna magna injection. Tau mRNA and protein levels in brain tissues were assayed using RT-qPCR and ELISA. Additionally, a cell-based tau seeding assay was used to measure the presence of pathological tau in brain lysates. Tau pathology and neurodegeneration in the brains of mice treated at 9M of age were also assessed by histology. We found that the tau mRNA and protein levels were significantly reduced in the AAV9-hTaui group and were unaffected in the AAV-Scr groups. Consistently, the tau seeding assay showed reduced levels of pathological tau in brains from PS19 mice treated with AAV9-hTaui and was unchanged in the control groups. At functional output levels, our one-time treatment was able to rescue the survival rate, loss in body weight, and the hind limb clasping phenotype in the PS19 mice. In a separate safety study, AAV9 carrying a mouse-specific Tau miRNA (mTaui) was ICM delivered to 3M old WT mice to determine how knock-down of endogenous tau is tolerated in the adult brain. In life assessments supported that tau reduction did not affect weight gain, survival, hind-limb clasping, or behaviors related to motor function, anxiety and cognition up to 12 months post-dosing. Histopathology of tissues are ongoing. Together, this study presents a one-time, vectorized delivery of a tau-specific miRNA as a potential treatment for tauopathies.

Vector Product Engineering, Development, and Manufacturing

277 A Sequence-Upgraded PolyA LTR (SupA-LTR™) Imparts Enhanced Transcriptional Insulation to New 4th Generation Lentiviral Vectors from Both 5' and 3' Genic Regions in Target Cells

Jordan Wright, Ben M. Alberts, Daniel D. Chipchase, Kyriacos A. Mitrophanous, Nicholas G. Clarkson, Dan C. Farley

Oxford BioMedica, Oxford, United Kingdom

The structure of 3rd generation lentiviral vectors (LVVs) has not appreciably changed over the last two decades, and such LVVs have been widely adopted for *ex vivo* applications. The development of LVVs for use in directly administered *in vivo* applications is being re-invigorated through more specific targeting and improvements in both production scale and product quality. Indeed, regulatory authorities are placing very significant importance upon on the safety and quality aspects of viral vector gene therapy products generally. Consequently, we have been seeking to improve LVV genome design to further mitigate potential risks associated with high dose applications.

An unintended consequence of the deletion of U3 promoter sequences within SIN-LTRs was the removal of overlapping polyadenylation enhancer sequences, leading to reduced transcription termination efficiency with SIN-LTRs compared to the full length LTR. Termination at the native polyA signal within the R region is not sufficiently rescued by retention of the native 'GU-rich' downstream enhancer (DSE) within U5. This results in increased transcriptional read-in/out of the integrated LVV cassette, and concomitant interactions with the host transcriptome, as well as some potential effects on transgene expression. Moreover, there is currently no mechanism to control transcription read-in on the anti-sense strand, and therefore some integration events may be lost to dsRNA formation and associated innate responses. Others have improved polyadenylation efficiency on the sense strand by insertion of heterologous upstream enhancer elements (USE) within the SIN region. Here we have developed 'sequence-upgraded polyA-LTRs' (supA-LTRs) that not only contain a USE but also an optimally placed DSE on the sense strand. This is achieved by two modifications within the LVV expression cassette: [1] the careful insertion of a synthetic DSE into the 5' R region, and [2] the use of an 'R-embedded' heterologous polyadenylation sequence to replace the 3' R-U5 sequence entirely, thereby placing the polyA signal upstream of R sequences required for 1st strand transfer. Due to the spatial nuances of polyA-cleavage of vector genomic RNA, and subsequent reverse-transcription, the resultant supA-LTRs that flank the integrated cassette harbour an optimally spaced USE-pA-DSE configuration. Additionally, an inverted polyA-DSE is incorporated, so that the integrated LVV cassette is also transcriptionally insulated from the 3' direction. This results in up to 50-fold and 100-fold reduction of transcription through supA-LTRs compared to SIN-LTRs in sense and anti-sense, respectively. Interestingly, the greatest block to 5' transcription read-in to the integrated LVV cassette is observed when supA-LTRs are combined with other features of our 4th generation LVVs that have an inactivated major splice donor site within the packaging signal. Additionally, we find a modest but beneficial increase in transgene expression of up to 2-fold when employing supA-LTRs. Further aspects to the characterisation of supA-LTRs in LVV production and in target cells will be presented. We anticipate the use of supA-LTRs will be of great assistance to the field in providing additional safety and utility to the next generation of LVVs.

278 Fitting-Out 4th Generation Lentiviral Vectors: New Technology to Improve Their Production, Quality, Safety, Capacity and Utility

Jordan Wright, Ben M. Alberts, Cristina Nogueira, Kyriacos Mitrophanous, Nicholas Clarkson, Dan C. Farley

Oxford Biomedica, Oxford, United Kingdom

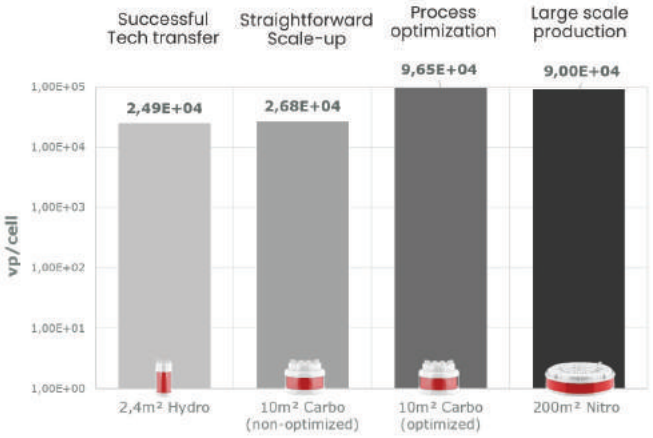
The development of Lentiviral vectors (LVVs) based on HIV-1 has focussed on a 3rd generation vector structure that has not appreciably changed over the last two decades. The clinical success in using LVVs to deliver therapeutic genes to dividing and non-dividing cells is built upon their safety features. Nevertheless, as clinical use expands there is a need to continually improve product quality and safety, and researchers are seeking to produce and deliver LVVs with ever larger, more complex transgene cassettes. Here we provide a summary of a suite of new technologies that can be adopted to create a new class of 4th generation LVV genomes where vector production, quality, safety, capacity and utility are further improved. Our 4th generation LVVs come in two core designs: [1] Rev-dependent or '2KO-LVVs' and [2] Rev-independent or 'MaxPax' LVVs. Both of these genome types harbour the same key modification of an inactivated major splice donor (MSD) site within the packaging sequence. We and others have shown that the MSD within 3rd generation LVVs can aberrantly splice to transgene cassette splice acceptor sequences during LVV production, leading to less full-length vector genomic RNA (vRNA), and a substantial amount of truncated (transgene encoding) vRNA. We show that 2KO-LVVs and MaxPax-LVVs do not produce such truncated RNAs, and consequently contain a far higher proportion of full length vRNA within resulting LVV particles. Since MSD-inactivation alone leads to a reduction in LVV out-put titres, we have engineered different solutions to overcome this in each 4th generation LVV type. 2KO-LVVs titres are maximised by the co-expression of a modified U1 snRNA that can bind to the LVV packaging sequence during production, which effectively serves as a chaperone-like molecule to increase the pool of packageable vRNA for assembly. For MaxPax-LVVs, the attenuating effects of the MSD-inactivation are abrogated by the use of a synthetic intron or 'Vector-Intron' (VI) to replace the Rev-response element. The splicing-out of the VI during pre-vRNA biogenesis stabilises the vRNA and consequently does not contribute to overall vRNA length - an important factor in maintaining RNA pool steady state levels and vRNA packaging efficiency. Thus, together with other deletions within the packaging sequence, MaxPax-LVVs can package ~1kb additional sequence, increasing transgene capacity. Since transgene cassette introns cannot be retained by MaxPax, this vector is ideal for very large or multiple transgene payloads where minimal cis-acting elements are employed, and introns are not required. Where transgene introns are desirable, the 2KO-LVV design should be considered. Both of these 4th generation LVV genome types employ 'sequence-upgraded polyA' or supA LTRs, providing improved transcriptional insulation for the integrated LVV in patient cells. Current 3rd generation LVVs employ self-inactivating (SIN) LTRs that are not only deleted in HIV-1 U3 promoter sequences to improve safety, but concomitantly lack polyA enhancer sequences required for efficient transgene transcription termination. These supA-LTRs have been configured to reduce transcriptional read-in to the cassette from chromatin by up to 50-fold from both 5' and 3' directions, as well as increase transgene expression by up to 2-fold. Layered on top of these other features is the option to employ the 'Transgene Repression In vector Production' system. The TRiP system™ works maximally within these 4th generation LVVs to minimise the variable effects of transgene expression during LVV production (doi: 10.1038/ncomms14834). Employing TRiP can enhance out-put titres, simplify downstream processing, and ensure that transgene protein is not embedded within final LVV product.

279 Suspension-Based Adenovirus Production Process Development and Scale-Up in scale-™ Fixed-Bed Bioreactors

Cedric Meeus[1], Thomas Bouckenooghe[1], Emilie Gateau[1], Benedicte Dehouck[1], Sylvain Fauquenoy[1], Marco Soriani[2], Maria Ferraiuolo[2], Alessia Noto[2], Stefano Colloca[2], Hanna P. Lesch[1]

[1]Exothera, Jumet, Belgium,[2]ReiThera Srl, Roma, Italy

Suspension-cultured HEK293 cells and serum-free conditions have become an industrial standard for adenovirus production. To maximize the virus titers, a good cell state and high cell density are required. Commonly operated in batch, cell density achieved is low and the implementation of a more complex feeding strategy can be reached only with an external perfusion system. In this study, the manufacturing of a non-replicative Gorilla Adenovirus vector (GRAd, proprietary of ReiThera) in suspension cells was adapted to the scale-X™ bioreactor. The scale-X™ fixed-bed bioreactor family has been designed to ensure flexible and scalable manufacturing for high cell density processes without a need for additional feeding systems. The proof of concept showed a direct adaptation of the suspension cell-based process to scale-X™ hydro (2.4m²). The cells were entrapped in the fixed-bed structure with the productivity of 2.49 x 10^4 viral particle (VP)/cell (figure 1). The intermediate scale (scale-X™ carbo 10m²) enabled a linear process scale-up. The process optimization by higher cell density at infection, production phase and medium volume increased the viral particle titers to 9.65 x 10^4 VP/cell. Further scale-up to 200m² scale using scale-X™ nitro bioreactor, never performed for adenovirus production, led to a large-scale consistent cell growth and titer of 9.00 x 10^4 VP/cell (total yield 3.53x10^{16} VPs). As a conclusion, the scale-X™ family provided an efficient way to make process transfer on small scale, proved straightforward scalability and process optimization on the middle scale, and yielded high titer adenovirus manufacturing on a large scale.



280 Lentiviral Vector Production Using Suspension Adapted HEK293T Cells in Serum Free Media

Matthew B. Welty[1], Sreedhar Thirumala[2], Madelyn Beck[3], Kimberley House[3], Tsai-Yu Lin[4], Aaron M. Shaw[4], Alisha Moore[3], Quynh Mai Trinh[1], Emily L. Hopewell[5], Daniela Bischof[4], Kenneth Cornetta[6]

[1]Brown Center for Immunotherapy, IU School of Medicine, Indianapolis, IN,[2]Indiana University Medical School, Indianapolis, IN,[3]IU School of Medicine, Indianapolis, IN,[4]Indiana University School of Medicine, Indianapolis, IN,[5]Indiana University School of Medicine, Zionsville, IN,[6]Indiana University, Indianapolis, IN

As more cell and gene therapies make their way to the market, there will be an increasing demand for clinical grade lentiviral vectors. Adherent HEK293T cells have been used in vector manufacture but as batch sizes increase, the required surface area makes the process cumbersome and expensive. To solve this, we generated a suspension adapted HEK293T cell line HEK293T(IUS) able to grow in serum-free conditions and evaluated the line's potential to generate high titer vector. A series of three Design of Experiment (DOE) trials were performed to optimize transfection conditions of this new cell line. The optimized conditions were then used in a WAVE bioreactor to successfully produce three 4-5-liter batches of vector product. Downstream processing with tangential flow filtration generated diafiltered, concentrated material which was evaluated for vector physical and infectious titer. **Methods:** HEK293T(IUS) cells were transiently transfected with a four plasmid, third generation, VSV-G pseudo typed lentivirus vector expressing GFP. PEIpro® transfection reagent and sodium butyrate were used to enhance transfection. JMP software was used for the DOE experiments which compared the effects of several culture parameters on transfection efficiency and vector titer. Physical titer was determined by p24 assay. To determine a functional titer, adherent HEK293 cells were transduced with the vector supernatant and GFP expression was measured by flow cytometry. Following the results of the DOE, the culture volume was increased twenty times from 15mL to 300mL in shake flasks using the optimized conditions. Three 4-5 L lentiviral vector productions were then performed using the WAVE bioreactor platform and the optimized transfection conditions. The cells were expanded in shake flasks and a WAVE bag until enough cells were generated to begin the transfection. The transfection was then performed in the WAVE bag according to the DOE optimized parameters. After the optimized time period, the supernatant was collected, clarified, treated with DNAse, diafiltered, and concentrated using TFF. **Results and Conclusion:** The DOE compared the effects of several transfection parameters on the functional titer. The use of Sigmacoat® did not significantly increase vector titer. The only significant two factor interactions found were the interactions polyplexing time with Pluronic acid concentration leading to a reduction in titer (p=0.02165 and F Ratio=9.48) and the interaction between plasmid DNA concentration per 10^6 cells and the PEI volume per 10^6 cells increasing the titer (p=0.009, F Ratio=12.38). The optimal conditions were found to be 3 million cells per mL, 0.25 µg plasmid DNA per 10^6 cells, 1.0 µL PEIpro® per 10^6 cells, 5 minutes polyplexing, and no media change. The result of the 300mL cultures were found to be slightly better than a 15mL scale indicating larger scale up is possible. The infectious titers of the WAVE bag were compared to an optimized clinical adherent cell production run and were found

to be similar. Further development could better tailor the procedure to the features of the WAVE reactor thus improving yield generated and allowing scalability to higher volumes. In conclusion, we successfully optimized the transient transfection of a suspension adapted HEK293T cell line. We also demonstrated the production feasibility of 5L in a WAVE bioreactor. The HEK293T(IUS) cell line will be made available from the NGVB (www.NGVBCC.org).

281 Development of a Scalable Lentiviral Manufacturing Upstream Process with a Suspension Producer Line for Cell Therapy Applications

Kimchi A. Strasser[1], Anja Pertl[1], Jana Bauer[1], Georg Huber[1], Bianca Volkmann[2], Irene Ferreira[2], Michael Salomon[1]

[1]Process Development Department, SIRION Biotech (a PerkinElmer company), Munich, Germany,[2]Cell & Gene Therapy Clinical Support Department, SIRION Biotech (a PerkinElmer company), Munich, Germany

In the last years, lentiviral vectors have advanced from being a genome delivery tool to becoming a vital part of several cell therapies. With the fast evolution of the cell- therapy field, new demands have emerged, which cannot be met using conventional lentiviral manufacturing technologies. To enable the development of affordable and effective cell therapies, well known lentiviral manufacturing bottlenecks, e.g., predictable upscaling processes, maximized recovery rates and high functional titers, need to be addressed. Here, we focus on upstream and downstream scalability. A key component of a scalable upstream process is a suspension producer cell line. We analyzed the productivity of two commercially available suspension cell clones, ThermoFisher's Virus Producing Cells (VPC) 2.0 and 1.0 (data not shown), as well as an adherent cell clone (HEK-T from CLS) used as control. The productivity studies of VPC 2.0 were conducted using the commercially available reagents, i.e., Viral Production medium and the LV-MAX™ Transfection Kit. The reagents for culturing and transfecting the adherent cell line were DMEM supplemented with 2 mM glutamine and PEI. Per VPC 2.0 cell, the number of lentiviral particles (i.e., genome copies or GC measured by qPCR) found in the crude fraction was in average 4,1E3 (n=3; culture volume = 240 mL; total number of cells on day of transfection = 1,1E9). While per adherent cell was 1,6E3 genome copies (n= 3; area= 6,320 cm2; total number of cells on day of transfection = 6,6E8). Hence, the productivity of the VPC 2.0 was 2.5-fold higher than that of the adherent cell line. Next, we tested if the productivity of VPC 2.0 is affected during the upscaling by using the following volumes: 30, 60, 120, and 240 mL. The total number of lentiviral particles in the crude fraction (i.e., productivity) were 2.6E9 GC/mL (n=3) for the 30 mL; 2.7E+09 GC/mL (n=3) for 60 mL; 1.9E+09 GC/mL (n=3) for 120 mL and 2.7E7 GC/mL (n=3) for 240 mL. The productivity of VPC 2.0 cell, therefore, was not affected by upscaling the culture volume, except for the 120 mL condition. Next, we focused on the scalability of the clarification process by analyzing two different methods: ultrafiltration and filtration using the SartoClear Dynamic kits with diatomaceous earth as a filter aid. Although recovery rates were similar for both methods, clarification via diatomaceous earth reduced the processing times, which is a prerequisite for clarifying large volumes. Further work is planned to optimize the scalability of the subsequent downstream steps. This includes testing scalable ion exchange monoliths and an affinity purification method based on an agarose base-bead, e.g., CaptureSelect™ Lenti VSVG Affinity Matrix. This study illustrates that the strategic development of upstream and downstream processes is key to eliminating lentiviral manufacturing bottlenecks, a must for the development of affordable and effective cell therapies.

282 Intensified Production Process for Gorilla Adenoviral Vector GRAd: Yield, Purity, Potency and Stability Results

Stefano Colloca, Adriano Leuzzi, Alessia Noto, Eleonora Lilli, Giuseppina Miselli, Alessandro Moretti, Canosa Andrea Valeria, Cenesi Flavia, Gentile Michela, Scala Romina, Angelo Raggioli, Stefania Capone, Leonardo Sibilio, Antonella Folgori, Fabiana Grazioli, Federico Napolitano, Virginia Ammendola

ReiThera, Roma, Italy

Simian adenoviruses derived from the chimpanzee, bonobo, and gorilla, are not known to circulate and/or cause pathological illness in humans, consequently have low/no seroprevalence (0%-18%) in the human population and therefore it can be ideal viral vectors for vaccine and advanced therapy applications. Adenoviral vectors derived from simian adenovirus and more specifically from great apes have been studied in millions of human subjects using vaccine vectors encoding different antigens (relevant to Ebola, malaria, hepatitis C, human immunodeficiency virus [HIV], respiratory syncytial virus [RSV] and COVID-19) have shown that this vaccine platforms are safe and can generate potent, durable, and high-quality T cell and antibody (Ab) responses.Reithera has developed a COVID-19 vaccine using a novel gorilla adenovirus classified into species C. This adenovirus isolated from a captive animal was converted into a replication-defective adenoviral vector generating GRAd-COV2 vaccine. GRAd-COV2 has completed the phase II clinical trial in 2022 showing a good safety profile and a strong immunogenicity.In parallel Reithera has developed a production process based on the proprietary high yield packaging cell line ReiCell 35S based on low passage HEK293 cells. The process was designed to provide high volumetric yield by exploiting perfusion and high cell density at infection in single use stirred tank bioreactor. The downstream platform was designed on orthogonal purification process based on selective host cell DNA precipitation step and cell debris removal by depth filtration followed by anion exchange membrane chromatography, HCDNA trimming step by endonuclease digestion, mixed mode polishing chromatography and formulation by TFF. The process was set up in 2L bioreactor and scaled up to 1000L and 2000L single use STR. The analytical results demonstrated that the process provides a very high yield (>60%) with the final product meeting all specification in terms of potency and purity. In addition, the final product was demonstrated to be stable at +2-8°C for more than one year. In conclusion, this novel GRAd vector is an attractive vaccine platform suitable for development and production of high-throughput vaccines against pathogens or diseases requiring the generation of a well-coordinated immune response.

283 Lentiviral Vector Engineering: Impact on Manufacturing and Vector Performance

Ana S. Formas-Oliveira, Tiago A. Vaz, Mariana Valentim Ferreira, Ana S. Coroadinha
iBET, Oeiras, Portugal

Background and novelty Advanced therapy medicinal products transformed medicine, and past unmet medical needs are now being treated with cell and gene therapy approaches targeting the cause of the disease. Gene therapies are based on the transfer of genetic material to the patients' cells and lentiviral (LV) vectors are one of the preferred delivery systems, particularly when targeting hematopoietic cells (e.g. hematopoietic stem cells, T lymphocytes). LV vector engineering can be used to improve their efficacy and manufacturing. Herein, we describe vector engineering strategies, at the level of LV enzyme and envelope glycoproteins, enabling constitutive manufacturing through stable cell lines and effective T-cell transduction. **Experimental approach** The ideal LV vector manufacturing process should rely on stable producer cell lines and perfusion systems, enabling high cell density and long-term production. In contrast, most bioprocesses for LV vectors are either based on transient transfections or inducible producer cell lines that generally constrain production to short-term runs. LV vector protease and VSV-G envelope glycoprotein are cytotoxic, challenging the development of constitutive stable cell lines. To address these obstacles, we either eliminated or reduced the cytotoxicity of LV vector components by engineering less active LV protease and highly efficient non-toxic envelope glycoproteins. The LV vector protease was engineered by mutating the catalytic center at amino acid 26. As an alternative to the VSV-G envelope, gammaretrovirus glycoproteins (4070A, GaLV, and RD114) were evaluated and engineered to pseudotype LV vectors. These glycoproteins do not induce cytotoxicity, ultimately allowing the development of stable LV producer cells. **Results and discussion** Reducing LV cytotoxicity enabled the use of constitutive promoters. The mutated protease T26S generated similar titers to the wild-type one when using VSV-G, but not when pseudotyping with gammaretrovirus glycoproteins. Novel 4070A, RD114, and GaLV-derived glycoproteins were developed with the aim of improving its cleavage by T26S protease and increasing LV vector titers. Engineering the glycoproteins enable to overcome titer differences observed between LV vector productions using wild-type and T26S protease. Transduction of human peripheral blood mononuclear cells (PBMCs) with pseudotyped LV vectors 4070A, RD114, and GaLV novel envelopes showed successful T-cell modification, and at similar efficiencies as obtained with VSV-G LV vectors. Proof-of-concept LV vector producer cell lines constitutively and stably producing infective titers above 10^6 $TU.mL^{-1}.day^{-1}$ were successfully established. The producer cells showed to be stable over 3 months of subculture. Bioreaction studies showed continuous vector production over 10 days. Process intensification, enabling high cell densities, through perfusion resulted in improvement of titer to 10^7 $TU.mL^{-1}.day^{-1}$. This work shows LV vector engineering can enable the development of more effective manufacturing processes and improve vector performance.

Cancer - Oncolytic Viruses

291 A Personalised Neo-Antigen Viro-Immunotherapy Platform for Triple-Negative Breast Cancer

Renato Baleeiro, Peng Liu, Louisa S. Chard, Carmela Di Gioia, Ai Nagano, Lauren Cutmore, Jun Wang, Claude Chelala, Nicholas R. Lemoine, Yaohe Wang
Centre for Cancer Biomarkers & Biotherapeutics, Barts Cancer Institute, Queen Mary University of London, London, United Kingdom

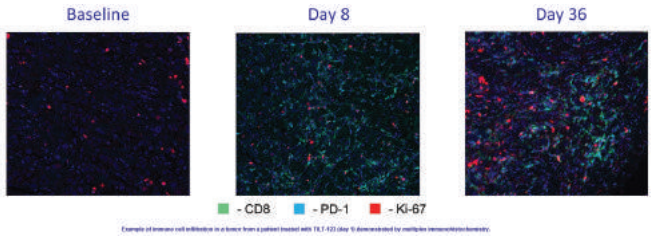
Triple-negative breast cancer (TNBC) corresponds to approximately 20% of all breast tumours, with a high propensity for metastasis and a poor prognosis. Because TNBC displays a high mutational load compared to other breast cancer types, a neo-antigen-based immunotherapy strategy could be effective. One major bottleneck in the development of a neo-antigen-based vaccine for TNBC is the selection of the best targets, *i.e.*, tumour-specific neo-antigens which are presented at the surface of tumour cells and capable of eliciting robust immune responses. Here, we used bioinformatic tools and cell-based assays to identify immunogenic neo-antigens that can be presented by the patients' HLA class I alleles. We further validated our approach by generating neo-antigen-specific CD8+ T-cells capable of recognising a human TNBC cell line expressing the mutated gene. A further hurdle to overcome in development of novel neo-antigen-based therapies is delivery, as this process must engage and enhance immune activation against antigens. We have developed a new generation of a highly tumour-specific oncolytic Vaccinia virus (VV) and show that it can directly destroy tumour cells independently of antigen expression, change the tumour microenvironment and attract effector T-cells and maintain their activation. Using a preclinical model of TNBC we show that long peptides encompassing neo-antigens can be delivered in a mixed solution with an oncolytic VV in a prime/boost regimen to induce neo-antigen-specific CD8+ T-cell response, slow tumour growth and increase survival.

292 Emerging Data from the Use of TILT-123, an Oncolytic Adenovirus Armed with TNFa and IL-2 in Patients with Solid Tumors

Victor Cervera-Carrascon[1,2], Inge Marie Svane[3], Tuomo Alanko[4], Katriina Peltola[5], Brigitte Dreno[6], Marco Donia[3], Eva Ellebaek[3], Tine Monberg[3], Jorma Sormunen[4], Juha Kononen[4], Riitta Korpisaari[4], Marjut Jaakola[5], Amir Khammari[6], Susanna Juteau[5], James Clubb[1,2], Santeri Pakola[2], Lyna Haybout[2], Joao M. Santos[1,2], Riikka Havunen[1,2], Suvi Sorsa[1,2], Akseli Hemminki[1,2,5]
[1]TILT Biotherapeutics Ltd, Helsinki, Finland,[2]University of Helsinki, Helsinki, Finland,[3]CCIT, Copenhagen University Hospital, Herlev, Denmark,[4]Docrates Cancer Center, Helsinki, Finland,[5]Helsinki University Hospital, Helsinki, Finland,[6]INSERM, CNRS, INCIT, Nantes Université, Nantes, France

The therapeutic landscape in oncology has notably changed in the last decade after the approvals of immunotherapeutic drugs such as immune checkpoint inhibitors (ICIs) and other T-cell therapies. The

myriad of clinical trials conducted increasingly allow us to understand how and when to use those therapies. One of the major limitations discovered is that many patients do not respond to immunotherapies. TILT-123 (Ad5/3-E2F-d24-hTNFa-IRES-hIL2) is an oncolytic adenovirus engineered to increase the activity of the immune system towards the tumor, and to unlock efficacy for subsequent immunotherapies, in patients that otherwise do not benefit. Over a decade of lead optimization and preclinical testing, paved the way for clinical studies to assess safety and efficacy of TILT-123. Since 2020, four Phase I studies have been initiated: a monotherapy (NCT04695327) and combinations with TILs (NCT04217473), pembrolizumab or avelumab (NCT05271318, NCT05222932). Two of the trials (NCT04695327, NCT04217473) were phase I open-label, dose-escalation clinical trials, that have the primary endpoint of establishing safety of the treatments in patients with injectable advanced refractory and recurrent solid tumors, that cannot be treated with curative intent. The secondary endpoints include correlative analyses performed to better understand the pharmacokinetic and pharmacodynamic properties of TILT-123. Virus specific detection techniques were utilized in different biological samples such as tumor, blood, urine, and saliva at various timepoints following drug administration, in order to understand the presence and persistence of the agent. At the same time, cell phenotyping, proteomic and transcriptomic effects were evaluated on available samples to measure the immunological impact in the tumor milieu. RECIST 1.1, iRECIST, and a PET-based criteria were used to assess efficacy. Interim data (n=18 patients) supports the safety of TILT-123 and no DLTs were reported. Expected adverse events associated with oncolytic adenoviruses such as fever, nausea, chills, and fatigue, appeared typically as low grade according to the CTCAE v5.0. Antitumor efficacy derived from the use of TILT-123 has been observed in several patients. The dose escalation had a direct correlation with the increased detection of the virus in blood up to 14 days post administration. Cytokine and chemokine (IL-12, CXCL9, CXCL10, CXCL11, CXC3CL1, CCL3, CCL4) signatures were observed in blood suggesting that the treatment triggered immune trafficking and activity. Likewise, analysis of tumor samples revealed increasing diversity of CD8 and CD4 T lymphocyte subsets.



Emerging data from clinical trials suggests that TILT-123 has an adequate safety profile and can reshape the tumor microenvironment resulting in antitumor activity, at the tested doses. Studying biological samples allowed a better understanding on the mechanism of action of this gene therapy product.

293 Addition of αTIGIT Checkpoint Blockade to MV-s-NAP-uPA + αPD-1 Combination Immunotherapy Enhances Long-Lasting Immunity in a Syngeneic Murine Glioblastoma Model

Susanna C. Concilio, Kimberly Viker, Susan McGrath Clark, Steven Robinson, Ianko D. Iankov, Evanthia Galanis

Molecular Medicine, Mayo Clinic, Rochester, MN

Introduction: Glioblastoma multiforme (GBM) remains the most aggressive and lethal primary brain tumor with dismal survival despite multimodality treatment. GBM is an immunologically "cold" tumor, marked by heterogeneity, few tumor-specific neoantigens, and poor immune cell infiltration. Attempts to treat GBM with immune checkpoint blockade (ICB) therapy against programmed death receptor 1 (PD-1) and cytotoxic T-lymphocyte associated protein 4 (CTLA-4) have been largely unsuccessful. Our group has previously shown that combination of an engineered oncolytic measles virus strain, MV-s-NAP-uPA, and αPD-1 ICB significantly increases survival and immune activation in syngeneic glioma models. Neutrophil activating protein (NAP) derived from *Helicobacter pylori* is an immunostimulatory protein and can elicit strong Th1 immune responses. Inclusion of NAP in the MV backbone enhances its immunostimulatory potential. Analysis of GBM-bearing mice treated with αPD-1 with or without MV-s-NAP-uPA revealed upregulation of the checkpoint T cell immunoglobulin and ITIM domain (TIGIT), but not T cell immunoglobulin and mucin-domain containing 3 (TIM-3) or CTLA-4 on several immune populations, including macrophages, CD4 and CD8 T cells. TIGIT binds to CD155 and CD112; CD155 is documented to be overexpressed in several tumors including GBM. TIGIT-receptor ligation induces immunosuppressed phenotypes in CD4 and CD8 T cells, natural killer (NK) cells, and macrophages. We hypothesized that combined anti-PD1 and anti-TIGIT blockade in combination with MV-s-NAP immunovirotherapy would result in synergistic efficacy**.** **Methods:** The previously described engineered measles strain MV-s-NAP-uPA is capable of infecting murine cells via urokinase-type plasminogen activator receptor (uPAR) and expresses a secretory form of NAP (s-NAP). C57/BL6 female mice were implanted with syngeneic CT-2A murine glioblastoma cells orthotopically and then treated twice with MV-s-NAP-uPA intratumorally. Mice received αPD-1 and/or αTIGIT ICB therapy on a 3-day cycle for 3 or 6 treatments. Mice were followed for survival and rechallenge or were sacrificed at pre-determined timepoints for analysis via immunohistochemistry (IHC), flow cytometry, or cytometry by time of flight (CyTOF). Cytokine analysis was performed on plasma samples from various timepoints. Mice were rechallenged six months later with CT-2A or B16-F10 melanoma intracranially to evaluate tumor-specific long-term immune memory and response. **Results:** MV-s-NAP-uPA, αPD-1, and αTIGIT combinatorial therapy resulted in near 100% survival rates, superior to all other tested regimens. Cytokine analysis revealed a Th1-skewed systemic cytokine milieu upon combination treatment. CyTOF analysis is ongoing; findings will be associated with survival outcomes. Rechallenge experiments with surviving mice showed that the anti-tumor response is CT-2A-specific, suggesting a long-lasting tumor-specific immunity. **Conclusions:** Triple combination therapy with MV-s-NAP-uPA, αPD-1, and αTIGIT appears to be the most

promising treatment evaluated in this study. These mice survive long-term and do not exhibit detectable side effects. Correlative analysis is ongoing. We are also currently assessing any toxicological constraints of this triple therapy prior to clinical translation.

294 A First-in-Human Phase I Clinical Trial of Intratumoral Administration of a Measles Virus Derivative Expressing the *Helicobacter pylori* Neutrophil-Activating Protein in Patients with Metastatic Breast Cancer

Siddhartha Yadav[1], Ianko Iankov[2], Kim Viker[2], Tufia Haddad[1], Karthik V. Giridhar[1], Roberto Leon-Ferre[1], Matthew P. Goetz[1], Vera J. Suman[3], Evanthia Galanis[1]

[1]Department of Oncology, Mayo Clinic, Rochester, MN,[2]Department of Molecular Medicine, Mayo Clinic, Rochester, MN,[3]Department of Quantitative Health Sciences, Mayo Clinic, Rochester, MN

Background: Engineering measles virus (MV) to express secretory *Helicobacter pylori* neutrophil-activating protein (s-NAP) enhances the immunostimulatory potential of MV. We present safety results from a first-in-human phase 1 trial of MV-s-NAP in women with metastatic breast cancer (MBC). **Methods:**A 3+3 Phase I clinical trial was conducted to determine the maximally tolerated dose (MTD) of a single intratumoral administration into a single lesion of MV-s-NAP. Dose-limiting toxicities (DLTs) included: grade 3+ hematologic/non-hematologic toxicity, viremia > 6 weeks from viral administration, and serum creatinine > 2 x baseline, at least probably related to treatment. Participants are observed for 3 months following injection for Viral shedding (tested by qRT-PCR in mouth gargle and urine), viral replication in the tumor (using Vero cell overlay assay), high mobility group box 1protein(HMGB1) expression and immune response to MV and NAP transgene (by ELISA and virus neutralization assay) and then for 2 years for disease events. **Results:**Seven women with ER+/Her2+ MBC, were enrolled as of January 30, 2023; three at dose level 1 (DL1: $TCID_{50}$:$1x10^8$), three at DL2 ($TCID_{50}$:$3x10^8$), and one at DL3 ($TCID_{50}$:$1x10^9$). Data are available for DL1-2. No dose-limiting toxicities (DLT) were observed. The most common grade 1-2 toxicities reported were: tumor pain (5 pts), and nausea (2 pts). No evidence of shedding was seen. Viral replication was detected in two patients on day 3, including one being a 3-fold increase of serum HMGB1 on day 8 persisting 6 weeks. There was no detectable increase in anti-NAP antibodies. All 6 of these patients have progressed. **Conclusions:** No DLTs were observed for DL1-2 of MV-NAP. Moreover, no detectable increase in anti-NAP was seen with viral replication seen in 2 of 6 patients.

295 Temozolomide Chemotherapy Enhances Dual Blockade of an Oncolytic Virus Expressing an Anti-CD47 Antibody for Breast Cancer Brain Metastases

Tasha Barr, Lei Tian, Jing Wang, Michael Caligiuri, Jianhua Yu

City of Hope, Duarte, CA

Limited therapeutic options are available for breast cancer brain metastases (BCBM). Thus, there is an urgent need for novel approaches. We previously engineered an effective oncolytic herpes simplex virus-1 (oHSV) expressing a full-length anti-CD47 monoclonal antibody (mAb) with a human IgG1 scaffold (OV-αCD47-G1) to treat ovarian cancer and glioblastoma (*Nat Commun,* 2021 Oct 8;12(1):5908; *Clin Cancer Res,* 2022 Jan 1;28(1):201-214). Here, we demonstrated the combination of OV-αCD47-G1 and temozolomide (TMZ) is a promising and practical strategy to improve BCBM treatment efficacy. We found TMZ treatment increased CD47 expression in both mouse and human breast cancer cells, while TMZ treatment alone had no adverse effect on OV-αCD47-G1 infection and had no effect on macrophage phagocytosis against breast tumor cells either. However, compared to OV-αCD47-G1 treatment alone, TMZ combination with OV-αCD47-G1 increased macrophage phagocytosis against breast tumor cells by enhancing the blockade of the CD47-SIRPα signaling pathway. Compared to OV-αCD47-G1 alone or TMZ alone, the combination of OV-αCD47-G1 and TMZ dramatically activated the transcription of typical macrophage cytokine genes in both human and mouse macrophages that were previously reported to respond to IgG1 antibodies, such as Il1β, Il6, Il12, Ccl2, Ccl4, and Nos2. TMZ combination with OV-αCD47-G1 also led to greater activation of human NK cell cytotoxicity through more effective binding to the Fc receptors when compared to treatment with OV-αCD47-G1 or TMZ alone. To evaluate the efficacy of OV-αCD47-G1 combined with TMZ for the *in vivo* treatment of BCBM, we utilized our previously described orthotopic model of human BCBM by i.c. injecting 1×10^5 firefly luciferase (FFL) gene-expressing human breast cancer cells (MBA-MD-231-FFL) into athymic nude mice (*Oncotarget*, 2016 May 10;7(19):27764-77). After tumor implantation, animals received an i.c. injection with OV-αCD47-G1, control OV, or saline as a placebo control with or without TMZ. OV-αCD47-G1 combined with TMZ improved survival of tumor-bearing mice better than OV-αCD47-G1 alone or TMZ alone. To avoid the cross-species interaction of human CD47 and mouse SIRPα, which is not physiologically relevant, we established a fully immunocompetent mouse model by replacing the anti-human CD47 antibody expressed from oHSV with anti-mouse CD47 antibody. Briefly, we constructed the anti-mouse CD47 antibodies (Clone: A4) on mouse IgG2b (equivalent to human IgG1) and mouse IgG3 (equivalent to human IgG4) scaffolds, termed as A4-IgG2b and A4-IgG3, respectively, as well as the corresponding oHSVs expressing A4-IgG2b (OV-A4-IgG2b) or A4-IgG3 (OV-A4-IgG3). Combination treatment with the mouse counterpart of OV-αCD47-G1, OV-A4-G2b, also enhanced mouse NK cell cytotoxicity, macrophage phagocytosis, and prolonged survival of mice bearing BCBM compared to the single treatments. The combination therapy enhanced the infiltration of macrophages, NK cells, and T cells compared to the single treatment in the tumor microenvironment. Collectively, our study indicates OV-αCD47-G1 combined with TMZ could improve immune-virotherapy for patients with BCBM. The translation of the study into the clinic, including IND-enabling studies, is ongoing.

296 Clinical Activity of Oncolytic Virus Voyager-V1 in Patients with Relapsed Refractory Lymphoma

Kah-Whye Peng[1], Nora Bennani[1], Joselle Cook[1], Javier Munoz[2], Stephen Broski[3], Lianwen Zhang[1], Nandakumar Packiriswamy[4], Brenda Gions[5], Susan Geyer[1], Thomas E. Witzig[1], Stephen J. Russell[6], Martha Q. Lacy[1]

[1]Mayo Clinic, Rochester, MN,[2]Mayo Clinic, Phoenix, AZ,[3]Radiology, Mayo Clinic, Rochester, MN,[4]Imanis Life Sciences, Rochester, MN,[5]Mayo Clinic, Scottsdale, AZ,[6]Vyriad, Rochester, MN

Voyager-V1 (VV1) is an oncolytic Vesicular Stomatitis Virus (VSV) encoding interferon beta and sodium iodide symporter (NIS) gene. Interferon beta confers tumor selectivity and enhances host antitumor immunity while the NIS gene allows noninvasive imaging of sites of viral infection using PET or SPECT. Mechanism of action of VV1 was established in early dose escalation studies showing infection of tumor cells through NIS imaging after intratumor injection of the virus. Immunohistochemical staining showed increase in immune cell infiltrates of injected tumors, supporting the rationale to combine VV1 with immune checkpoint antibodies. A number of clinical trials investigating safety and activity of VV1 are ongoing, utilizing VV1 as a monotherapy, or in combination with cemiplimab, an anti-PD1 antibody. Here, we report the results from our phase 1 clinical study evaluating the safety and tolerability of one intravenous (IV) infusion of VV1 in patients with relapsed refractory multiple myeloma and T cell lymphoma (TCL). This was a classical 3+3 phase I trial, starting at 5e9 TCID50 dose level 1 through 1.7e11 TCID50 dose level 4 given as a single IV dose. No dose limiting toxicities were observed. An expansion cohort at dose level 4 was added to enroll additional patients with TCL due to early signs of clinical activity. To date, 12 patients with relapsed refractory TCL have received one IV dose of VV1 at 1.7e11 TCID50. Two complete responses (CR) and five partial responses (PR) were recorded, with one CR lasting 30 months, and the other CR is ongoing at 15 months with no additional therapies. Adverse events were manageable, with transient decreases in lymphocyte counts and grade 1-2 cytokine release syndrome that is transient and resolving by 24h. Two cohort are added to the study to enroll 20 additional T cell lymphoma and 10 additional B cell lymphoma patients to obtain additional safety and efficacy signal and deeper analysis of biomarkers of responses.

297 Novel Oncolytic Therapy VET3-TGI Restricts TGFb1 and Augments Type-1 Immune Response in TME, Leading to Superior Therapeutic Efficacy in Multiple Preclinical Tumor Models

Ravi Muthuswamy[1], Carly Carter[1], Ming Zhang[1], Dan Byrd[2], Steve Thorne[2]

[1]Immunology, KaliVir Immunotherapeutics, Inc., Pittsburgh, PA,[2]KaliVir Immunotherapeutics, Inc., Pittsburgh, PA

Counteracting immunosuppressive TGFβ1 and enhancing Type-1 immune responses in tumor microenvironment, can lead to better anti-tumor immunity and durable clinical response. Current study developed a novel vaccinia virus known as VET3-TGI for oncolytic immunotherapy. VET3-TGI expresses soluble TGFβ mini-monomers, which acts as dominant negative inhibitor of TGFβ1 (TGFβi) and IL-12 to promote IFNγ/Type-1 responses in tumors. Additionally, CXCR3 was added to promote systemic delivery of VET3-TGI virus selectively to tumors and enhance tumor specific expression of therapeutic transgenes. The expression of transgene proteins: IL-12, TGFβi and CXCR3 was analyzed by ELISA, western and FACS. In vitro chemotaxis assays were used to analyze chemotactic response of CXCR3 to CXCR3 ligands. TGFβi was analyzed for their ability to alleviate TGFβ1 imposed suppression of proliferation and IL-12, for increased induction of GZMB/IFNγ in CD8 T cells. The therapeutic efficacy of VET3-TGI over control virus was tested in three pre-clinical *in vivo* mice tumor models (MC38, RENCA, EMT6), which demonstrated potent therapeutic activity, including 100% CRs, even at doses several logs below equivalent clinical doses. Post-mortem analysis in those tumor tissues showed that VET3-TGI showed reduced systemic toxicity and improved systemic delivery to tumors expressing CXCR3 ligands even in the face of pre-existing anti-viral immunity. Multiplex immunofluorescence analysis revealed the enhanced filtration of $CD3^+CD8^+$ T cell in tumors of VET3-TGI treated mice compared to control mice. RNA seq analysis of tumor samples showed VET3-TGI tumors showed profound changes of tumor microenvironment with polarization to type-1 immune response. Dramatic increase in IFNγ inducible genes: Type-1 inflammatory chemokines, interferon responsive factors, innate immunity, antigen presentation and concomitant decrease in TGFβ1 associated genes is evident in the analyses. Altogether, VET3-TGI demonstrated good ability to counter TGFβ1 mediated immunosuppression and dramatically enhance anti-tumor immune response leading to safe and potent therapeutic activity in multiple mouse tumor models. Based on the above, VET3-TGI is selected as the lead clinical candidate for upcoming clinical trials. Currently, clinical manufacture and toxicology testing is undergoing with a human version of this virus.

Preclinical Development of Novel Cell Therapies for Human Disease

284 Gene-Editing to Eliminate Automaticity Prevents Arrhythmias after Engrafting Human Pluripotent Stem Cell-Derived Cardiomyocytes

Kenta Nakamura[1], Silvia Marchianò[1], Lauren E. Neidig[1], Jordan M. Klaiman[1], Hans Reinecke[1], Leslie P. Blakley[1], Elaheh Karbassi[1], Aidan M. Fenix[1], Faith A. [1]University of Washington, Seattle, WA,[2]Sana Biotechnology, Seattle, WA,[3]Vanderbilt University, Nashville, TN,[4]University of Torino, Torino, Italy

Background: Pluripotent stem cell-derived cardiomyocyte (PSC-CM) transplantation is an emerging strategy to treat subacute myocardial infarction (MI), but transient engraftment-related arrhythmia (EA) is

major barrier to clinical translation. We hypothesize that EA is induced by pacemaker-like automaticity of developmentally immature graft. We initiated a CRISPR-Cas9 genome editing screen to identify the culprit ion channels. **Methods:** After testing single, double, and triple gene edits we found that knocking out the depolarization-associated genes *HCN4, CACNA1H,* and *SLC8A1*, combined with overexpression of the hyperpolarization-associated gene *KCNJ2,* resulted in PSC-CM that are electrically quiescent but excitable by external pacing. 150x10^6 gene edited (n=3) and wildtype (n=7) PSC-CMs were transplanted into a minipig model of EA and observed for up to 7 weeks on continuous ECG for engraftment and arrythmia. **Results:** Genetically edited PSC-CM successfully engrafted and structurally coupled with host myocardium. No significant EA occurred after transplanting edited PSC-CM and all three subjects completed study. Low burden of isolated premature ventricular contractions (PVCs) and short episodes of non-sustained ventricular tachycardia (NSVT) occurred, but no sustained arrhythmias were observed. Heart rate and arrhythmia burden (36% vs 3% of the study duration) were significantly reduced ($p<0.001$). Conversely, wildtype PSC-CM controls demonstrated uncontrolled and sustained ventricular tachycardia (VT). Of the seven WT control subjects, four survived to study completion; three expired or were euthanized due to unstable VT or ventricular fibrillation. All grafts were structurally and electrically coupled with host myocardium. **Conclusion:** EA appears to be driven by an accelerated automaticity of early PSC-CM grafts. Genetically editing PSC-CM to abolish intrinsic pacemaker-like activity may prevent arrhythmia or at minimum, reduce arrhythmic burden and lethality. This study identifies ion channels involved in EA and supports a novel strategy to improve safety and tolerability of PSC-CM-based cardiac remuscularization therapy.

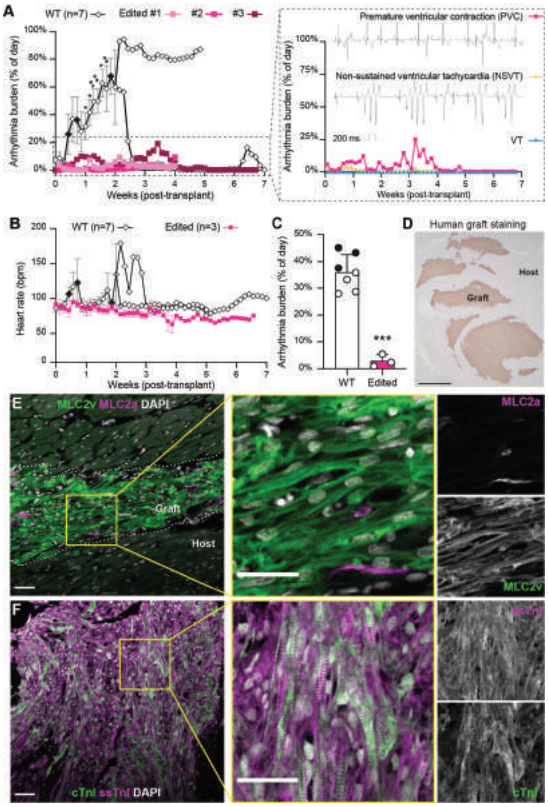

Figure. Edited PSC-CM do not cause significant arrhythmia following transplantation in minipig. (A-C) Arrhythmia burden and heart rate of minipigs following transplantation of edited PSC-CM. Black symbol denotes mortality/euthanasia due to unstable arrhythmia. Inset showing quantification of PVC, NSVT and VT burden in edited subject #3. **(D)** Representative edited PSC-CM graft at 7-weeks post-transplant, stained with human-specific β-myosin heavy chain. Scale bar = 1 mm. **(E, F)** Low and high magnification immunofluorescence images of edited PSC-CM grafts 4 weeks post transplantation marked by MLC2v/MLC2a and ssTnI/cTnI staining. Dotted lines indicate host/graft interface. Scale bars = 50 μm for low magnification; 20 μm for high magnification.

285 Engineering Stage-Specific Developmental Cues to Generate Non-Allogenic, iPSC-Derived CAR T Cells for Immunotherapy

Sang Pil Yoo[1], Claire Engstrom[1], Suwen Li[1], Patrick Chang[1], Xuegang Yuan[1], Ralph Valentine Crisostomo[1], Christopher S. Seet[2], Donald B. Kohn[1], Gay M. Crooks[1]

[1]UCLA, Los Angeles, CA,[2]Department of Medicine, UCLA Health, Los Angeles, CA

Introduction: Though chimeric antigen receptor (CAR) T cell therapy has produced remarkable results in treatment-refractory malignancies, the manufacturing process is challenging due to *de novo* generation of each therapy and variability in T cell phenotypes. A potential solution to this problem is the generation of CAR T cells *in vitro* from an infinitely renewing, allogeneic source of human pluripotent stem cells (hPSCs). There are two critical barriers to generating CAR T cells from hPSCs: 1. Expression of certain CAR transgenes early in T cell differentiation diverts development towards the innate lymphoid pathway instead of the conventional T lineage. 2. Removal of the endogenous T cell receptor (TCR) to prevent alloreactivity blocks development, as maturing T cells can no longer undergo positive selection. We addressed these barriers by deploying both an innovative gene editing strategy that allows stage-specific expression of transgenes, and a novel *in vitro* method to induce differentiation of mature conventional T cells. **Results:** The Artificial Thymic Organoid (ATO) is an *in vitro* method for generating mature, single positive (SP) CD8+ and SP4+ T cells from multiple stem cell sources including iPSCs. The ATO's ability to support positive selection from CD4+CD8+ (DP) precursors results in the robust production of mature, conventional T cells which carry a diverse repertoire of TCR expression on the cell surface (Fig 1A). We established a CRISPR-based gene editing strategy to achieve stage-specific expression of biologically active transgenes (e.g. CARs). Using this approach, we have shown: 1. Conventional T lineage production was blocked when a 2nd-gen CD19 CAR was expressed throughout differentiation. However, when the same CAR was placed under the control of the endogenous Granzyme A *(GZMA)* promoter, normal T cell differentiation in ATOs was unperturbed and mature, naïve CD45RA+CD62L+CD8α+CD8β+ CAR T cells were generated from T-iPSCs (Fig 1C). *GZMA* is expressed only in SP8/SP4 T cell and absent in earlier T stages. Resulting iPSC-derived CAR T cells

demonstrated antigen-specific cytokine response and proliferation. 2. To address alloreactivity, we ablated surface TCRαβ/CD3 expression by disrupting the T cell receptor alpha chain constant *(TRAC)* region (Fig 2A). We restored positive selection by transiently expressing an exogenous TCR driven by the *RAG1* promoter. *RAG1* is expressed during the double negative (DN) through double positive (DP) T cells but absent in SP8/SP4 T cells (Fig 1B). Thus, expression of the transgenic TCR occurred only during the critical period of positive selection (DP stage) and was absent after SP8/SP4 maturation (Fig 2B). In conjunction with CAR expression via *GZMA*, we thus generated mature, naïve TCRαβ-CD3- CAR T cells from T-iPSCs (Fig 2C). **Conclusion:** The developmental blocks that can occur during T cell differentiation from iPSCs as a result of genetic manipulation of CAR/TCR expression can be overcome through CRISPR-mediated, stage-specific expression of transgenes.

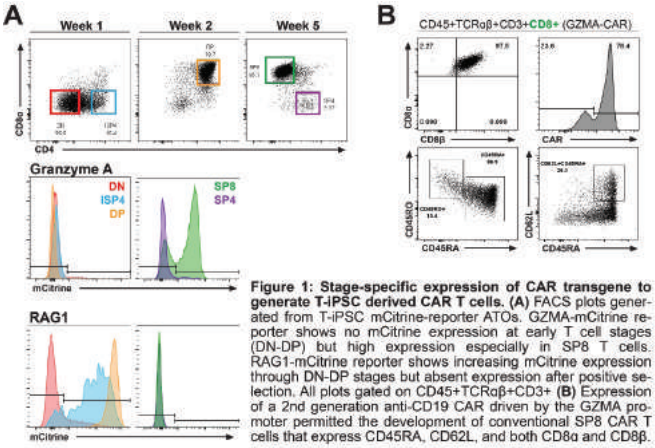

Figure 1: Stage-specific expression of CAR transgene to generate T-iPSC derived CAR T cells. (A) FACS plots generated from T-iPSC mCitrine-reporter ATOs. GZMA-mCitrine reporter shows no mCitrine expression at early T cell stages (DN-DP) but high expression especially in SP8 T cells. RAG1-mCitrine reporter shows increasing mCitrine expression through DN-DP stages but absent expression after positive selection. All plots gated on CD45+TCRαβ+CD3+ **(B)** Expression of a 2nd generation anti-CD19 CAR driven by the GZMA promoter permitted the development of conventional SP8 CAR T cells that express CD45RA, CD62L, and both CD8α and CD8β.

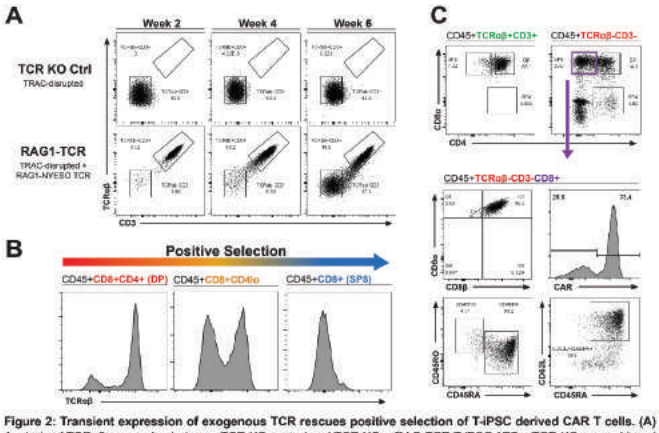

Figure 2: Transient expression of exogenous TCR rescues positive selection of T-iPSC derived CAR T cells. (A) Analysis of TCRαβ expression between TCR KO control and TCR KO + RAG-TCR T-iPSC ATOs. TCR KO was achieved by disrupting *TRAC* exon 1. All plots gated on CD45+. **(B)** Analysis of TCRαβ downregulation in TCR KO + RAG-TCR T-iPSC ATOs at week 6. As DP T cells undergo positive selection, TCRab and CD3 are downregulated and remain absent. **(C)** Analysis of SP8 CAR T cells from TCR KO + RAG-TCR + GZMA-CAR T-iPSCs at week 6. After positive selection, TCRαβ is downregulated and CAR is expressed using the GZMA promoter. Fully matured, TCRαβ -CD3- SP8s express naïve makers CD45RA, CD62L, conventional T markers CD8α, CD8β, and the 2nd generation anti-CD19 CAR.

286 Electrophysiological Maturation of Human Pluripotent Stem Cell-Derived Cardiomyocytes *via* Gene Editing

Silvia Marchiano[1], Kenta Nakamura[1], Hans Reinecke[1], Lauren Neidig[1], Michael Lai[2], Filippo Perbellini[2], Shin Kadota[3], Xiulan Yang[1], Jordan M. Klaiman[1], Lesley P. Blakely[1], Paul Fields[1], Elaheh Karbassi[1], Aidan Fenix[1], Lil Pabon[1], Lili Wang[4], Bjorn Knollmann[4], R. Scott Thies[2], Steven Kattmann[2], Nathan Sniadecki[1], W. Robb MacLellan[1], Alessandro Bertero[5], Charles E. Murry[6]

[1]University of Washington, Seattle, WA,[2]Sana Biotechnology, Seattle, WA,[3]Department of Regenerative Science and Medicine, Shinshu, Japan,[4]Vanderbilt University School of Medicine, Nashville, TN,[5]University of Turin, Torino, Italy,[6]UW Medicine, Seattle, WA

Background: Automaticity, or the ability to spontaneously depolarize and fire action potentials (APs), characterizes the electrophysiological phenotype of human pluripotent stem cell-derived cardiomyocytes (hPSC-CMs), immature fetal CMs and mature pacemaker cells. The ion channels regulating AP formation are best understood in sinoatrial node CMs; however, whether those mechanisms apply to hPSC-CMs remains controversial. Moreover, arrhythmogenicity of transplanted hPSC-CM is a major barrier to safe clinical development of cardiac remuscularization therapy. We hypothesized that the hPSC-CMs' automaticity is modulated by developmentally regulated ion channel genes, and moreover, that genetic manipulation of these channels will result in hPSC-CMs that are quiescent-yet-excitable and thus safe for therapeutic use. **Methods:** To promote hPSC-CMs maturation we transplanted GCamP3-labeled hPSC-CMs into infarcted rat hearts as well as cultured them in vitro for up to 1 year. GCamP3-labeled graft were then isolated with laser-capture microdissection and we performed bulk RNAseq on both *in vivo* and *in vitro* samples at different time points. We analyzed the expression kinetics of all ion channels and used these to guide our CRISPR-Cas9 screening of ion channels involved in automaticity. **Results:** HPSC-CMs transplanted *in vivo* matured faster compared to *in vitro* long-term cultures, and the changes in genes involved in AP regulation reflect the presence of automaticity in immature hPSC-CMs. An extensive CRISPR screen revealed that the removal of pacemaker currents encoded by the genes *HCN4* and *CACNA1H*, the additional knockout of *SLC8A1* (encoding NCX1) and the addition of the hyperpolarizing potassium current I_{K1} (*KCNJ2*) yielded hPSC-CMs that are quiescent-yet-excitable. When transplanted *in vivo*, this quiescent-yet-excitable cell line electrically integrated with the host myocardium and beat in synchrony without inducing malignant arrhythmias. **Conclusion:** Systematic screening of ion channels revealed that automaticity in hPSC-CMs relies on both Ca^{2+} trafficking and voltage-membrane regulation. This study supports the concept that electrophysiological maturity of hPSC-CMs can be engineered through gene editing and be applied to cardiac remuscularization therapy.

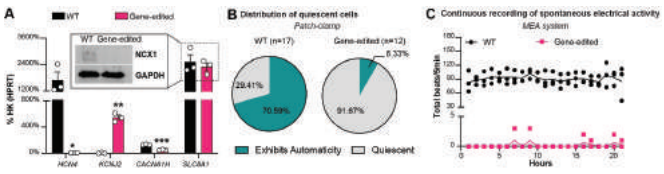

Figure 1. (**A**) RTqPCR and WB of ion channels targeted to remove automaticity in hPSC-CMs. (**B, C**) Patch-clamp and Multi-Electrodes Array (MEA) analysis showing decreased automaticity in gene-edited hPSC-CMs.

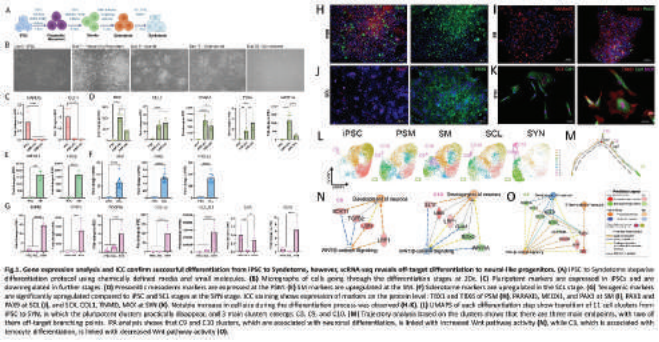
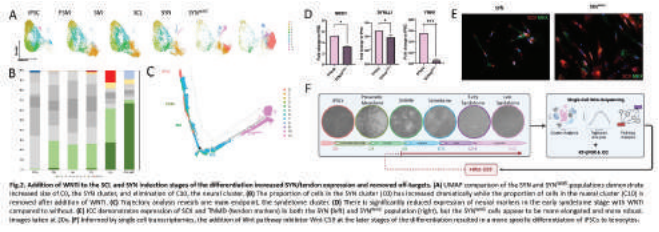
287 Induced Human Pluripotent Stem Cells Differentiation to Syndetome Informed by Single Cell Analysis

Victoria Yu, Angela Papalamprou, Wensen Jiang, Julia Sheyn, Tina Stefanovic, Melissa Chavez, Angel Chen, Chloe Castaneda, Dmitriy Sheyn

Regenerative Medicine Institute, Cedars-Sinai Medical Center, Los Angeles, CA

Tendon injuries contribute to 45% of musculoskeletal consultations in the US alone and can be attributed to tendons' poor innate healing capacity. Besides invasive surgical intervention, to date there is no consensus on a biological or pharmacological approach for the healing process that is clinically practical. Bone marrow mesenchymal stromal cells and adipose stem cells have been explored as potential cell therapies, but they have limited self-renewal capacity and phenotypic heterogeneity. iPSCs have potential because they do not have these limitations. To date, there are very few protocols for tenogenic differentiation from human iPSCs, largely in part to the limited understanding of tendon development origins and how they differentiate from precursors. We sought to investigate a method of differentiation from human iPSCs to tenocytes that is more efficient and specific. Human iPSC lines were differentiated to Syndetome (SYN) in a stepwise manner through the presomitic mesoderm and somite (Fig1a). Successful differentiation was confirmed through significant upregulation or downregulation of known marker genes that characterize each step, along with IF (Fig1B-K). For further characterization, single cell RNA-sequencing (scRNA-seq) was conducted. From scRNA-seq analysis, we identified 11 distinct cell clusters (C0-C10), with clusters C3, C9, and C10 dominating the SYN stage (Fig1L). C3 expressed tenocyte markers, whereas C9 and C10 expressed neuronal markers. Trajectory analysis revealed that C3 is the main differentiation endpoint, but C9 and C10 in the later stages have branching off-target differentiation endpoints (Fig1M). IPA analysis shows that C9 and C10 can be characterized by increased Wnt activity leading to neuronal differentiation, whereas C3 shows decreased Wnt activity leading to tenocyte differentiation (Fig1N-O). Because Wnt family members were identified as being crucial in the generation of neural by-products, the addition of a Wnt pathway inhibitor Wnt-C59 (WNTi) was added to the later stages of the differentiation (Fig2A). ScRNA-seq post WNTi treatment revealed that the addition of WNTi not only dramatically increased the SYN population but also eliminated the side-products, resulting in a more specific cell population differentiating towards the tenogenic lineage (Fig2). In this study, we successfully differentiated iPSCs to tenocytes in a stepwise manner. ScRNA-seq trajectory analysis revealed off-target differentiation because of Wnt pathway activity. The addition of WNTi was used to address this, and further transcriptomics confirmed decreased off-target products and increased SYN/tendon specificity and efficiency. Elucidating the mechanism of the Wnt signaling pathway using a development-inspired protocol can lead to more powerful and specific differentiation protocols for cell therapy applications. iPSC-derive tendon progenitors can be an off-the-shelf cell source to tendon injuries that are currently untreatable or have poor surgical outcomes.





288 Microglia Replacement with Bone Marrow-Derived Cells after Transient Inhibition of the Colony-Stimulating Factor 1 Receptor (CSF1R) is Superior to Standard Myeloablative Conditioning in Neuropathic Lysosomal Storage Diseases

Pasqualina Colella, Maria Valentina Suarez-Nieto, Ruhi Sayana, Edina Poletto, Luisa Natalia Pimentel Vera, Jessica Arozqueta Basurto, Natalia Gomez-Ospina

Stanford University, Palo Alto, CA

Allogeneic hematopoietic stem cell transplantation (HSCT) is the standard of care for several neurometabolic diseases. Recently, autologous transplantation of gene-modified hematopoietic stem and progenitor cells (HSPCs) showed significant benefits in clinical studies for severe leukodystrophies and neuropathic lysosomal storage diseases. The therapeutic effect of HSCT for these diseases relies on the ability of transplanted HSPCs to durably reconstitute the hematopoietic system and repopulate solid organs as tissue-resident myeloid cells in recipients pre-conditioned with myeloablative doses of Busulfan. The transplant of either donor-derived HSPCs or autologous gene-modified/edited HSPCs represents a promising approach to providing healthy cells and cross-correcting protein deficiencies in many neurologic and neurometabolic diseases. Despite advances in autologous approaches, the slow-paced and modest central nervous system (CNS) repopulation by bone marrow-derived cells remains

a key limitation to adequately address severe, rapidly progressing neurological diseases requiring prompt intervention. To address these limitations, we developed a novel conditioning regimen that enables fast, robust, and stable engraftment of HSPC-derived microglia-like cells in the CNS. The regimen combines Busulfan and PLX3397, a CSF1R inhibitor, which specifically depletes microglia/macrophages. In transplants of C57BL/6 mice with bone marrow (BM) from CAG:GFP/GFP mice, the combined regimen resulted in a 15-fold increase in the fraction of BM-derived GFP+ microglia-like cells in the brain compared to Busulfan alone (89±5% vs. 6±2.4% at 3 months, 86±4% vs. 23±17% at 7 months). The novel regimen also significantly accelerated the repopulation of the CNS. At early time points after BM transplant, the brain GFP+ fraction remained low with Busulfan (2.9±0.7%, 40 days) while it was substantial at 28 days (31±19%) and peaked at 40 days (92.7±1.5%) with PLX3397. Single-cell RNA-seq of brain-engrafted BM-derived and host CD45+CD11b+ cells showed tissue-specific cell signatures and a predominant homeostatic microglia-like phenotype. Normal hematopoietic reconstitution, neurobehavior, and the absence of brain inflammation confirmed that PLX3397 has no added toxicities. The addition of PLX3397 in xenogeneic transplants of human genome-edited CD34+ HSPCs in immunocompromised mice resulted in human cell chimerism in the brain without affecting their bone marrow engraftment or differentiation. To examine the combined regimen's potential in disease treatment, we used it to condition a mouse model of Mucopolysaccharidosis type I-Hurler (B6.129S Idua-W392X). We observed increased brain donor chimerism (3-fold) which resulted in a 4-fold increase in biochemical correction compared to Busulfan alone, confirming the superiority of this approach. Our findings provide comprehensive proof-of-concept of the efficiency and safety of a novel conditioning regimen to improve the efficacy and widen the application of HSCT for neurometabolic and neurological diseases.

289 Constitutive IL-7 Receptor (C7R) Signaling Enhances the Persistence of EBV-Specific T-cells

Sandhya Sharma, Thomas Shum, Bilal Omar, Cliona M. Rooney

Baylor College of Medicine, Houston, TX

Background: Almost 30% of Hodgkin's and Non-Hodgkin Lymphoma (HL and NHL) patients carry the Epstein-Barr Virus (EBV) genome in a type-2 latency state characterized by the expression of 4 viral type-2 latency antigens (T2-Ags)- EBNA1, LMP1, LMP2 and, BARF-1. Our lab and various others have used T-cells specific against these T2-Ags to target EBV-positive lymphoma with promising results in both autologous and allogeneic settings. However, there are challenges to enhancing the efficacy of EBV-specific T-cells (EBVSTs), including a lack of T-cell functional persistence in the suppressive tumor microenvironment (TME), attributed to a lack of cytokine support in-vivo. Interleukin-7 (IL-7), has both growth-promoting and anti-apoptotic effects on T-cells. However, limited IL-7 availability and downregulation of the IL-7 receptor in activated T-cells limit IL-7 signaling in-vivo. We previously showed that transgenic expression of a constitutively active IL-7 receptor (C7R) enhanced the persistence and anti-tumor efficacy of chimeric antigen receptors (CAR) T-cells in neuroblastoma and glioma xenograft murine model. Hence, we **hypothesized** that EBVSTs expressing constitutively active IL-7 receptor (C7R) to enable cytokine-independent proliferation will have increased persistence and potency in EBV+ malignancies. **Methods:** Expression of C7R was achieved by retroviral transduction of EBVSTs, which were further expanded with peptide libraries and cytokines to generate C7R-EBVSTs and unmodified EBVSTs. On day 16 post-expansion, EBVSTs were evaluated for their proliferation, antigen specificity and further in-vitro characterization. For in-vivo studies, we subcutaneously established EBV-transformed lymphoblastoid cell line (LCL) in NSG mice. EBVSTs were infused iv once the tumor reached a volume of ~130 mm^3. **Results:** EBVSTs expressing C7R (65%±25% transduction, n=6), were generated with stable specificity for T2-Ags (5064±2988 vs. 4683±2134 SFCs per 10^5EBVSTs) using an IFNg ELISpot assay; C7R-EBVSTs vs. unmodified EBVSTs). C7R-EBVSTs demonstrated antigen-specific cytotoxicity as measured by chromium release assay, enhanced STAT5-signaling (STAT5 MFI of 778±66 vs. 139±9 as measured by flow cytometric analysis) and enhanced in-vitro persistence in cytokine-starved cultures (35±2 days vs. 16±3 days for unmodified EBVSTs). C7R enhanced EBVST proliferation and decreased the frequency of Annexin V positive cells (indicating fewer apoptotic cells) in C7R-EBVSTs compared to unmodified EBVSTs when cultured in presence of TGF-beta, an immunosuppressive component of TME (14±2% vs. 26±3%. % Annexin V+ T-cells, n=3). In our murine model, mice receiving C7R-T2-EBVSTs cleared tumor by day 60, compared to day 240 ± 62 mm^3in response to unmodified EBVSTs; $p<0.000$, n=5/group). C7R-T2-EBVSTs also demonstrated enhanced persistence (67 days vs. 27 days for unmodified T2-EBVSTs). **Conclusion:** We successfully generated C7R-EBVSTs, which demonstrated enhanced antigen specificity and potency in-vitro and in-vivo. C7R provided protective effects against TgFb, an immunosuppressive component of the TME. Finally, the demonstration of enhanced T-cell persistence and potency along with enhanced STAT5 signaling provides a clinically translational platform. We are currently in the process of translating our findings to a phase I/II clinical trial against EBV-associated malignancies.

290 Stomach-Derived Human Insulin-Secreting Organoids for Diabetes Cell Therapy

Joe Qiao Zhou

Weill Cornell Medical College of Cornell University, New York, NY

A leading strategy to reverse β-cell loss in Type 1 diabetes (T1D) and advanced T2D to achieve long-lasting normoglycemia is the transplantation of functional insulin-secreting cells. To overcome the shortage of human cadaveric islets, multiple approaches were developed to produce insulin-secreting organoids that mimic human islet function. We established a new technology for scalable production of pancreatic islet-like organoids from biopsy-derived human gastric stem cells (hGSCs) (manuscript under review at *Nature Cell Biology*, article available online at https://www.biorxiv.org/content/10.1101/2022.12.15.520488v1). These organoids contain gastric insulin-secreting (GINS) cells that resemble pancreatic β-cells and able to stably and durably reverse diabetes after transplantation. hGSC cultures can be reliably established from pinhead-sized tissues and expanded to 10^9 cells within 2 months, enabling both allogenic and autologous cell products. After sequential activation of the inducing factors NGN3 and PDX1-MAFA, hGSCs transitioned through a $SOX4^{High}$ endocrine and

a GAL^{High} GINS precursor before adopting the β-cell fate at efficiencies close to 70%. GINS cells were aggregated into islet-like organoids and acquired glucose-stimulated insulin secretion (GSIS) 10 days post differentiation. Notably, glucose-responsive GINS organoids can be produced from multiple donors. Moreover, GINS organoids responded to repeat glucose challenges as well as to the clinical anti-diabetes drugs Glibenclamide, Diazoxide, and GLP-2 analogues. scRNA-seq revealed that GINS organoids contained four endocrine cell types that closely resembled the four major human islet cells, namely, β-, α-, δ-, and ε-cells. Consistent with their functional competence, GINS cells expressed key genes involved in β-cell identity, metabolism, insulin synthesis and secretion, and ion channel activities. To characterize GINS cells in vivo, we transplanted GINS organoids under the kidney capsule of immune-compromised NSG mice. The grafts could live for more than 6 months and contained abundant insulin^{+} cells. Transplantation of 6 million GINS cells into STZ-induced diabetic mice rapidly reversed hyperglycemia and maintained glucose homeostasis for over 100 days until graft removal. Glucose tolerance was normalized in the rescued mice. We examined over 30 GINS grafts from one to six months post transplantation and found no evidence of EdU^{+} or Ki67^{+} proliferating cells, indicating that GINS organoids pose minimal tumorigenic risk. In summary, human GINS organoids have significant favorable attributes as a cell therapy product for insulin-dependent diabetes: (1) very low tumorigenic risk, (2) consistent and simple 3-step induction protocol, and (3) rapid acquisition of functionality in vitro. Ongoing work is focused on simplifying the manufacturing process and enhancing autoimmune resistance in the T1D setting.

Cell Therapy Product Engineering and Development | Non-Cancer

298 Immune Profiling of Respiratory Syncytial Virus (RSV) for the Development of Targeted Immunotherapy

Penelope Georgia Papayanni, Kiriakos Koukoulias, Manik Kuvalekar, Ayumi Watanabe, Yovana Velazquez, Carlos A. Ramos, Ann M. Leen, Spyridoula Vasileiou

Center for Cell and Gene Therapy, Baylor College of Medicine, Texas Children's Hospital and Houston Methodist Hospital, Houston, TX

Background: RSV-associated respiratory viral infections are a major public health problem affecting the immunologically naïve/compromised population. For example, RSV-induced bronchiolitis and pneumonia are the leading cause of hospitalization in infants and young children worldwide, while in adult allogeneic hematopoietic stem cell transplant (HCT) recipients mortality rates as high as 80% have been reported in those in whom infections progress from the upper to the lower respiratory tract (LRTI). At the national level, the current (2022-23) RSV surge has resulted in a sharp rise in hospitalization rates, surpassing last year by almost 3-fold (https://www.cdc.gov/rsv/research/rsv-net). Our group has previously demonstrated the feasibility, safety and clinical efficacy of administering allogeneic ex vivo expanded multivirus-specific T cells (multi-VSTs) as a banked, off-the-shelf product for the treatment of EBV, CMV, BKV, HHV6, AdV and SARS-CoV-2 infections/disease in immunocompromised individuals. Given the RSV-associated morbidity and the paucity of preventative or therapeutic agents, we sought to characterize the cellular immune responses to RSV with a view to developing a targeted T-cell therapy product for those at highest risk of severe disease. **Methods:** To first identify immunogenic and protective RSV antigens we exposed PBMCs from healthy donors to pepmixes (overlapping peptide libraries) spanning the 11 RSV-encoded antigens of which 2 [Nucleoprotein (N) and Fusion (F)] were identified as immunodominant and advanced for VST manufacturing. We subsequently utilized our optimized VST manufacturing process and culture in a G-Rex device in medium supplemented with activating cytokines to generate RSV-specific VSTs (RSV-VSTs) with activity against these immunodominant targets. **Results:** We achieved a mean 5.2±1-fold increase in cell numbers (mean±SEM; n=13) that were comprised of CD3+ T cells (94.1±1.2%), with a mixture of cytotoxic (CD8+; 28.9±5.2%) and helper (CD4+; 71.1±5.2%) cells. These cells had a phenotype consistent with effector function and memory potential, as evidenced by upregulation of the activation markers CD25, CD69, and CD28 and expression of central (CD45RO+/CD62L+) and effector memory markers (CD45RO+/CD62L-) with minimal PD1, Tim3 or LAG3 expression. The antiviral activity of the expanded cells was confirmed by IFNγ ELISpot and all 13 lines proved to be reactive against the target antigens (N: 3587±939 SFC/2x10^{5}; F: 3526±743). As demonstrated by surface and intracellular flow cytometry, both CD4+ and CD8+ T cell subsets exhibited antiviral properties via IFNγ/TNFα production and upregulation of activation/costimulatory markers. Reactive cells were polyfunctional and primarily Th1-polarized as evidenced by IFNγ, Granzyme-B, IL-2 and GM-CSF production measured by FluoroSpot and Luminex array. Finally, the expanded cells were able to kill viral pepmix-loaded autologous PHA blasts with minimal/no activity against non-antigen-expressing autologous and allogeneic targets. **Conclusion:** Healthy donor-derived RSV-VSTs are Th1-polarized, polyfunctional and selectively able to kill viral antigen-expressing targets with no auto- or alloreactivity, indicative of their safety for clinical use. A clinical trial evaluating their use in HCT recipients as part of an off-the-shelf multi-respiratory virus-directed product is currently underway (NCT04933968, https://clinicaltrials.gov).

299 Co-Engineering Synthetically Programmed Cells and Biomaterials for Regenerative Medicine

Joanne Lee[1], Hannah Brien[1], Bonnie Walton[1], Zachary Eidman[1], Satoshi Toda[2], Wendell Lim[3], Jonathan M. Brunger[1]

[1]Vanderbilt University, Nashville, TN,[2]Kanazawa University, Kanazawa, Japan,[3]University of California, San Francisco, San Francisco, CA

Introduction: A major objective of regenerative engineering is to overcome tissue degeneration and combat inflammation typical of pathologic states caused by injury, metabolic disorders, autoimmunity, and aging. One approach toward achieving these goals is delivery of biologic drugs, such as pro-inflammatory cytokine antagonists; however, the absence of means to reliably tune dosage leads to a compromise between treatment efficacy and adverse events. An alternative method is to transplant engineered tissue substitutes. One critical shortcoming of this approach is a lack of control over

transplanted cell behaviors. Here, we present a method combining cell engineering and biomaterial design to overcome such limitations. We leverage synthetic biology tools to create a customizable platform where cells engage materials to respond to dynamic features of the transplant niche with engineered, defined behaviors.**Materials and Methods:** Our system leverages the synthetic Notch (synNotch) receptor platform to program cellular responses to cues in their microenvironment. Like the native Notch receptor, synNotch is a juxtacrine receptor that regulates ligand-dependent transcriptional programs in cells. By exchanging Notch's extracellular domain with alternative recognition motifs and intracellular domain with synthetic transcription factors, we create synNotch receptors that produce user-specified sense/response behaviors. Since we can customize synNotch to drive expression of any transgene, we can tune defined cellular responses to selected orthogonal inputs, reducing crosstalk from native pathways. SynNotch, like native Notch, requires force on the order of piconewtons for activation. Thus, soluble monomeric ligands do not activate synNotch. We leveraged this feature to create biomaterials capable of capturing synNotch ligands, resulting in a privileged material:cell channel of communication, requiring co-localization of the engineered cell, the designer biomaterial, and the selected synNotch ligand. We termed our system MATRIX for material activated to render inducible expression. Here, we implemented MATRIX to enable engineered cells to respond to GFP, a bioinert cue, and activate cells for various regenerative functions.**Results and Discussion:** Deploying CRISPR epigenetic regulators could help modify the transcriptome in inflammatory environments. As a test of the potential for transcriptome modification, we used the MATRIX platform to potentiate effective knockdown of K-cadherin gene transcripts mediated by CasRx (Fig. 1A). Delivery of a TNF antagonist, soluble TNF receptor 1, initiated by MATRIX led to reduced inflammatory NF-κB pathway activation (Fig. 1B). Finally, MATRIX was able to induce pluripotent stem cells to differentiate into neurons as denoted by staining for the neuronal marker TUJ1 (Fig. 1C).**Conclusions:** The MATRIX platform is highly versatile with custom inputs and outputs. MATRIX represents an innovative approach to co-engineer cells and biomaterials for increased cellular and spatiotemporal control, as the requirement for co-localization of all components gates responses spatially. Continued development of the MATRIX platform will extend its capabilities into 3D hydrogels for eventual *in vivo* studies.

300 SEC-seq: Association of Molecular Signatures with Antibody Secretion in Thousands of Single Human Plasma Cells

Rene Yu-Hong Cheng[1,2], Joseph de Rutte[3,4], Cade E. K. Ito[5,6], Andee R. Ott[5], Lucie Bosler[3], Wei-Ying Kuo[3], Jessie Liang[3], Brian E. Hall[7], David J. Rawlings[5,8], Dino Di Carlo[3,4,9], Richard G. James[2,5,10]

[1]Seattle Children Research Institute, Seattle, WA,[2]Molecular Engineering and Science Institute, University of Washington, Seattle, WA,[3]Partillion Bioscience, Los Angeles, CA,[4]Department of Bioengineering, University of California - Los Angeles, Los Angeles, CA,[5]Center of Immunotherapy and Immunity, Seattle Children Research Institute, Seattle, WA,[6]Department of Lab Medicine and Pathology, University of Washington, Seattle, WA,[7]Luminex Corporation, Seattle, WA,[8]Department of Immunology, University of Washington, Seattle, WA,[9]Department of Mechanical and Aerospace Engineering, California NanoSystems Institute, Los Angeles, CA,[10]Brotman-Baty Institute for Precision Medicine, Seattle, WA

Protein secretion drives many functions in vivo; however, methods to link secretions with surface markers and transcriptomes have been lacking. By accumulating secretions close to secreting cells held within cavity-containing hydrogel nanovials, we demonstrate workflows to analyze the amount of IgG secreted from single human antibody-secreting cells and link this information to surface marker expression and transcriptional profiles from the same cells. Measurements using flow cytometry and imaging flow cytometry corroborated an association between levels of IgG secretion and CD138 expression. Using oligonucleotide-labeled antibodies and droplet-based sequencing, we show that pathways encoding protein localization to the endoplasmic reticulum, NADH complex assembly, and mitochondrial respiration were most associated with high IgG secretion. Altogether, this method links secretion information to cell surface and single-cell sequencing information (SEC-seq) and enables exploration of links between genome and secretory function. Our method lays the foundation for numerous discoveries in immunology, stem cell biology, and we envison applying this method to better engineer a cell therapy with high secretory therapeutic protein capacity.

301 Pancreatic Islet-Specific Engineered Treg Are Therapeutic in Mouse Models of Type 1 Diabetes

Travis Drow[1], Noelle Dahl[1], Ashley Landuyt[2], Hunter Kellog[2], Gene I. Uenishi[2], Akhilesh K. Singh[3], Peter J. Cook[1], David J. Rawlings[4]

[1]Seattle Childrens Research Institute, Seattle, WA,[2]GentiBio, Inc, Cambridge, MA,[3]Seattle Childrens's Research Institute, Seattle, WA,[4]University of Washington, Seattle, WA

Immunosuppressive regulatory T cells (Treg) have tremendous promise as a cell-based therapy for tissue-specific autoimmune disease. Importantly, antigen-specific Treg display greater therapeutic efficacy than polyclonal Treg in mouse models of autoimmunity. However, expansion of rare naturally occurring antigen specific Treg to clinical scale represents a major therapeutic challenge. To address this, we have devised strategies to generate antigen-specific engineered regulatory T cells (EngTreg) from CD4+ T cells using homology directed repair

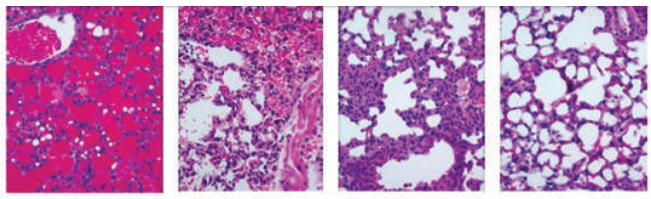
(HDR)-based gene-editing of the *FOXP3* and *TRAC* loci, enforcing constitutive expression of the endogenous *FOXP3* gene while simultaneously replacing the endogenous T cell receptor (TCR) with a defined autoantigen-specific TCR. In previous work, we showed that antigen-specific EngTreg exhibit robust in vitro and in vivo suppressive function and achieve these functions independently of epigenetic events required to retain *FOXP3* expression in sorted Treg. In the current study, as a key step towards clinical application, we describe modeling of antigen-specific EngTreg function in animal models of type 1 diabetes (T1D). Using CD4+ T cells derived from transgenic non-obese diabetic (NOD) mice expressing the BDC2.5 islet-specific TCR, we generated mouse-equivalent islet-specific EngTreg by performing HDR-based gene-editing of the mouse *Foxp3* locus, inserting a strong promoter immediately upstream of the first coding exon to drive constitutive *Foxp3* expression. We modelled T1D by adoptively transferring either islet-specific monoclonal BDC2.5+ T effector cells (Teff) or polyclonal diabetogenic Teff isolated from hyperglycemic NOD mice into immunodeficient NOD-*scid*-IL2rγ^{NULL} (NSG) mice and demonstrated that these cells track to the pancreas and drive T1D in a manner dependent on T cell dose and clonality. Next, using these models, we demonstrate effective therapeutic intervention with EngTreg at both prevention and treatment timepoints corresponding to pre-diabetic and established disease states, respectively. Adoptively transferred BDC2.5 EngTreg homed to the pancreas and preserved islet β-cell integrity and insulin secretion. These data highlight both the direct and bystander suppressive capacity of antigen-specific EngTreg in the context of preventing or treating T1D.

302 New Generation Trained Mesenchymal Stromal Cell Therapy for Treatment for Rare Autoimmune Diseases

Hulya Bukulmez[1], Adrienne Dennis[1], Jane Reese-Koc[2], Scott Sieg[3], Mark Chance[4], Steven N. Emancipator[5]

[1]Pediatrics, Pediatric Rheumatology, MetroHealth Medical Center, Case Western Reserve University, Cleveland, OH,[2]National Center for Regenerative Medicine, School of Medicine, Case Western Reserve University, Cleveland, OH,[3]CFAR Immune Function Core Laboratory, Department of Internal Medicine, School of Medicine, Case Western Reserve University, Cleveland, OH,[4]Center for Proteomics and Bioinformatics, School of Medicine, Case Western Reserve University, Cleveland, OH,[5]Department of Pathology, School of Medicine, Case Western Reserve University, Cleveland, OH

Background: Results from >100 clinical trials of cell therapy using untrained mesenchymal stem cells (MSCs) show that they are safe, but their clinical efficacy is variable.**Objectives:** We have developed a novel MSC-based cell therapy (HXB319) that potently reduces inflammation and halts organ damage. We show the efficacy of HXB319 in treatment of autoimmune diffuse alveolar hemorrhage (DAH).**Methods:** We engineered an MSC based cell therapy (HXB319) using a combination of cytokines and growth factors, and verified anti-inflammatory activity by flow cytometry, RT-PCR, and mass spectrophotometry. *In vivo* efficacy was assessed by treating autoimmune induced DAH in C57Bl/6 mice by intraperitoneal (IP) injection of pristane. Seven days later, some mice were treated with either MSCs or HXB319 (2X10^6 cells, ip). At sacrifice (day 14), peritoneal lavage fluid and lung tissue were sampled. **Results:** HXB319 cells showed significantly increased expression of anti-inflammatory genes (IDO and CD274), and markers of angiogenesis (CD146 and PDGFR-β). Protein pathway analysis showed significant upregulation of protein pathways that reduce inflammation (IL1RN, IDO), and fibrosis (with upregulation of HGF, c-MET signaling, while improving vascularization (VEGF). A pristane-induced, autoimmune, diffuse alveolar hemorrhage (DAH) model was utilized for proof-of-concept *in vivo* studies. In the DAH model, the mortality is typically above 75% beyond 14 days after pristane injection. *When delivered in vivo,* HXB319 reduced lung inflammation and significantly reduced alveolar hemorrhage (27.2%) vs. naked MSC treatment (75%) (Fig.1).



DAH DAH-MSC DAH-HXB319 C57B/6

Fig.1: Representative H and E staining of the pristane induced DAH model lungs, 20 x magnification

Pulmonary gene expression of IL-6, and serum IL-1 beta levels were only significantly reduced by HXB319 at day 14. Peritoneal lavage from mice treated with HXB319 showed reductions in total cells recovered, neutrophils, monocytes and NK cells compared to mice given MSCs or untreated DAH mice, but only the reduction in neutrophils was statistically significant (Table 1). Treatment with HXB19 cells significantly decreased the proportion of RORγT cells (Th17) in both CD4+ and CD8+ populations, and significantly increased the proportion of FoxP3+ cells among CD4+ cells (Tregs). Moreover, the proportion of CD4+ cells double-positive for RORγT and FoxP3 was significantly reduced.

Table 1: Splenocyte cell sorting

Cell Population	C57B/6	DAH	DAH-HXB319	DAH-MSC
PMN[a]	0.004 ± 0.001	0.53 ± 0.05*	**0.29 ± 0.10***	0.69 ± 0.10*
NK cells[a]	0.02 ± 0.01	0.10 ± 0.02*	0.05 ± 0.01	0.12 ± 0.03*
CD4$^+$ RORγT^{+c}	59.0 ± 0.66	83.3 ± 1.38*	75.0 ± 2.2*	77.8 ± 1.8*
CD8$^+$ RORγT^{+c}	59.7 ± 1.57	92.3 ± 0.78*	82.3 ± 3.4*	86.9 ± 2.0*
CD4$^+$ FoxP3^{+c}	0.29 ± 0.04	0.46 ± 0.67*	0.94 ± 0.15*	0.87 ± 0.10*
FoxP3$^+$ / RORγT^{+d}	0.48 ± 0.07	0.56 ± 0.09	1.27 ± 0.05*	1.14 ± 0.15*

Conclusions: Novel HXB319 cell therapy, phenotypically engineered to control inflammation, is a potent anti-inflammatory, anti-fibrotic, and angiogenic allogeneic cell therapy. A single dose may suppress severe autoimmune disease activity, such as pulmonary hemorrhage.

303 Human Chimeric Antigen Receptor-Mesenchymal Stem Cells (CAR-MSCs) Display Enhanced Trafficking and Immunosuppressive Efficacy

Olivia Sirpilla, R. Leo Sakemura, Saad Kenderian
Mayo Clinic, Rochester, MN

Allogeneic mesenchymal stromal cells (MSCs) are widely studied for their potential as a cell therapy treatment for autoimmune diseases due to their inherent homeostatic capabilities in the body. Although clinical trials have demonstrated the safety of MSC therapy, their therapeutic efficacy in autoimmune disease treatment remains insufficient due to two major limitations: **1)** poor **trafficking** of MSCs to target tissues and **2)** suboptimal i**mmunosuppressive** activity by MSCs following their ex vivo culture. We hypothesized that chimeric antigen receptor mesenchymal stromal cells (CAR-MSCs) could be created for the treatment of autoimmune disease based on CAR construct design. Here, we predicted that trafficking could be improved by a **1) single chain variable fragment** (scFv) designed for binding to target tissues of interest fused to **2) intracellular signaling domains** designed to promote immunosuppressive enhancement of MSCs. As a proof of concept for CAR-MSC therapy, we created CAR-MSCs directed to E-cadherin (Ecad) expressed on epithelial colon tissues susceptible to immune cell attack especially in etiologies such as graft-vs-host disease (GvHD) and irritable-bowel-disease. We hypothesized that anti-Ecad CAR-MSCs (EcCAR-MSCs) with human and mouse Ecad cross-reactivity and a CD28ζ intracellular signaling domain would induce trafficking and antigen-specific immunosuppression at these inflammatory target tissues. We transduced CAR into adipose-derived MSCs via lentiviral vector enhancement creating CAR-MSCs and tested both their immunosuppressive capabilities and trafficking to the colon *in vivo*. To test CAR-MSC **immunosuppressive efficacy**, GvHD xenograft models were induced via intravenous injection of human peripheral blood mononuclear cells into NOD-SCID-$\gamma^{-/-}$ mice. Mice were treated by intraperitoneal injection of CAR-MSC, untransduced (UTD-MSC), or vehicle control. We found that CAR-MSC treatment in these mice prevented their weight loss (**a**), decreased their clinical GvHD score (**b**), increased human T cell suppression (**c**) pushed T cells towards a Treg-like phenotype (**d**), and improved overall survival as compared to controls (**f**). Antigen-specific stimulation of CAR-MSCs were evaluated by RNAseq analysis of stimulated and unstimulated CAR-MSCs and UTD-MSCs. Here, a distinct upregulation of immunosuppressive gene signatures was found in Ecad stimulated CAR-MSCs only (**g**). Finally, study the impact of scFv specificity on the **trafficking** and treatment efficacy of CAR-MSCs, we employed our GvHD xenograft model and compared the effects of Luciferase^{+} CAR-MSCs with a randomized control scFv to our anti-Ecad scFv CAR-MSCs. We found that anti-Ecad CAR-MSCs led to a significant prevention of GvHD induced weight loss (**h**) and that CAR-MSCs with an anti-Ecad scFv preferentially trafficked to the colon in our mouse models (**i**). In summary, our findings introduce CAR-MSCs as a novel therapeutic platform to enhance MSC antigen-specific immunosuppression and trafficking for improved treatment outcomes in GvHD and other autoimmune diseases.

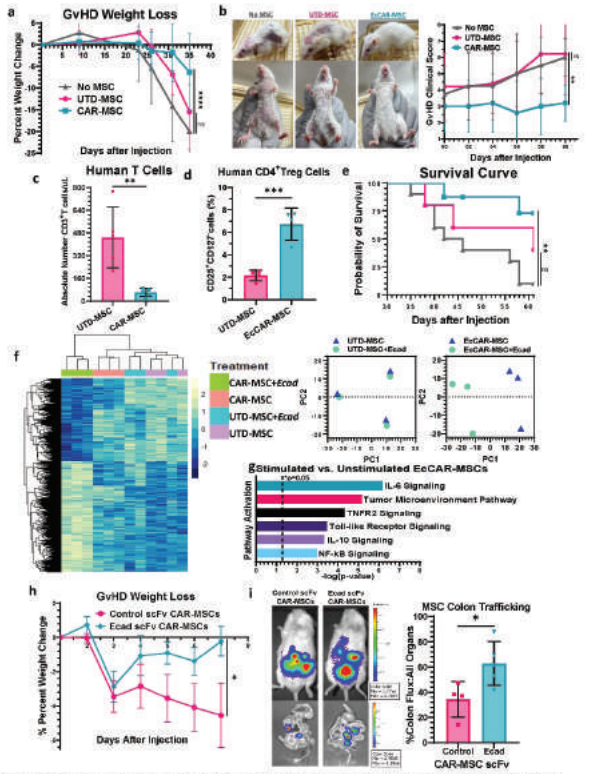


Fig. 1| CAR-MSC vs. UTD-MSC treatment in GvHD mouse model induced by human PBMCs injection into NSG mice displaying **a)** %bodyweight loss across treatment groups **b)** Clinical GvHD scoring across groups with symptoms including diarrhea, posture, activity, fur and skin integrity **c)** Number of human CD3^{+} T cells/uL in the peripheral blood of CAR-MSC vs. UTD-MSC treated mice **d)** %CD4^{+}CD25^{+}CD127^{-} T cells identified in cell populations **e)** Survival outcomes across GvHD treatment groups **f)** Gene expression profiles by RNAseq of stimulated and unstimulated CAR-MSCs vs. UTD-MSCs where UTD-MSCs cluster by MSC donor, while CAR-MSCs cluster by stimulation status. **g)** Gene set enrichment analysis of stimulated vs. unstimulated CAR-MSCs **h)** %bodyweight loss across mice receiving Luciferase^{+} anti-Ecad scFv CAR-MSCs vs. random control scFv CAR-MSCs with **i)** CAR-MSC flux ratio of trafficking to the colon. (ns=p≥.05, *p≤.05, **p≤.01, ***p ≤ .001, ****p≤.0001 by t-test, ANOVA, or Kaplan survival analysis, n≥3 MSC donors)

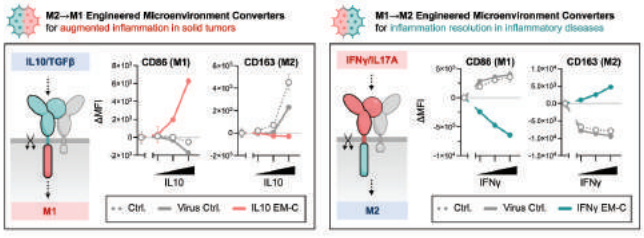
304 Engineered Microenvironment Converters (EM-Cs): Macrophages Expressing Synthetic Cytokine Receptors Rebalance Pro-/Anti-Inflammatory Signals in Disease Microenvironments

David Christopher Sloas, Yuhao Huangfu, Rehman Qureshi, Michael Ball, Thomas Condamine, Michael Klichinsky, Yumi Ohtani
Carisma Therapeutics, Philadelphia, PA

Background: Cytokines mediate the balance of pro- and anti-inflammatory signals in tissue microenvironments. Dysregulated or imbalanced cytokine expression supports numerous diseases by promoting deleterious immunosuppression or inflammation. As examples, anti-inflammatory cytokines found in solid tumors suppress immune activation and safeguard the tumor, whereas pro-inflammatory cytokines in fibrotic tissues drive chronic inflammation. Rebalancing inflammation/immunosuppression by rectifying cytokine signals thus offers a flexible strategy for treating many diseases. However, doing so through traditional cytokine blockades is besieged by safety risks due to systemic effects. Macrophage-based immunotherapies instead offer the potential to localize to diseased environments, detect pathogenic cytokines, and proportionately rebalance inflammation as needed. Here,

we engineered macrophages with synthetic cytokine switch receptors (SR) to develop a cell therapy platform for modulating pro-/anti-inflammatory signals. Macrophages are homeostatic regulators capable of initiating and resolving inflammation, and we leveraged this natural proficiency using SRs that convert tumor-related immunosuppressive (M2) signals into pro-inflammatory (M1) responses for tumor microenvironment (TME) modulation, or vice versa for inflammatory diseases. We termed this platform "Engineered Microenvironment Converters" (EM-C) and evaluated its modular ability to target several disease-associated cytokines. **Methods:** EM-Cs targeting IL10, TGFβ, IFNγ and IL17A were generated by expressing SR in primary human macrophages and monocytes. M2-to-M1 SR were designed to convert IL10 or TGF-β into pro-inflammatory stimuli, and M1-to-M2 SR were designed to IFNγ or IL17A into immunosuppressive signals. The in vitro response of EM-Cs to their target cytokine was monitored using phenotypic characterization of surface molecules, measurement of cytokine release, mRNA profiling, and biochemical analysis of downstream signaling. Co-culture assays with bystander cells were used to assess the ability of EM-Cs to alter their microenvironment. **Results:** Pro-inflammatory EM-Cs converted IL10 and TGFβ, two prevalent immunosuppressive cytokines in the TME, into pro-inflammatory signals by upregulating M1 markers, cytokines, and pathways in a dose-dependent manner. EM-Cs furthermore repolarized bystander M2 macrophages towards a pro-inflammatory phenotype following co-culture. Anti-inflammatory EM-Cs converted IFNγ and IL17A, two cytokines canonically overexpressed in inflammatory disease, by upregulating M2 markers and suppressing cytokines and pathways associated with chronic inflammation.**Conclusion:** We present a novel immunotherapy platform that harnesses macrophages as "living converters" to locally regulate cytokine imbalance for oncology and inflammatory applications. We demonstrate EM-Cs in the M2-to-M1 and M1-to-M2 direction, showcasing a modular ability to control the inflammatory status of microenvironments without systemic cytokine antagonism.



Gene Targeting and Gene Correction: Hemoglobin, Muscle, and Eye

[1]NHLBI/NIH, Bethesda, MD,[2]Boston Children's Hospital, Boston, MA,[3]Jazan University, Jazan, Saudi Arabia,[4]CMB, St. Jude Children's Research Hospital, Memphis, TN,[5]St. Jude Children's Research Hospital, Memphis, TN,[6]MCCB, University of Massachusetts Chan Medical School, Worcester, MA

β-hemoglobinopathies are the most common monogenic disorders with significant morbidity and mortality. Elevated fetal hemoglobin (HbF) expression can mitigate the phenotype and CRISPR-Cas9 mediated editing of HbF repressors in autologous hematopoietic stem/progenitor cells (HSPCs) has emerged as a promising new therapeutic intervention. Early data from clinical trials targeting the +58 DNase region of the erythroid-specific enhancer of the *BCL11A* gene are promising, yet variability in the HbF response led us to speculate that combined editing of the +58 and +55 enhancers could maximize the effect. Combined editing with 3×NLS-SpCas9 protein and 2 sgRNAs in rhesus CD34+ HSPCs provided higher mean levels of HbF (81.9%) among erythroid progeny than single-edited (~55%) and non-edited control groups (18.3%) without affecting enucleation or colony-forming unit ability. Next, we transplanted 3 rhesus macaques with CD34+ HSPCs following combined editing after confirming HbF reactivation (70.1 - 95.8% in edited *vs* 7.3 - 20.6% in control groups) and editing frequencies (88.6 - 98.1%) *ex vivo*. Busulfan-conditioned animals transplanted with edited cells recovered with typical reconstitution kinetics and displayed long-term stable editing frequencies (91.7 - 95%) among peripheral blood (PB) granulocytes (127 - 200 weeks post-infusion). Animals displayed high levels of F-cells (51 - 93%) and γ-globin (32 - 75%) early post-transplantation which gradually reduced and stabilized to 27 - 52% and 13 - 38%, respectively. Along with control animals, two of the HbF stabilized editing animals were phlebotomized to induce stress erythropoiesis. An absolute increase in F-cells (17% and 33%) and γ-globin expression (12% and 20%) over stable levels were noted for only edited phlebotomized animals. Further, phlebotomized animals were treated with an HbF inducing agent, hydroxyurea (HU), that provided an additional absolute increase in F-cells (13% and 16%) and γ-globin (14% and 15%) levels in only edited animals. The augmented levels came back to stabilized levels after stopping both phlebotomy and HU treatments. Administering HU without phlebotomy to the 3rd edited animal along with a control animal also led to a significant absolute increase in F-cells (26%) and γ-globin (16%) levels in the edited animal with no change noted in the control. Editing analysis among sorted cell lineages from PB and

bone marrow (BM) including erythroid progenitors and CD34+ HSPCs revealed high levels of editing except CD3+ T-cells, probably due to relatively less lymphotoxic busulfan conditioning. Further clonal analysis demonstrated that only a small portion of the clones was unedited (<8%) and the remaining clones were mutated by roughly equal contributions of indels, programmed inversions and deletions (n= 232 - 272). Additionally, most of BM cells displayed disrupted core enhancer $TGN_{7\text{-}9}WGATAR$ half E-box/GATA binding motifs (n= 399 - 544). In summary, combined editing of the *BCL11A* +58 and +55 enhancers provides clinically relevant HbF levels which can be augmented pharmacologically to maximize the HbF response. Combined edited cells displayed long-term durability (~4 years) with sustained HbF induction without hematologic disturbances and may serve as a long-term solution for patients with β-hemoglobinopathies.

306 EPI-321, a Potential Cure for FSHD

Abhinav Adhikari, Siddaraju Boregowda, Hao Zheng, Osmar Aguirre, Andrew Norton, Xiao Yang, Tracy Luong, Danny Ko, Linsin Smith, Ryan Swan, Boonyanudh Jiyarom, Feng Jiang, Timothy Daley, Daniel Hart, Yanxia Liu, Alexandra Collin de L'Hortet

Epic-Bio, South San Francisco, CA

Facioscapulohumeral muscular dystrophy (FSHD) is one of the most prevalent skeletal muscular dystrophies. FSHD is characterized by DNA hypomethylation of D4Z4 repeat units of a macrosatellite array found at the distal end of chromosome region 4q35, which causes a myotoxic expression of DUX4, disrupting numerous signaling pathways that converge on muscle cell death. DUX4 expression is stochastic, which complicates the development of drugs to inhibit its protein expression. There is no cure for FSHD and current standard of care focuses on managing the symptoms to improve patient quality of life. At Epic Bio, we leverage our proprietary GEMS (Gene Expression Modulation System) platform to develop a treatment for FSHD that targets the D4Z4 epigenome and to permanently suppress DUX4 expression. Our product, EPI-321, is an AAV serotype rh74 vector encoding a catalytically inactive Cas protein fused to gene-suppressing modulators, under the expression of the CK8e promoter and a guide RNA targeting D4Z4. EPI-321 was shown to robustly suppress DUX4 expression and downstream cascade *in vitro* in FHSD patient derived myocytes, indicating proper binding on D4Z4 and subsequent epigenomic silencing. Next, the functionality of EPI-321 in patient-derived myocytes was determined by examining their apoptotic rate upon treatment with NucView® Caspase 3/7 dye. A significant decrease and return to normal myocytes apoptotic levels was observed. Finally, to evaluate *in vivo* efficacy of EPI-321, we examined the FSHD cell content 24 days following one-time intravenous administration of EPI-321 in a humanized murine model of FSHD. In this model, EPI-321 resulted in a phenotypic rescue with 55% increased survival of skeletal muscle cells. Taken together, these data support the development of EPI-321 as a one-time gene therapy treatment for FSHD patients. We plan to file an IND by year end 2023, and anticipate initiating first-in-human trials in 2024.

307 Efficient Engraftment of Genome Edited CD34+ HSPCs in CD45 Antibody-Drug Conjugate (ADC) Conditioned Non-Human Primates

[1]NHLBI/NIH, Bethesda, MD,[2]Magenta Therapeutics, Cambridge, MA,[3]Boston Children's Hospital, Boston, MA,[4]MCCB, UMass Chan Medical School, Worcester, MA

Sickle cell disease (SCD) is the most common monogenic inherited disorder that affects red blood cells (RBC) and leads to acute and chronic complications including pain crises, strokes, end organ damage and early mortality. As sickle cell patients with mutations resulting in persistent postnatal elevated pancellular fetal hemoglobin ($\alpha_2\gamma_2$, HbF) expression have ameliorated disease severity, autologous transplantation with hematopoietic stem and progenitor cells (HSPCs) edited with CRISPR-Cas9 to inactivate the HbF repressor *BCL11A* erythroid enhancer is under development for treatment of SCD and β-thalassemia. While early clinical trials show promising results, morbidity and mortality due to cytotoxic chemotherapy-based pre-transplant conditioning are significant barriers. We developed a single-dose anti-CD45 antibody-drug conjugate (MGTA-45 ADC) conditioning regimen targeting blood cells including hematopoietic stem cells (HSCs) with minimal off-target toxicities. MGTA-45 robustly killed primary human HSCs and peripheral blood (PB) mononuclear cells (MNCs) (5.8-6.6 pM, n = 4) *ex vivo*. In humanized mice, a single dose of MGTA-45 (1 mg/kg, n = 5) achieved >95% depletion of human HSCs in bone marrow and immune cells in PB and bone marrow while isotype-ADC had minimal effect. In cynomolgus macaques, a single dose of ≥0.15 mg/kg MGTA-45 resulted in >95% bone marrow CD34+/CD90+ HSC and broad peripheral immune depletion (n = 3-6 per dose). MGTA-45 had rapid *in vivo* clearance ($t_{1/2}$ < 1.2 hour at 0.2 mg/kg), facilitating use in transplantation. For transplant studies, rhesus macaque CD34+ HSPCs were electroporated with 3×NLS SpCas9 protein and two RNAs targeting the +55 and +58 *BCL11A* erythroid enhancers. The edited cells showed editing of 93.15 - 98.65%, with γ-globin expression of 82 - 89% following erythroid differentiation compared to controls with 10 - 31% γ-globin. The edited HSPCs were autologously infused 10 days after MGTA-45 administration. At 0.2 mg/kg MGTA-45 (n=1), editing reached 62% of target alleles among short-lived granulocytes, reflecting the HSC compartment, with a follow up of 72 weeks to date. At 0.3 mg/kg MGTA-45 (n=2), granulocyte editing reached 82 - 84% and remained stable through 24 and 32 weeks to date. γ-globin expression and F-cell levels reached 67 - 82% and 80 - 93% in these animals respectively, at week 10-13, comparable to control animals receiving dual edited cells after conditioning with myeloablative busulfan at 5.5 mg/kg × 4 days (n=3). Editing in other lineages including monocytes, NK cells, B cells, erythroid precursors and CD34+ HPSCs ranged from 79-93% for the animals given 0.3 mg/kg MGTA-45 and 34-63% for the animal given 0.2 mg/kg MGTA-45. At

16 - 69 week post-transplantation, T cell editing was 14-21% following MGTA-45 conditioning (8-31% for busulfan treated animals at 25 - 34 weeks). We conditioned two additional animals with 0.2 mg/kg MGTA-45 and infused autologous HSPCs transduced with a barcoded lentiviral vector. At 4 - 8 months follow-up, the animals are highly polyclonal, similar to TBI or busulfan conditioned animals. In summary, MGTA-45-based conditioning is myeloablative and achieved polyclonal early engraftment at levels equivalent to TBI or myeloablative busulfan. This approach allowed robust engraftment with *BCL11A* enhancer edited HSCs and achieved potentially therapeutic levels of HbF. These data support the use of MGTA-45 conditioning for diverse transplantation applications.

308 *In Vivo* Genetic Eye Disease Correction Using Split AAV-Mediated Adenine Base Editing

Jack Sullivan[1], Alissa Muller[2,3], Wibke Schwarzer[2,3], Mantian Wang[2,3], Cindy Park-Windhol[1], Pascal Hasler[3], Pierre-Henri Moreau[4], Thierry Azoulay[5], Lucas Janeschitz-Kriegl[2,3], Arnold Szabó[6], Hendrik P. [1]Beam Therapeutics, Cambridge, MA,[2]Institute of Molecular and Clinical Ophthalmology Basel, Basel, Switzerland,[3]Department of Ophthalmology, University of Basel, Basel, Switzerland,[4]SILABE, Université de Strasbourg, Niederhausbergen, France,[5]Clinique Vétérinaire Agoravet, Strasbourg, France,[6]Department of Anatomy, Semmelweis University, Budapest, Hungary

Purpose: Stargardt disease (STGD) is an inherited blinding disorder. The vision loss in STGD patients is associated with the toxic build-up of lipid-rich deposits in the retinal pigment epithelial (RPE), which supports and nourishes the retinal photoreceptors, primarily cones. STGD is caused by mutations in the *ABCA4* gene. Currently, there is no approved therapy. The most frequent variant c.5882G>A, p.G1961E, a G to A point mutation which affects approximately 15% of STGD patients, is a potential target for adenine base editors (ABEs). We developed a dual adeno-associated viral (AAV) vector split-intein adenine base editing strategy to correct the *ABCA4* (c.5882G>A, p.G1961E) gene. **Methods:** To develop the base editing strategy, we designed and tested different guide RNAs (gRNAs) in combination with the ABEs to target the c.5882G>A mutation in an *ABCA4*^{1961E} HEK293T cell line which carries the mutation on a lentivirus insert. To assay base editing in relevant target cells (photoreceptors and RPE cells), we developed an engineered human retinal organoid model and humanized mouse model carrying the *ABCA4* c.5882G>A mutation. We identified a gRNA to show the highest efficiency at the c.5882G>A target base at position 7 (A7) inside the base editing window. Importantly, there is an adjacent adenine (A8) at the 3rd position in codon 1961 (wobble base) that can also be edited at similar efficiencies and does not affect the amino acid sequence (silent change). This wobble base (A8) can be used as a surrogate assay in models which lack the c.5882G>A mutation. Throughout the study, we analyzed A7 target base editing (*ABCA4*$^{1961E/E}$ retinal organoids, and humanized *ABCA4*$^{hu1961E/G}$ mice) and A8 wobble base editing on wild-type human retinal explants and in RPE/choroidal explants. Finally, we subretinally injected adult cynomolgus macaques and assayed base editing rates of the bulk genomic DNA, bulk RNA, and on the DNA from sorted rods and cones. **Results:** Base editing efficiency was similar at the Stargardt target base (c.5882G>A) and the adjacent silent base (c.5883A) in mutant models (i.e., lentivirus-carrying HEK293T cells and *ABCA4*$^{1961E/E}$ retinal organoids). Our split-intein adenine base editor AAV vector led to editing at the A8 base of 5-15% in retinal organoids and 10-20% in human retinal explants, assayed at the genomic DNA level. We also injected the optimized vector construct into mutation carrying mice and achieved high *in vivo* gene correction, where ~50% of photoreceptors and ~80% of RPE cells showed editing. In injected macaques, base editing rates were found to be ~50% in cones, ~25% in rods and ~70% in RPE cells. To analyze genome-wide off-target effects of our base editing strategy on human retinal explants, we performed targeted deep sequencing and no off-target base editing was identified. **Conclusions:** We have developed a highly effective and precise base editing strategy for Stargardt disease for the correction of the *ABCA4* (c.5882G>A, p.G1961E) mutation in various mouse, human and macaque models. We not only show gene editing in primate photoreceptors and RPE cells but demonstrate the ability to correct the disease-relevant mutation in retinal organoids and mice. These results demonstrate that AAV-mediated base editing can lead to a precise genetic change in the retina in vivo.

309 *In Vivo* HSC Base Editing for Gene Therapy of Sickle Cell Disease in a Mouse Model

Chang Li[1], Aphrodite Georgakopoulou[1], Sucheol Gil[1], Hans-Peter Kiem[2], Andre Lieber[1]

[1]University of Washington, Seattle, WA,[2]Fred Hutch, Seattle, WA

Sickle Cell Disease (SCD) results from a single nucleotide transversion (A to T) in the sixth codon of the β-globin gene. Precise genome engineering in hematopoietic stem cells (HSCs) represents a potential curative option for SCD patients. We aimed to correct the SCD phenotype by converting the sickle mutation (GTG) into a benign G-Makassar variant (GCG) using in vivo base editing in HSCs. We have developed a next-generation gene therapy approach involving *in vivo* transduction of mobilized hematopoietic stem cells. The central idea of this *in vivo* approach is to mobilize HSCs from the bone marrow, and while they circulate at high numbers in the periphery, transduce them with an intravenously injected HSC-tropic, helper-dependent adenovirus (HDAd) gene transfer vector system. Transduced cells return to the bone marrow where they persist long-term. For efficient HDAd vector production, we utilized miRNA-regulated gene expression, virus associated RNA (vaRNA), and anti-CRISPR inhibitors to suppress transgene expression in HDAd producer cells. HDAd vectors expressing the latest version of an adenine base editor (ABE8e) linked with a Cas9 variant (NRCH) under a human PGK or EF1α promoter were successfully produced. *Ex vivo* transduction of lineage-minus (Lin$^-$) cells from SCD mice (Townes/CD46) with HDAd-PGK-Maka or HDAd-EF1α-Maka followed by transplantation into irradiated recipient mice led to 55.2% to 88.2% stable correction of the sickle cell mutation (GTG>GCG; V6>A) in peripheral blood cells. The HDAd-EF1α-Maka was chosen for downstream experiments due to its higher activity. In an *in vivo* HSC transduction setting, involving HSC mobilization by G-CSF/AMD3100, intravenous injection with HDAd-EF1α-Maka, and short-term selection with low doses of

O^6BG/BCNU, an average of 23% (range 17-35%) correction of the sickle mutation was achieved. Deep sequencing of week 16 bone marrow samples revealed that most of the edited alleles contained the expected GTG>GCG conversion. Less than 1.5% byproducts (mostly short deletions) around the guide RNA-targeting region were found, consistent with the property of base editors to function independently of double-stranded DNA breaks. Phenotypic correction was observed in treated Townes/CD46 mice, including reticulocyte counts, spleen sizes, hematological and histological parameters. We did not observe significant adverse effects related to *in vivo* transduction/selection. Lin^- cells were isolated from *in vivo* transduced animals and plated for colony-forming unit (CFU) assay as well as transplanted into irradiated C57BL6 recipient mice. The CFU assay showed that 19.2% and 12.5% of colony-forming stem cell progenitors had monoallelic and biallelic correction, respectively. The editing levels remained stable at week 12 after transplantation (ongoing). In $CD34^+$ cells from a SCD patient, transduction with HDAd-EF1α-Maka led to 11% GTG>GCG conversion at the sickle mutation site. This is significantly higher than the 4.5% correction level with a prime editing strategy (HDAd-PE5max) reported previously. We are currently conducting studies in SCD $CD34^+$ cells from additional donors. Our *in vivo* approach requires only one non-integrating vector, only intravenous/subcutaneous injections, and minimal *in vivo* selection. This technically simple approach has the potential for application in resource-poor countries where SCD is prevalent.

310 Optimization and Characterization of Genome Editing of Human Hematopoietic Stem Cells to Induce Fetal Hemoglobin towards SAGES-1 Clinical Trial

Varun Katta[1], Kiera O'Keefe[1], Yichao Li[1], Rachael K. Wood[1], Cicera R. Lazzarotto[2], Rachel Levine[1], Thiyagaraj Mayuranathan[1], Young-In Kim-Hoehamer[1], Alicia Powers[1], Naoya Uchida[3], Timothy Lockey[1], Shondra M. Pruett-Miller[1], Akshay Sharma[1], John F. Tisdale[3], Sheng Zhou[1], Jonathan Yen[1], Mitchell J. Weiss[1], Shengdar Q. Tsai[1]

[1]St. Jude Children's Research Hospital, Memphis, TN,[2]Beam Therapeutics, Cambridge, MA,[3]NIH, Bethesda, MD

Sickle cell disease (**SCD**) is a severe blood disorder caused by a point mutation in the *HBB* gene. One promising genome editing strategy to treat SCD is to reactivate anti-sickling fetal hemoglobin (HbF). Results of ongoing clinical trials targeting the erythroid specific enhancer of BCL11A to induce durable levels of HbF are encouraging. We targeted alternative downstream repressor-binding sites in the γ-globin gene promoters and identified -115 site as more potent inducer of HbF (32% ± 1.5) compared to -196 *ZBTB7A* repressor binding site (16.8% ± 0.9) in erythroid progeny of $CD34^+$ transplanted *NBSGW* mice. Here we describe IND-enabling studies to advance a planned St. Jude Autologous Genome Edited Stem Cell (SAGES-1) clinical trial. To evaluate the efficacy of -115 γ-globin promoter editing, we edited plerixafor-mobilized $CD34^+$ HSPCs from one healthy donor and three individuals with SCD and transplanted them into *NBSGW* mice. We attained high-frequency editing in $CD34^+$ HSPCs before (85.6% ± 0.9) and after 17 weeks of transplantation (74.2% ± 2.9) that resulted in strong HbF induction (27.6% ± 1.7) in red cell progeny derived from mice bone marrow. Single-cell western blots revealed that 49.3% to 58.2% of edited erythroblasts exhibited γ-globin expression compared to unedited controls (<6%). By single-cell RNA-sequencing, we noticed similar upregulation of γ-globin transcripts in edited erythroblasts. Importantly, functional effects of broad HbF induction assessed where edited cells exhibited three-fold reduction in sickling under hypoxia. To assess associated genotoxicities, we applied CHANGE-seq to discover and rhAMP-seq to validate genome wide off-target activity. We observed no detectable off-target mutations above background at 194 candidate nominated off-target sites. We further characterized genomic re-arrangements by Uni-Directional Targeted Sequencing (UDiTaS) and noted no recurrent translocations at day 5 and 14. By long-range PacBio sequencing analysis, we observed a dominant 4.9kb deletion resulted from simultaneous double strand beaks in *HBG1* and *HBG2* promoters. We further confirmed by digital droplet PCR 29.8 % ± 1.3 of 4.9 kb deletions observed in edited $CD34^+$ HSPCs. To produce genome editing components required for autologous cellular therapy, we optimized a tag-free purification method to generate GMP-grade Cas9-3xNLS with high purity (>99.7% by RPLC) and low endotoxin. Potential guide RNA contaminants were identified by a modified gRNA sequencing assay where we observed 82.2% to 84.2% of the 5' protospacer sequence perfectly matches to the targeted gRNA sequence with no detectable contaminants from unrelated sequences. We optimized editing of healthy donor $CD34^+$ HSPCs at clinical scale using Maxcyte electroporation system. In our first two pre-GMP engineering runs, using plerixafor mobilized HSPCs, clinical scale CL1.1 cartridge, GMP-like Cas9 protein, and GMP-like sgRNA, we achieve ~92% editing in bulk HSPCs and further xenografted into *NBSGW* mice. At 17 weeks, we noticed 70-84% editing efficiency with no alterations to lineage or engraftment compared to unedited HSPCs. Furthermore, we observed 23.5-26% HbF in erythroid cells isolated from the bone marrow, well in range of expected therapeutic range. In summary, we describe a roadmap for rigorous evaluation of -115 γ-globin promoter editing approach to induce therapeutically effective levels of HbF for SCD therapy to support a planned SAGES1 first-in-human clinical trial.

311 Correction of Multisystem Smooth Muscle Dysfunction Syndrome in a Mouse Model via Base Editing

Sabyasachi Das, Christiano Alves, Vijaisrinivasan Krishnan, Hannah Stutzman, Leillani Lyn Ha, Siobhan McCarthy, Claire Shamber, Ahmed Rahman, Takahiko Imai, Lai James, Allan Golstein, David Chung, Casey Maguire, Mark Lindsay, Patricia L. Musolino, Benjamin Kleinstiver

Massachusetts General Hospital, Boston, MA

Multisystemic smooth muscle dysfunction syndrome (MSMDS, OMIM #613834) is an ultrarare genetic smooth muscle myopathy with major dysfunction in the vascular, respiratory, enteric, and genitourinary systems. Cases described to date have been monogenic, associated with the missense variation at arginine 179 of the ACTA2 gene, most commonly creating a missense variant (R179H). Since this disease is caused by a single base G-to-A mutation, it is an ideal target for gene knockout or correction via CRISPR technologies. To scalably evaluate

effective genome editing approaches to correct the ACTA2R179H mutation, we first developed a clonal HEK 293T cell line bearing the R179H substitution. We designed and tested various combinations of prime editors and pegRNAs, selecting the most optimal pair to generate several ACTA2R179H cell lines of varying zygosity. Using heterozygous or homozygous cell lines, we evaluated dozens of CRISPR-Cas strategies to knockout or correct the mutant allele, via nucleases and base editors, respectively. With adenine base editors (ABEs), we achieved high levels of correction of the disease-causing G-to-A mutation, when paired with different gRNAs that position the edit window of the ABE deaminase domain over the mutated nucleotide (relying on either WT SpCas9 or our engineered PAM variants). Sequencing from transfections in the ACTA2R179H cell line revealed that although ABE8e-SpCas9 could correct the mutation, the intended edit was accompanied by very high levels of unwanted editing of nearby 'bystander' adenines. However, an SpCas9 PAM variant paired with an alternate gRNA (shifting the edit window of the base editor) enabled efficient and specific correction of the target base with minimal bystander editing. To investigate the translatability of our base editing approach in vivo, we created a knock in murine model of MSMDS with an exon advancement strategy that allows for controlled cre-inducible mutant allele expression (Acta2R179H/fl). The mutant allele in heterozygosity was activated using Cre recombinase driven by the smooth muscle cell (SMC) specific Myh11 promoter. Myh11-Cre:Acta2R179Hfl/+ mice exhibit multiple phenotypes consistent with MSMDS including neurovascular dysfunction with neurodegeneration, aortic enlargement, intestinal dysmotility, and premature death. For in vivo delivery of the ABE, we cloned an intein-split construct compatible with dual adeno-associated virus (AAV) delivery. The constructs were packaged in two AAV serotypes, including AAV9 and our novel AAV capsid optimized for murine vascular delivery. Analysis of Myh11-Cre:Acta2R179Hfl/+ mice retro-orbitally injected at P3 with dual AAVs revealed highly efficient and specific genomic correction of the R179H causing mutation in multiple tissues (~60% in hepatocytes). Importantly, the P3 injected mice exhibited a dramatic phenotypic recovery, including improved weight gain, rotarod and open field performance, reduced aortic diameters, and vastly extended life span. Together, we optimized an efficient therapeutic approach to improve clinical outcomes in a mouse model of MSMDS via in vivo base editing.

Pharmacology/Toxicology Studies: In Vitro and In Vivo Safety

312 Tissue-Restricted Promoter Selection as a Mitigation Strategy for Dorsal Root Ganglia Toxicity Due to AAV9 Treatment of Yucatan Pigs

Jason A. West, Alice Liou, Rebecca Reese, Jacob Wainer, Nidhi Khanna, Suya Wang, Keiko Ishida, Nicole Picard, Camila Lubaczeuski, Emily Cozzi, Jay Caplan, Harith Rajagopalan

Fractyl Health, Inc., Lexington, MA

Adeno-associated virus (AAV)-induced dorsal root ganglia (DRG) toxicity has been observed in several species including nonhuman primates and pigs and is characterized by neuronal degeneration, mononuclear cell infiltration, and in rare instances, hindlimb ataxia and paresis (Hinderer et al. *HGT* 2018; Hordeaux et al. *HGT* 2020). Route of administration (ROA) and vector dose have been correlated with the severity of DRG toxicity, which can be mitigated by limiting transgene expression in DRG (Hordeaux et al. *STM* 2020; Guibinga et al. *ASGCT* 2022). We have developed a novel, endoscopic ultrasound (EUS)-guided, automated delivery system and route of administration (ROA) to enable direct injection of AAV to the pancreas to improve the risk-benefit profile of gene therapy for metabolic diseases, such as type 2 diabetes. Our aim was to characterize DRG toxicity due to AAV in our porcine preclinical model and develop a mitigation strategy for this potential off-target effect. Yucatan pigs (30-40kg) were utilized to establish the EUS procedure and pancreatic ROA since the porcine digestive tract anatomy, including the pancreas, is similar to humans. EUS-guided injection of AAV9 encoding for an enhanced green fluorescent protein (GFP) reporter under the control of a strong ubiquitous promoter (scAAV9-CMV-GFP) led to dose dependent pancreatic transduction, with greater than 40% of all cells exhibiting GFP expression at the highest dose tested. The dose range tested was 5E12-1.5E14 VG, corresponding to ~1E11-5E12 VG/kg, with a total of 11 pigs tested with scAAV9-CMV-GFP (n=2-4 per group). Biodistribution analyses from multiple organs are consistent with high pancreatic and limited off-target AAV tissue exposure. However, local pancreatic administration of AAV resulted in dose dependent AAV transduction of DRG. We also observed corresponding DRG toxicities including inflammation, elevated serum neurofilament light chain (NF-L), and hindlimb ataxia and paresis in one animal dosed at 5E13 VG (1.3E12 VG/kg). In order to assess promotor restriction as an additional DRG toxicity mitigation strategy, we tested 1E13-5E13 VG doses of an AAV encoding for GFP under the control of a β-cell-restricted promoter to prevent transgene expression in off-target tissues. Promotor restriction eliminated GFP expression in DRG and the spine as well as any signs of DRG toxicity, including inflammation or elevation in NF-L across all animals evaluated (n=7). This suggests that the initial DRG toxicity finding may have been due to the strength of the ubiquitous CMV promoter and/or the immunogenicity of the GFP payload as previously documented (Hordeaux et al. *HGT* 2020; Guibinga et al. *ASGCT* 2022). Together, these studies highlight the sensitivity of the pig as an animal model for DRG toxicity, as well as promoter restriction as a viable

strategy to mitigate DRG toxicity in addition to using a local ROA. Additional AAV, ROA, and procedure experiments and analyses are ongoing to evaluate the risk-benefit profile of local pancreatic gene therapy for metabolic disease.

313 Preclinical Safety Assessment of an Investigational Gene Replacement Therapy for the Treatment of *RPE65*-Mediated Inherited Retinal Dystrophies

Weiwei Wu[1], Sheng He[1], Qi Yang[1], Chenhua Yang[1], Jingyu Zhang[1], Jipeng Song[1], Mengke Zhu[1], Linyu Shi[1], Xuan Yao[1], Hui Yang[1,2]

[1]HuidaGene Therapeutics Co., Ltd., Shanghai, China,[2]Center for Excellence in Brain Science and Intelligence Technology, Chinese Academy of Sciences, Shanghai, China

Background: Inherited retinal dystrophies (IRD) are a group of progressive blinding genetic diseases caused by mutations in any one of the over 250 causative genes. An estimated 1000-2000 people in the United States have the IRD disease caused by the mutations in *RPE65* gene, which encodes all-*trans* retinyl ester isomerase, an enzyme critical to the visual cycle. We developed an investigational gene therapy product, HG004, containing AAV-mediated human retinal pigment epithelium 65kDA protein (AAV-*hRPE65*) gene. Here we reported the results of its preclinical safety assessment study after injection in non-human primates (NHPs). **Methods:** HG004 was assessed in a 3-month good laboratory practice (GLP) toxicology study in NHPs after bilateral subretinal injection at three dose levels. Clinical observation, ophthalmoscopic examination (including optical coherence tomography, intraocular pressure, fundus photography, fundus fluorescein angiography, electroretinogram, and etc.), detection of vector shedding and immune response assessment were conducted during the study period. Histopathology and vector biodistribution in tissues were evaluated at 4-week and 13-week termination as well. **Results:** In terms of pharmacokinetic properties, HG004 was mainly distributed in the retina tissues, especially in the retina and choroid (above 10^6 copies/μg) (Fig.1a). The copy numbers of DNA and mRNA in other tissues were much lower than those seen in the retina tissues. No HG004 distribution was detected in the reproductive system on D92 (Fig.1a), and HG004 basically no longer entered the environment with the excretion 1-week post-injection (Fig.1b). Additionally, there were no drug-related systemic toxicity of HG004 observed after 4-week and 13-week post-injection. The adverse reactions (such as retinal injury at the site of needle entry, vitreous inflammatory cell exudation, and locally relevant changes in the area covered by the drug) mainly occurred in the retinas of both vehicle and tested group of monkeys, suggesting that these events were mainly caused by the injection procedure. Finally, the results of immunotoxicity assessment showed that there were no drug-related abnormalities found in whole blood samples of monkeys after injection, and no AAV or RPE65 antigen-specific T cells immune response was detected. **Conclusions:** Overall, HG004 was generally well tolerated, and there were no systemic toxicity reported. Therefore, HG004 is relatively safe for subretinal injection as a potential treatment of inherited retinal dystrophies due to *RPE65* dysfunction. The results of this China-manufactured gene therapy study for *RPE65*-associated inherited retinal dystrophies support the recent investigational new drug (IND) clearance from FDA in January 2023.

314 *In Vitro* Toolbox to Investigate AAV-Induced Immune-Associated Hepatotoxicity

Fabrice A. Müller[1], Rebecca Xicluna[2], Hélène Haegel[2], Cristina Bertinetti-Lapatki[2], Laura Suter-Dick[1,3]

[1]School of Life Sciences, University of Applied Sciences and Arts Northwestern Switzerland, Muttenz, Switzerland,[2]F. Hoffmann-La Roche Ltd, Basel, Switzerland,[3]Swiss Centre for Applied Human Toxicology (SCAHT), Basel, Switzerland

Adeno-associated virus (AAV) vectors have emerged as promising in vivo gene delivery tools for gene therapy. They are mostly non-integrative, are able to transduce various tissues and have a low immunogenic profile. Despite these advantages, there are still reports of severe immune-associated hepatotoxicity after AAV administration in clinical trials. The mechanism behind this liver immune response is still not clearly understood. Here, we aimed to investigate the effect of AAVs on liver cells and to better understand which cell populations and by which mechanisms they may elicit a hepatic immune response. We used human liver in vitro models: HepaRG (hepatocyte cell line), hTERT-HSC (hepatic stellate cell line) and THP-1 (macrophage cell line, used as a Kupffer cell surrogate) that were exposed to different AAV-GFP serotypes (AAV2,3,8 & 9) and titers (MOI 10^3 - 10^6). Transduction efficiency was investigated by PCR, fluorescence microscopy and image quantification. Cellular responses were studied using cell viability and gene expression assays, immunofluorescent staining, and multiplex cytokine panel screens. Titer- and serotype-dependent decreases in cell viability were observed in HepaRG and hTERT-HSC but not in THP-1. Hepatic cells could be transduced using AAV, as the vector genome (GFP gene) could be detected in all three cell lines transduced with all four tested serotypes. However, protein expression of GFP was cell and serotype dependent. At a MOI of 10^6, AAV2 was able to transduce all three tested cell lines, whereas AAV3, 8 and 9 were able to transduce only HepaRG and THP-1. Transduction also elicited varied cellular responses: AAV2 increased αSMA gene and protein expression and decreased TGF-β gene expression in hTERT-HSC suggesting a direct activation of HSC. THP-1 appeared also activated by AAV2 and AAV8 as indicated by increased gene expression of CD80, CD206, HMOX and CXCL10 (IP-10). Immunostimulatory potential of AAV2 and AAV8 on hepatic cells was also suggested by the increased secretion of various pro-inflammatory cytokines and chemokines in all three cell lines, with IL-6 levels strongly increased in HepaRG and THP-1. Based on these studies in liver cell surrogates, an immune response to AAV-mediated liver gene therapy may be potentially driven by the activation of hepatic stellate cells and Kupffer cells, and increased secretion of

pro-inflammatory cytokines and chemokines by parenchymal and non-parenchymal cells. Further studies will focus on more complex 3D human in vitro models to gain insight into AAV-induced immune-associated hepatotoxicity and eventually help improving the safety of AAV vectors in gene therapy.

315 Investigating the Impact of Empty AAV Capsids on Safety and Efficacy Following Intracisterna Magna Administration in New Zealand White Rabbits

Pete Clarner, Jimmy Tran, Kate Henry, Galina Marsh, Connor F. Seeley, Junghae Suh, Jinkuk Choi
Biogen, Cambridge, MA

Recent reports of treatment-emergent serious adverse events from recombinant AAV-mediated gene therapy have highlighted the need to better understand the effect of quality attributes of the AAV material on safety and efficacy outcomes. A particularly important topic which has been receiving a lot of attention is the impact of empty AAV capsids. Empty AAV capsids are process-related impurities generated during AAV production which lack the transgene DNA that is present in "full" AAV particles. There are significant gaps in understanding how the presence of empty capsids impacts safety and efficacy of AAV preparations. Additionally, there are no definitive regulatory guidelines on acceptable levels of empty capsids. Route of administration (ROA), dose, target, and indication can all potentially influence the impact of empty capsids, further increasing the complexity of this issue. To support an internal therapeutic program and using a rabbit model, we investigated the potential impact empty capsids may have on AAV performance *in vivo*. New Zealand white rabbits were dosed with 1.0E+13 genome copies of an AAV vector by intracisterna magna (ICM) injection. This AAV vector expresses a small RNA under the control of ubiquitous promoter and knocks down expression of human superoxide dismutase 1 (SOD1). Study materials were prepared by transient transfection in HEK293 cells followed by affinity chromatography purification. Cesium chloride (CsCl) gradient ultracentrifugation was then applied to isolate and enrich full and empty capsid populations. Target percentage full:empty ratios were achieved by combining these enriched populations and confirmed through analytical characterization. Rabbit study groups (n = 3 per group) were administered vehicle control, enriched full (1.0E+13 viral particles), 75% full and 25% empty (1.33E+13 viral particles), 50% full and 50% empty (2.0E+13 viral particles), and enriched empty capsids (1.0E+13 viral particles). The three groups which were administered full capsids all received the same genome copy dose. Findings were compared across groups to assess both transduction and safety endpoints. In-life observations, clinical chemistry, and hematology analyses showed no significant differences across study groups. Additionally, blood and cerebrospinal fluid (CSF) analysis of neurofilament (NF), a biomarker for neurotoxicity, showed elevations in study groups which received any percentage of full capsids, but no difference across these groups. Conversely, the vehicle control group and the group which received enriched empty capsids saw no elevations in NF. Biodistribution, transgene expression, and histopathology analyses are on-going. These results demonstrate that ICM co-injection of up to 1.0E+13 empty AAV capsid particles to rabbits does not significantly impact common safety endpoints. We will continue to evaluate the potential impact of empty capsids on transduction and microscopic pathology.

316 Intraparenchymal Dosing in Beagle Dogs Using Convection Enhanced Delivery Guided by Real Time MRI

Morgan K. Foret, Said Maghezzi, Erik Larson, Clotilde Leblond Lecrux, Nehla Bennamoune, Kim Bujold, Michelle Stoute, Christian Li, Simon Authier, Srishti Vats
Charles River, Laval, QC, Canada

In the clinic, convection-enhanced delivery (CED) is routinely used in patients for targeted intraparenchymal brain dosing, spanning a multitude of neurological indications. As non-clinical toxicology studies require drug delivery methods to closely mirror those used in the clinic, expanding the number of non-rodent preclinical models for CED proves valuable. To achieve CED, standard procedures incorporate real-time MRI to target and verify local delivery to desired brain regions by employing a step-infusion paradigm coupled with a contrast agent such as gadolinium. We have established this procedure in non-human primates (NHPs) and have successfully delivered novel neurological therapeutics to multiple brain regions tailored to each respective indication. Expanding on this progress established in NHPs, we have developed a Beagle dog model as an additional non-rodent non-clinical alternative. Up to six different parenchymal sites per animal have been dosed at rates of 120 to 300 μL per hour with dose volumes ranging between 30 to 50 μL per site. The radial error in relation to the planned target is the submillimetric range. By incorporating real-time MRI, it is possible to accurately target relevant brain regions while also monitoring dose distribution over time. As observed in NHPs, Beagle dogs recover well from the surgeries and presented with minimal procedure-related clinical signs including mild tremors, cutaneous changes, and decreased activity which were expected after surgery and resolved within approximately 4-days after the procedure. From an ethical standpoint, Beagle dogs represent an advantageous alternative to non-human primates. This work demonstrates an additional non-clinical model for CED using real-time MRI, with a workflow that utilizes clinically relevant methods and devices, ultimately addressing the need for alternative non-rodent non-clinical models for assessing toxicology of neurological therapeutics.

317 Target Cell and Tissue Specificity of a Novel CD8-Targeted Fusosome for Direct *In Vivo* Delivery of CD19 or a CD20 CAR to CD8+ T Cells

Sundeep Chandra
Sana Biotechnology, South San Francisco, CA

To overcome conventional *ex vivo* CAR T limitations, Sana is developing a novel gene therapy platform that can deliver CAR transgenes directly to T cells via systemic administration of a fusosome (a novel integrating viral vector whose target specificity can be altered by engineering viral envelope proteins). Although anti-CD19 CAR T cells have been clinically validated to be effective with an acceptable

safety profile, the use of a novel gene therapy approach for *in vivo* delivery rather than the conventional *ex-vivo* delivery presents unique safety challenges. To assess *in vivo* safety, we selected Nemestrina macaques as they are the only nonclinical model permissive to transduction by an integrating vector. Because the CD19-directed CAR does not cross react in macaques, we designed a surrogate vector with the same CD8-targeting fusogen, but with a payload to express a CD20-directed CAR, allowing us to assess: activity, biodistribution, and potential toxicities related to vector or CAR. To support the safety assessment, we evaluated the fusosome's CD8-targeting binder and CAR's on- and off-target binding by performing cell and tissue specificity: 1) testing a complete panel of frozen human and Nemestrina tissues in a tissue cross reactivity (TCR) study, and 2) evaluation of binding, expression, and activity in a select panel of primary and immortal cell lines as well as target cell co-culture systems. TCR: Representative scFvFc fusion proteins directed at either CD8, CD19 (human CD19+ tumor cell), or CD20 (NHP B Cell), were tested to evaluate cell and tissue specificity. The CD8 binder on our fusosome used to target CD8+ T cells is a single-chain variable fragment (scFv) that was isolated from a fully human synthetic scFv library via phage display. CARs are synthetic immune receptors (binders) that comprise an scFv that directs the pharmacological activity of CAR T cells to tumor target cells. Several rounds of screening against human CD8ab and cyno CD8a were performed to isolate binders with cross-reactivity to macaques. CD8+ SupT1 cells or CD19+/CD20+ Ramos cells served as assay positive controls for CD8 and B cell targets, respectively. TCR studies confirmed both cell and tissue specificity of all binders, with no detectable off-target binding of the CD8-directed fusosome, and specific binding of both CAR binders (CD19 or CD20) to B-cell rich regions of lymphoid tissues. In vitro: In primary cells, on-target binding was observed on T cells. Off-target binding and transduction of primary human hepatocytes was observed with the CD8 fusosome at very high concentrations, substantially above the intended clinical therapeutic range. Importantly, immunoreactivity of the CD8-directed binder to hepatic tissue was not noted in either human or macaque livers in the TCR study. Furthermore, an *in vivo* biodistribution study in Nemestrina, showed no evidence of hepatic transduction by *in situ* hybridization or quantitative ddPCR, suggesting minimal safety risk for the intended therapeutic range. Target cell specificity of CD19-directed and CD20-directed CARs was further confirmed in target cell killing assays that showed *in vitro* transduction of 1) human and NHP CD8+ and not CD4+ T cells, 2) target-directed killing of CD19+ NALM-6 tumor cells, 3) target directed killing of CD20+ K562 and not CD20- K562 cells when co-cultured. Taken together, the data confirmed specific CAR expression in human and NHP CD8+ effector T cells followed by specific CD19+ or CD20+ target cell engagement and cell killing, supporting evaluation of *in vivo* administration of this novel CD8-directed fusosome for CAR T therapies.

318 Safety and Biodistribution Study of Intra-Articular Delivered ICM-203, an AAV Gene Therapy Vector for Osteoarthritis, in Normal Rodents and Osteoarthritis-Induced Beagle Dogs

Minsun Park[1,2], Ji-Ye Yoo[1], Yeonjin Kim[1], Minji Choi[1], Myung Seok Yoo[1], Heui-Young Ryu[1], Daegun Kim[1], Yong Na Yum[1], Dae-Won Kim[1,2]

[1]ICM Co., Ltd., Seoul, Korea, Republic of,[2]Yonsei University, Seoul, Korea, Republic of

Osteoarthritis (OA) is the most common degenerative joint disorder worldwide and a leading cause of locomotive disability in the elderly population. ICM Co., Ltd. has developed AAV based gene therapy for OA, called ICM-203. ICM-203 is an adenoviral-associated, recombinant gene therapy vector containing a bioengineered human Nkx3.2 transgene and intended for the treatment of patients with mild to moderate OA (KL grade 2 to 3). Nkx3.2 was initially identified as a pro-chondrogenic factor promoting cartilage development. Our previous studies have revealed that intra-articular (IA) delivery of ICM-203 was found to be capable of regenerating functional cartilage, suppress synovial inflammation, and restoring normal joint function in OA induced mice and beagle dogs. The IND-enabling safety and pharmacokinetic (PK) studies including the vector and mRNA biodistribution (BD) analyses were conducted in mice, rats, and beagle dogs. These study results were incorporated with toxicology studies and the results are presented here. PK studies were conducted in mice after ICM-203 IA injection. In the 26-week study ($1.4x10^{10}$ vg and $1.4x10^{11}$ vg per knee joint), vector DNA and transgene expression levels in target site remained relatively stable and persistent up to 26 weeks, demonstrating potentially prolonged therapeutic effects of ICM-203. Since ICM-203 is administered to a confined space of the joint; therefore, in the 90-day ($2x10^{10}$ vg and $2x10^{11}$ vg per knee joint) study, non-target distribution (blood, heart, kidney, liver, spleen, lung, lymph nodes, reproductive organs) of vector DNA and/or transgene expression was minimal. BD, toxicity, and immunogenicity of ICM-203 were examined in a GLP-compliant 90-day rat study, in which a single dose of ICM-203 was administered at $4x10^{10}$ to $4x10^{12}$ vg per knee joint via bilateral IA injection. ICM-203 vector DNA and transgene expression were quantitated with validated methods in the knee joint and non-target sites in the 90-day study course. Vector DNA and transgene expression levels were quantifiable in all tissues investigated at the high dose group with the highest vector DNA and transgene expression detected within the injection sites. No adverse effects were found in toxicological endpoints related to ICM-203 throughout the study. Formation of both neutralizing and transgene antibodies in response to the AAV5.2 capsid and expressed transgene protein, respectively, was confirmed and the IFN-γ splenocyte enzyme-linked immunospot (ELISpot) analysis showed immune recognition of the AAV5.2 capsid which was decreased over the 90-day time period. Twenty-seven-week safety study in OA-induced beagle dogs showed IA administration of ICM-203 with doses up to $2x10^{13}$ vg per knee joint was well tolerated. All general toxicological endpoints (mortality, physical examinations, gross pathology, hematology, clinical chemistry, and histopathological analyses) revealed no adverse effects related to ICM-203. The biodistribution analysis demonstrated that the majority of vector DNA and transgene expression retained in the injection site

for 27 weeks. Among non-target sites, very low levels (less than 1,000 copies of vector genome per microgram of gDNA) of vector DNA was detected in liver, spleen and lymph node. In addition, no abnormalities were found in terms of immunogenicity. Overall, these results were included in the ICM-203 IND submission and the program received no study hold comment from the US FDA in Oct 2022.

Cell Therapy Product Manufacturing

319 Efficient and Minimally Perturbative CAR-T Cell Engineering Using Peptide-Enabled CRISPR RNP Delivery

Joseph J. Muldoon[1,2], Dana V. Foss[3,4], David N. Nguyen[1,2,3], Daniel Carr[1,2,3], Srishti U. Sahu[3,4], Alexander Marson[1,2,3], Justin Eyquem[1,2], Ross C. Wilson[3,4]

[1]Department of Medicine, UCSF, San Francisco, CA,[2]Gladstone-UCSF Institute of Genomic Immunology, San Francisco, CA,[3]Innovative Genomics Institute, UC Berkeley, Berkeley, CA,[4]California Institute for Quantitative Biosciences at UC Berkeley, Berkeley, CA

Precision genome editing of primary human T cells offers the potential for sophisticated and durable cell therapies, but the use of electroporation for delivering genome-editing reagents is a source of cell toxicity and requires costly, cumbersome hardware and reagents. This manufacturing burden vastly limits the access and wide implementation of genome-edited T cell therapies. We developed a method called peptide-enabled RNP delivery for CRISPR engineering (PERC) to conduct precise editing without the need for electroporation. In this process, an RNP enzyme such as Cas9/gRNA or Cas12a/gRNA is mixed with a particular amphiphilic peptide and then applied to cells in culture, resulting in efficient gene knockout (up to 90%). Compared to electroporation, PERC produces significantly higher yields of edited cells, preserves the naïve and memory phenotype, and is less perturbative at the transcriptomic level. PERC can be paired with adeno-associated virus (AAV) bearing a homology-directed repair template for making efficient electroporation-free knock-ins, such as of a CAR transgene to the TCR alpha constant (*TRAC*) locus under endogenous promoter control, which has been shown to improve anti-tumor potency compared to virus-mediated pseudorandom integration. With PERC and AAV, we achieved up to 75% *TRAC*-CAR knock-in efficiency. As PERC is minimally perturbative, it can be used to edit multiple loci sequentially and thereby avoid chromosomal translocations, which arise when multiple RNPs are delivered simultaneously. Remarkably, we achieved above 25% dual knock-in at *TRAC* and *B2M* without detectable chromosomal rearrangement. Functionally, *TRAC* CAR-T cells produced using PERC maintained the advantage of their electroporation counterpart over pseudorandomly engineered CAR-T cells in targeting antigen-expressing tumor cells. Furthermore, multi-locus-edited CAR-T cells produced using PERC demonstrated therapeutic potency matching that of electroporation in an in vivo model of B-ALL. In summary, PERC paired with AAV enables efficient, convenient, non-toxic, minimally perturbative, and multi-locus editing. Looking forward, this approach has the potential to decrease the cell handling steps and infrastructure involved in making precisely engineered T cell therapies and could lower the barrier to point-of-care manufacturing.

320 A Minimal Workflow for *Ex Vivo* Magnetically-Assisted Lentiviral Vector Transduction of Hematopoietic Stem and Progenitor Cells for Gene Therapy Applications

Lois Bayigga[1,2], Molly Ellena Cassidy[1], Jack Castelli[1,3], Rachel Cunningham[1,3], Kim Anthony-Gonda[4], Rimas J. Orentas[4], Boro Dropulic[4], Cissy K. Mutuluuza[2], Jennifer E. Adair[1,3]

[1]Translational Science and Therapeutics Division, Fred Hutchinson Cancer Research Center, Seattle, WA,[2]Joint Clinical Research Centre, Kampala, Uganda,[3]Laboratory Medicine and Pathology, University of Washington, Seattle, WA,[4]Caring Cross, Inc., Gaithersburg, MD

Currently, there are 8 approved lentiviral vector gene therapies (LV-GT) but none of these were developed in low-and-middle income countries (LMICs), which harbor 90% of the world's disease population (PMID:36203001). Viral vector remains a financial and temporal burden limiting availability to LV-GT in LMICs as well as high income countries. Here we tested a minimal workflow utilizing a LV with high transduction efficiency at low doses to circumvent this limitation. Primary human hematopoietic stem and progenitor cells (HSPCs, CD34+) from G-CSF mobilized adult donors were transduced with either cocal virus envelope glycoprotein pseudotyped LV (cocal LV) or vesicular stomatitis virus envelope glycoprotein pseudotyped LV (VSV-G LV) encoding a green fluorescent protein (GFP) transgene. We evaluated three transduction processes: standard culture-based transduction, spinoculation and magnetically-assisted transduction (MAT). HSPC were pre-stimulated for 16h in StemSpan™ SFEM II media containing recombinant human stem cell factor (SCF), thrombopoietin (TPO) and Fms-like tyrosine kinase 3 ligand (FLT3-L) at 100ng/mL each. Cells were either first spinoculated at 400g for 1h or directly cultured in the presence of LV at 37°C, 5% CO_2. For MAT, LV were incubated in ViroMag STEM™ at a dilution of 1:500 for 20 minutes, then added to HSPC in culture media and placed on a CTS™ DynaMag™ magnet for 20 minutes. In all experiments cells were seeded at 2 x10^6/mL, transduced once at 10 transducing units (TU) per cell and cultured post-transduction in Iscove's Modified Dulbecco's Medium containing 10% fetal bovine serum and SCF, TPO, and FLT3-L for 10 days. No difference in viability or expression levels of low-density lipoprotein receptor (LDLR), the described receptor for both VSV-G and cocal, was observed across any condition. GFP detected in cells gene modified by cocal LV was 10-60% higher than in cells modified by VSV-G LV. MAT yielded 5-fold higher transduction efficiency in CD34+ cells in comparison to standard culture-based transduction and spinoculation. We evaluated *in vivo* engraftment of MAT-treated cells in *NOD/SCIDgamma*$^{-/-}$ (NSG) immunodeficient juvenile mice. Each mouse was injected with 1x10^6 human HSPCs either freshly transduced or transduced and then cultured in StemSpan™ for 2 days. Mice transplanted with freshly transduced cells had higher levels of engraftment (hCD45+) without transduction effects compared to mice receiving cultured cells ($p<0.005$). *In vivo* gene marking of total PB leukocytes at 28 weeks of age will be assessed at end of study. These

data suggest that MAT of cocal LV at low doses can greatly reduce viral vector burden for LV-GT. These data demonstrate proof of concept for a cost-effective minimal workflow for manufacturing LV-GT.

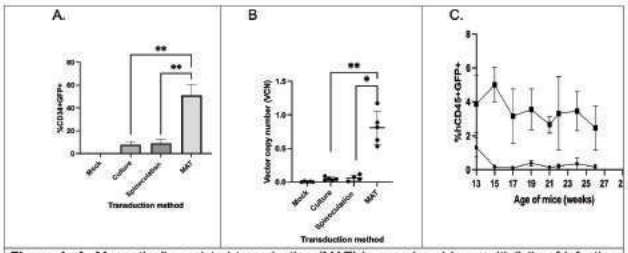

Figure 1: A. Magnetically-assisted transduction (MAT) is superior at low multiplicity of infection (MOI). Human CD34+ cells transduced with cocal LV at a single MOI of 10 TU/cell. **B.** Gene modified CD34+ cells had low LV copies per genome hence safe to use. **C.** Cultured CD34+ cells had better transduction (GFP+) than fresh cells.

321 'Off the Shelf' CD62L-Selected Multiplex Edited Umbilical Cord Blood CAR T Cells

Christos Georgiadis, Farhatullah Syed, Lauren Bor, Hong Zhan, Soragia Athina Gkazi, Annie Etuk, Roland PP Preece, Giorgio Ottaviano, Waseem Qasim

UCL Great Ormond Street Institute of Child Health, London, United Kingdom

Most allogeneic CAR T cell applications modify healthy donor lymphocytes, derived from adults under steady state apheresis conditions. Umbilical cord blood (UCB) T cells represent an attractive source of naïve T cells given their distinct ontogenetic origins and may offer enhanced properties of expansion and activation, compared to adult peripheral blood lymphocytes (PBL). By exploiting a characteristic feature of UCB T cell naivety, the expression of CD62L, T cells were enriched at scale using magnetic bead conjugated antibodies ahead of a semi-automated and compliant process. Selected CD62L+ UCB T cells were readily amenable to transduction with a CRISPR-CAR19 lentiviral vector, encoding CRISPR cassettes within the long-terminal repeats (LTRs), which mediated multiplexed editing of TCR α chain and CD52 gene after electroporation of SpCas9 mRNA, yielding cells with negligible GvHD potential and resistant to serotherapy, respectively. The resulting 'universal' CAR T cells were highly enriched for CAR expression (~85%) with residual TCRαβ T cells <1% in the final product. High-throughput molecular investigations confirmed on-target fidelity of genome edits with no significant 'off-target' editing at Digenome-Seq informed sites of predicted guide dependent activity. Predictable chromosomal translocations were quantified by digital droplet (ddPCR) and Fluorescence in situ Hybridization (FISH) (≤1 %) and other aberrations excluded by karyotype analysis of metaphase spreads. UCB CAR19 T cells mediated potent cytolytic activity against CD19+ Daudi targets and appropriate secretion of cytokines IFN-γ, TNF-α, IL-4 and IL-2 in vitro and demonstrated robust anti-leukemic effects in vivo using a xenograft model of B-cell malignancy, at levels comparable to PBL-derived CAR T cells. UCB enriched for CD62L-positive cells may provide an alternative source for banking universal CAR T cells from donors with common HLA types, which could reduce the need for intense lymphodepletion currently required for allogeneic CAR T cells.

322 Live Imaging on Single Cell Arrays (LISCA) as a Platform to Study Dynamics of mRNA Expression in Mammalian Cells

Judith A. Müller[1], Gerlinde Schwake[1], Sophia Rudorf[2], Joachim Rädler[1]

[1]Ludwig-Maximilians-Universität München, München, Germany,[2]Leibniz Universität, Hannover, Germany

Introduction: mRNA based therapies evolved into one of the most powerful therapeutic technologies. Over the last decades much effort was put into enhancing mRNA delivery and translation efficiency. The advent of lipid nanoparticles (LNPs) brought RNA delivery and in-vivo efficacy to the level of clinical applications. However, at the single cell level, delivery of LNPs is heterogeneous and the expression level and timing is poorly controlled. As opposed to the need of some applications local overexpression might have detrimental effects. In an effort to gain more control over expression, we utilize a frequently occurring motif in natural gene regulation employing downregulation via siRNAs. So-called incoherent feedforward loops (icFFLs), consisting of initiation and simultaneous or delayed down-regulation, lead to faster response of the out-put signal with reduced noise. Here we realize a regulatory gene expression motif encoded in lipid nanoparticles containing eGFP mRNA and eGFP targeting siRNA (Fig. 1). We show that codelivery of these counteracting components represent a icFFL with the expression output being determined by the ratio of mRNA and siRNA.

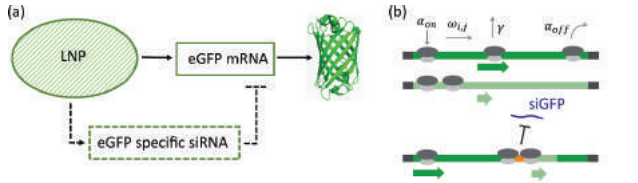

Figure 1: Controlling mRNA delivery: (a) icFFL LNP model and (b) modulation of ribosome movement to control mRNA stability under RNAi attack

Secondly, we demonstrate control over mRNA stability via codon modification. Synonymous re-coding of the mRNA's open reading frame is one approach to investigate and optimize the physics of mRNA stability. We evaluate the potential of bias in codon usage on influencing the ribosome density on the ORF and therefore the mRNA's translation and degradation kinetics.
Methods: We use live imaging on single cell arrays (LISCA) to record eGFP expression kinetics after transfection of hundreds of single cells in parallel. The approach enables high throughput investigation into transfection homogeneity to study the effect of icFFL LNPs. Describing the translation in biochemical rate equations, we analyse mRNA expression rates and stability at single cell level (Fig. 2).

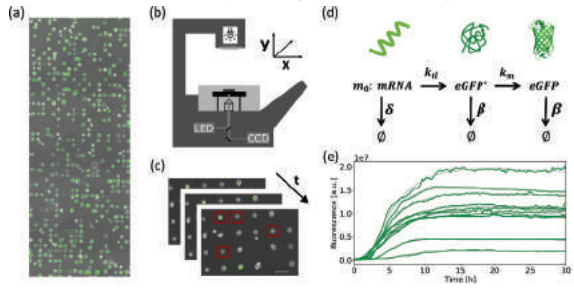

Figure 2: LISCA platform: (a) Exemplary overview of single transfected cells, (b) Time-lapse microscope setup (c) Time resolved images are analysed with in-house software (d) three stage maturation model to fit trajectories (d) exemplary fluorescence trajectories (green) with fit (grey)

Results: We find faster and more homogenous expression in eGFP time courses in cells transfected with icFFL LNPs. The asymptotic expression levels show power law decrease as a function of siRNA/mRNA ratio. Our approach demonstrates self-regulated expression via icFFL LNP based genetic programs. Furthermore, we could show that insertion of slow codon windows in the ORF enables tuning of the mRNAs stability under siRNA attack. We observe distinct differences in degradation rates for GFP mRNAs with various ORFs with different ribosome jam provoking slow codon windows in agreement with simulation. This change in stability is dependent on the absence or presence of siRNA.

323 Development of a GMP-Compatible Manufacturing Process for Highly-Edited, Stem-Like, Metabolically Fit, Virus Free CRISPR CAR T Cells

Dan Cappabianca[1], Dan Pham[2], Madison Bugel[1], Anna Tommasi[1], Matthew Forsberg[3], Sarah Caroline Gomes de Lima[4], Brooke Hrdlicka[1], Amani Gillette[2], Krishanu Saha[1], Christian Capitini[5], Melissa Skala[6]

[1]University of Wisconsin-Madison, Madison, WI,[2]Morgridge Institute for Research, Madison, WI,[3]Carbone Cancer Center, University of Wisconsin-Madison, Madison, WI,[4]University of Wisconsin-Madison, Center for Cell-Based Therapy, Regional Blood Cent, Brazil,[5]Pediatrics, University of Wisconsin-Madison, Madison, WI,[6]Morgridge Insitute for Research, Madison, WI

Six Chimeric Antigen Receptor (CAR) T-cell therapies have been FDA-approved to treat liquid tumors spawning immunotherapy research for a wide range of cancer indications. However, limited clinical success of these products in solid tumors due to a lack of persistence and anergic T-cell phenotypes have led researchers to search for new ways to manufacture CAR T cells. Recently, virus-free CRISPR CAR T cells have been produced through CRIPSR/Cas9-induced knockout of the endogenous TRAC gene. There cells have a favorable memory-enriched phenotype and can be manufactured quickly. Here, we further improved critical quality attributes of VFC CAR T cells through the addition of small molecules and a novel media switch post-electroporation (EP) to produce highly-edited, 'metabolically fit' cells. Cells were evaluated using spectral cytometry, Seahorse assays, and within in vivo xenograft neuroblastoma mouse models. Highly-edited VFC CAR T cells, up to 50% transgene positive, can be produced with the addition of the DNA-PK inhibitor M3814 (Nedisertib) post-EP. Additionally, the usage of two different basal medias, TexMacs and Immunocult XF, pre and post-EP respectively, endows VFC CAR T cells with superior efficacy in in vivo mouse models and a 'metabolically fit' phenotype that favors oxidative phosphorylation. This 'metabolically fit' phenotype combines glutamine and glucose restriction pre-EP which allows the cells to favor oxidative phosphorylation over glycolysis, to prime the cells for persistence in a hostile tumor environment and favors the formation of long-lasting memory cells. These findings shed light on the ease and efficacy of simple media changes during manufacturing to produce memory-enriched, potent T cell therapies.

324 Improving Genome Editing Efficiency and *In Vivo* Potency of CAR T Cells via Label Free Metabolic Imaging

Dan L. Pham, Dan Cappabianca, Krishanu Saha, Melissa Skala

University of Wisconsin - Madison, Madison, WI

Introduction: While Chimeric Antigen Receptor (CAR) T therapy is a promising treatment for hematological malignancies, its translation to solid tumor remains challenging. The number of CAR$^+$ cells (CAR T dosage) and stem-memory cell phenotypes have been correlated with long term treatment response. Low CAR knock-in efficiency can be compensated by long *in vitro* expansion to reach the desired dosage, but this causes T cells differentiation and exhaustion. Hence, strategies to improve nucleofection efficiency and expansion condition for a potent, persistent CAR T product is critical. As T cell metabolism strongly correlates with function, we used Optical Metabolic Imaging (OMI) to identify the optimal nucleofection timeframe to achieve highest genome editing efficiency, and the media-cytokine condition for highest *in vivo* CAR T efficacy. OMI allows non-invasive, real-time characterization of cell metabolism based on autofluorescence from metabolic coenzymes NAD(P)H and FAD by quantifying their relative abundance and binding activity.
Methods: Primary T cells were isolated from three healthy donors and activated with StemCell (αCD2/αCD3/αCD28) or TransAct antibody (αCD3/αCD28) for 12-72 hours prior to nucleofection for GD-2 CAR expression. T cell metabolic profile at the nucleofection timepoint was characterized with OMI. GD-2 CAR T cells were then expanded in a combination of media (ImmunoCult vs TexMacs) and cytokine (IL-2 vs IL-7) for 5 days before being evaluated for %CAR positivity, CAR T cell phenotypes, and OMI metabolic features. 5 million CAR$^+$ T cells were injected into NSG mice carrying xenograft GD-2$^+$ CHLA-20 and treatment response was determined after 21 days.

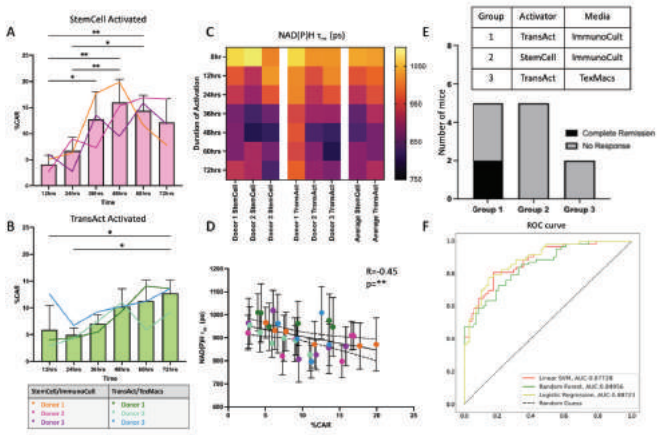

Figure 1. OMI identified optimal nucleofection timeframe and expansion condition for highly potent CAR T cells. (A-D) StemCell and TransAct activated T cells yielded highest %CAR positivity and lowest NAD(P)H t_m with activation duration of 36-48 hours and 48-72 hours, respectively. (E-F) Group 1 CAR T cells achieved highest rate of *in vivo* remission. OMI features allowed classification of CAR T cells from group 1 versus others with high accuracy (area under ROC curves > 0.80). *p<0.05, **p<0.01.
Results and Conclusions: T cells with different activation duration

and strategies yielded CAR knock-in efficiency varying from 5-20%, with StemCell and TransAct activated T cells having highest editing efficiency at 48 hours and 48-72 hours post activation, respectively (Fig. 1A-B). OMI revealed significant metabolic changes in T cells over the duration of activation, with lowest NAD(P)H mean lifetime (NAD(P)H t_m) observed in T cells activated for 36-48 hours with StemCell antibody and 48-72 hours with TransAct antibody, aligning with the timepoints of optimal transfection efficiency (Fig. 1C). OMI metabolic features (specifically NAD(P)H t_m) at nucleofection showed a significant negative correlation with CAR knock-in efficiency (Fig. 1D). CAR T cells with different activation and expansion conditions showed varied *in vivo* potency with the same dosage (Fig. 1E). CAR T cells from group 1 (TransAct activated, ImmunoCult + IL-2 expanded T cells) achieved highest rate of *in vivo* remission and displayed distinct metabolic features. A logistic regression classifier was successfully trained to classify highly potent CAR T cells (group 1) versus others based on OMI measurements with >80% accuracy (Fig. 1F). Our data demonstrated that OMI is sensitive to inform the optimal gene transfer timeframe and expansion condition to achieve potent CAR T cell products.

325 Evolution of a Hyperactive TcBuster Transposase Enables Highly Efficient Non-Viral Generation of CAR-NK and CAR-T Cells for Combination Cell Therapies

Joseph G. Skeate[1], Emily Pomeroy[1], Bryan Jones[2], Nicholas Slipek[1], Bryce Wick[1], Walker Lahr[1], Erin Stelljes[1], Xiaobai Patrinostro[2], Blake Barnes[2], Trevor Zarecki[2], Joshua Krueger[1], Jacob Bridge[3], Gabrielle Robbins[1], Madeline McCormick[1], David A. Largaespada[3], Neil Otto[2], Beau R. Webber[3], Branden S. Moriarity[1]

[1]Pediatrics, University of Minnesota - Moriarity Lab, Minneapolis, MN,[2]Bio-Techne, Minneapolis, MN,[3]University of Minnesota, Minneapolis, MN

Immunotherapy with chimeric antigen receptor (CAR) expressing NK and T cells engineered through viral vectors has shown exceptional efficacy against hematologic cancers in clinical trials. This method, however, is limited in cargo capacity, carries the risk of insertional mutagenesis, and large-scale manufacturing for clinical use is cost-prohibitive. CAR delivery via DNA transposon engineering is a viable alternative due to expedient and cost-effective production when compared to viral-based approaches. Here, we evolved and deployed a hyperactive TcBuster™ transposase (TcB-M) to deliver a CD19-CAR-DHFR-EGFP expression cassette (3.7 kb) to both primary human peripheral blood NK and T cells to achieve >90% CAR+ integration. Previously, the use of transposons in primary immune cells has been hindered by DNA toxicity and induction of a type I interferon response. We optimized methods to avoid this, including using DNase in recovery media and transposon delivery via Nanoplasmid vectors which have a small (<500 bp) backbone, high supercoiling, and can be rapidly moved towards GMP compliance. Our cargo contained a mutant dihydrofolate reductase (DHFR), resulting in our ability to select for CAR NK and CAR T with stable transposon integration using methotrexate (MTX) during manufacturing (**Fig 1A**).In vitro, CAR NK and CAR T cells elicited potent cytotoxicity against CD19+ Raji target cells within 24 hours (**Fig. 1B & C**). Within an in vivo Raji-challenged xenograft model, we found significant improvements in survival and decreases in tumor burden with single-dose therapies generated using TcBuster. To avoid CRS associated with high-dose CAR T therapy, we demonstrated that a sub-optimal dose of CAR T can be combined with CAR NK cells to improve survival with a single dose (**Fig. 1D**).

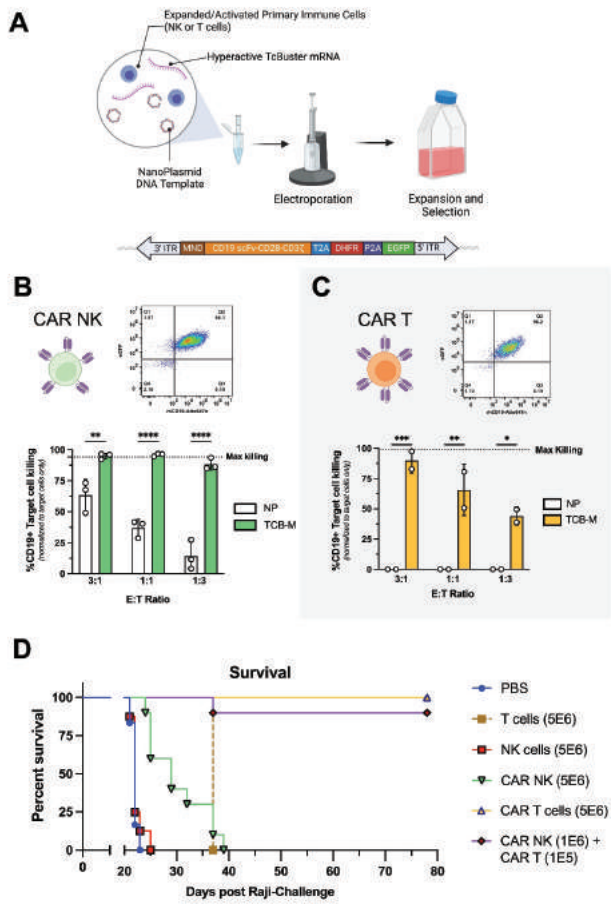

Figure 1. CAR NK and T cells engineered via TcB-M show enhanced in vitro and in vivo specific killing of target Raji cells and can be combined for an effective single-dose combination therapy. (A) Summary of hyperactive TcBuster (TcB-M)-based primary immune cell engineering with large-cargo construct (3.7kb, bottom) and expansion. (B) MTX-selected NK cells (n=3 donors) or (C) MTX-selected T cells (n=2 donors) from the pipeline show near 100% CD19-CAR expression and were co-cultured with luciferase-expressing, CD19+ Raji cells. Specific killing was measured by a luciferase-based assay. (D) Raji-tumor bearing NSG mice treated with a single dose CAR NK, CAR T, or a combination of sub-optimal CAR T + CAR NK show improved survival and control of tumor growth. Our work reveals an enhanced platform for rapid delivery of multicistronic vectors via transposition in both primary human NK and T cells. Through combining CAR NK and sub-therapeutic CAR T dosages, we were able to show significant improvements in survival outcomes in a xenograft tumor model that may translate to improved clinical outcomes with reduced risks of CRS development. Overall, this

non-viral approach to engineering represents a versatile, rapid, safe, and cost-effective option for manufacturing of cellular therapies over traditional viral delivery methods.

AAV Development for Eye, Muscle, Kidney and CNS

327 Massive Diversity Capsid Screening and Machine Learning Identify Next-Generation AAV for Targeted Tissue Biodistribution

Thomas A. Packard, Kevin C. Stein, Erica A. Cates, Jeremy E. Bazinet, W. Daisy Han, Yue Jiang, Maria F. Andrade, Thomas J. Long, David J. Huss, Ronald J. Hause, Adrian W. Briggs

Shape Therapeutics, Inc., Seattle, WA

Gene therapies using adeno-associated viruses (AAVs) hold great promise for the treatment of a wide range of diseases. However, current therapies using wild-type AAV often suffer from high transduction of off-target tissues, particularly in the liver and dorsal root ganglia (DRG). This limitation decreases therapeutic efficacy and increases toxicity, making the development of improved AAV capsids essential to advancing the clinical application of gene therapy. Previous capsid engineering strategies have generally been limited to libraries of relatively low diversity (e.g., <1 million capsid variants), thus sampling only a small portion of the vast possible space of capsid design, and typically only comparing single target tissues of interest to liver. To overcome these limitations, the AAVid™ capsid discovery platform leverages massive diversity capsid libraries and direct-to-non-human primate (NHP) biological selection to generate a high-resolution map of how the AAV mutational space affects capsid assembly and tissue tropism. A combinatorial library of one billion capsid variants was generated, featuring mutations in the sialic acid binding pocket of the AAV5 backbone (AAV5id). This library was screened in four adult cynomolgus macaques (two males, two females), resulting in the recovery of over 30 million unique AAVid capsid sequences from over 50 distinct tissues. A novel computational pipeline was developed to analyze this primary dataset, allowing for the identification and advancement into functional secondary screens of high-confidence capsid variants for a given tissue of interest (positive selection) while de-targeting other tissues (negative selection). Additionally, we developed generative machine learning (ML) strategies to design novel, unseen *in silico* capsid variant sequences predicted to have a high probability of tissue specificity. Using these methodologies, we identified CNS-, skeletal muscle-, and cardiac muscle-targeting capsid variants following intravenous administration of the primary screening library in NHPs. We validated these capsid variants in a secondary screen in four additional NHPs that quantified targeted functional transduction using universal or cell type-specific promoters. From this screen, we identified capsid variants with 10x to 1000x enrichment of DNA and RNA in target tissues relative to all other harvested tissues and compared with wild-type AAVs. Notably, our unseen, ML-designed capsid variants were overrepresented among the tissue-specific variants, highlighting the power of our generative ML approach. Our liver inclusion and exclusion score achieved an AUC of 0.96, allowing us to a priori design capsids with greatly reduced risk of hepatotoxicity. Overall, our results demonstrate the success of ML-guided discovery of next-generation AAV capsids with targeted biodistributions. With our data spanning nearly 50 unique tissues in NHP, this new generation of tissue-tropic AAVs will help advance the development of more effective and safer gene therapies against a wide variety of diseases.

328 Side-by-Side Comparison of Systemic AAV8, 9 and rh74 Transduction in Human Muscle

Matthew J. Burke[1], Yongping Yue[1], Jin Han[1], Caroline C. Parry[1], Michael E. Nance[1], Gang Yao[2], Dongsheng Duan[1,2,3]

[1]Department of Molecular Microbiology and Immunology, University of Missouri School of Medicine, Columbia, MO,[2]Department of Chemical and Biomedical Engineering, University of Missouri College of Engineering, Columbia, MO,[3]Department of Biomedical Sciences, University of Missouri College of Veterinary Medicine, Columbia, MO

Adeno-associated virus (AAV) serotype-8, 9, and rh74 are currently used in multiple clinical trials to treat inherited neuromuscular diseases (e.g., Duchenne muscular dystrophy, spinal muscular atrophy, and myotubular myopathy, etc.). These serotypes were chosen mainly because of their outstanding muscle transduction efficiency in mice following intravenous injection. It is unclear whether this superior systemic muscle transduction can be translated to humans. Previous studies have shown that AAV performance is species-dependent (Human Gene Therapy 24:584-594, 2013; Molecular Therapy-Methods & Clinical Development 1:14002, 2014; Human Gene Therapy 26:54-61, 2015). There is an urgent need to profile AAV transduction in human muscles following systemic delivery. To address this issue, we developed a human muscle xenograft model. In this model, human donor muscle was engrafted in the tibialis anterior compartment of adult immune-deficient NSG mice. Human muscle regeneration was examined 1, 2, and 4 months after grafting. Human muscle underwent degeneration and necrosis in the first month. Robust regeneration was observed in the second month by embryonic myosin heavy chain immunostaining. Human muscle was fully regenerated by the 4th month and expressed both type I and type II myofibers. On morphometric quantification, human myofibers occupied >75% of the total area of the grafts. A pilot dose-finding study was conducted using an AAV9 vector that expressed the heat-resistant placental alkaline phosphatase reporter gene under the transcriptional regulation of the Rous sarcoma virus promoter (RSV.AP). The dose of 5E+12 vg/kg yielded unsaturated AP expression and was used in subsequent studies. AAV8.RSV.AP (n=6), AAV9. RSV.AP (n=4), and AAVrh74.RSV.AP (n=5) were delivered to mature human muscle grafts via tail vein injection. One month after AAV injection, we quantified (i) AP expression by histochemical staining in cross-sections, (ii) AP activity in tissue lysate, (iii) AAV genome copy number, and (iv) AAV transcript copy number in human muscle grafts and host mouse livers. We have collected tissues from injected mice and are in the process of quantifying DNA, RNA, and protein-level transduction. We will report our results at the annual conference.

329 Identification of Natural Retinotropic AAV2 Variants with Functionally Enhanced VP1 Unique Regions

Mengtian Cui[1], Shun-Yun Cheng[1], Qin Su[1], Joae Wu[1], Jackson McGowan[1], Brian Rossmiller[1], Meiyu Xu[1], Guangchao Xu[2], Li Luo[2], Wanru Qin[1], Bo Tian[1], Yuquan Wei[2], Haijiang Lin[1], Claudio Punzo[1], Phillip WL Tai[1,3], Guangping Gao[1,3]

[1]UMass Chan Medical School, Worcester, MA,[2]Sichuan University, Chengdu, China,[3]Co-corresponding Authors, Worcester, MA

Adeno-associated viruses (AAVs) have become the ideal gene therapy vectors, particularly for treating inherited retinal diseases (IRDs). Several AAV vector-based clinical trials for IRDs are currently underway. Unfortunately, the large diversity of IRDs, which affect multiple retinal layers and cell types, complicates the development of novel treatments.Furthermore, concerns for low transduction profiles, vector-mediated toxicity at high doses, and immune side effects have sparked the need for novel capsids that can outperform contemporary serotypes following intravitreal (IVT) injection. To meet this need, we have identified from human tissues >200 AAV proviral capsid sequences and have screened their capacity to transduce retinal tissues by IVT injection in mice. Through this approach, we have identified two AAV serotype 2 (AAV2) variants that confer strong tropism to the retina. Interestingly, we found that these variants only differ from AAV2 by one or two residues found in the VP1 unique (VP1u) region. This poorly-studied region contains an essential phospholipase A2 (PLA2) domain, a calcium-binding domain, and nuclear localization sequences. VP1u is reported to play crucial roles in endosomal trafficking and escape, nuclear entry, and genome release *vitro*. Recent research by others have shown that enhancing PLA2 activity can simultaneously improve transduction and reduce immunogenicity, but how the PLA2 domain participates in AAV transduction and affects tropism remains unclear. We found that the two VP1u-altered variants, tentatively named v149 and v152, showed three-fold better transduction than AAV2. Furthermore, v149 and v152 exhibited near equal levels of transduction *in vitro* and *in vivo* as the leading retinotopic capsid, AAV2.7m8. When scAAV vectors packaged with v149 and v152 capsids are delivered by IVT injection in mice, transduction of amacrine and horizontal cells are two-fold better than what is achieved by AAV2 and AAV2.7m8; and two-fold more in ganglion cells and three-fold more in photoreceptors than conferred by AAV2. In exploring the function of the variant-defining residues, we showed that they confer higher cell surface binding and faster perinuclear localization. We also combined the variant-defining residues into one novel capsid design (AAV2.MC1), and tested its performance *in vivo*. We found that AAV2.MC1 is four-fold better than AAV2.7m8 following IVT injection (1E9 vg/eye). Furthermore, we demonstrate that because the VP1u region is highly conserved between the known AAV serotypes, the variant-defining residues of v149 and v152 have the capacity to be grafted onto other engineered capsids to further boost performance. For example, grafting the VP1u variant residues onto AAV2.7m8 increased transduction efficiencies in the mouse retina by three- to five-fold. Our major finding from this study is that transduction can be significantly impacted by the VP1u region, a domain that remains relatively untouched from current AAV capsid engineering efforts. These insights uncover new potential strategies for enhancing AAV vector performance via improving mechanisms for post-entry. This work also provides new retinal gene therapy capsids for evaluation.

330 Modification of Capsid Surface Residues in AAV2 for Improved Retinal Tropism

Jacqueline Bogedein[1], Sabrina Babutzka[1], Hildegard Buening[2], Stylianos Michalakis[1]

[1]Department of Ophthalmology, University Hospital, LMU Munich, Munich, Germany,[2]Laboratory for Infection Biology and Gene Transfer, Institute of Experimental Haematology, Hannover Medical School, Hannover, Germany

Recombinant adeno-associated virus (AAV) vectors are the current gold standard in retinal gene therapy. The availability of several naturally occurring serotypes combined with low toxicity and well-established production methods favor their use as vectors for gene therapies. In the context of retinal diseases, the AAV2 serotype is the most commonly used vector with a good native tropism for retinal cells. Despite the success, there are still hurdles, such as the need of challenging injection routes and viral component-induced immune responses after vector administration. To overcome such obstacles, AAVs with improved characteristics are needed. Here we aimed to optimize previously described next generation AAV variants by rational design to optimize cell-specific targeting and/or mitigate immune responses. Specifically, starting with AAV2.GL and AAV2.NN, surface exposed residues known to be part of previously described antibody recognition sites were modified by either peptide insertion or amino acid substitution, or a combination of both. The resulting variants, namely AAV2.GL.F, AAV2.GL.G, AAV2.GL.453 and AAV2.NN.F, AAV2.NN.G, AAV2.NN.453 could be produced at stable titers and lead to high transduction efficiencies *in vitro* (e.g. 66.19%, 53.06% 72.08%, compared to parent variants with 13.75% and 35.99% at a MOI of 250). Escape from neutralization was assessed using an *in vitro* neutralization assay. After pre-incubating the novel variants with human serum containing neutralizing antibodies, the transduction properties of the vector/serum mixture were evaluated. AAV2.GL and AAV2.NN already showed lower neutralization than wild type AAV2. Despite their improved transduction efficiency, the new, further modified capsid variants could not reduce neutralization by various human sera tested beyond that observed for AAV2.GL and AAV2.NN. The promising transduction potential was further examined after intravitreal injection in wild type mice by *in vivo* confocal scanning laser ophthalmology and by immunohistochemistry. To examine the superior behavior of the new capsid variants in a dose dependent manner, two doses (1E09 and 5E09 total vg) were tested. Results showed superior transgene expression three weeks post injection in all novel capsid variants compared to AAV2.GL and AAV2.NN. At the low dose, AAV2.GL.F was the variant that produced the highest retinal gene expression *in vivo*. The superior transduction behavior was also confirmed in an *ex vivo* human retinal tissue culture model, where all novel capsid variants resulted in high transgene expression. These results suggest that modification of individual capsid surface residues allows further enhancement of the transduction properties, efficiency, and tissue tropism of AAV capsids, while it may not be sufficient to attenuate neutralization.

331 Evolving Nephrotropic AAV Variants Using Ex Vivo NHP Kidney Perfusion and Human Kidney Organoids

Alan Rosales[1], Leo O. Blondel[2], Qimeng Gao[2], Andrew S. Barbas[2], Aravind Asokan[3]

[1]Biomedical Engineering, Duke University, Durham, NC,[2]Surgery, Duke University, Durham, NC,[3]Duke University, Durham, NC

Kidney diseases are estimated to affect 37 million people in the US, with nearly 810K Americans living with kidney failure - underscoring the crucial need for effective kidney gene delivery vehicles. Building on previously reported success in engineering cross-species compatible AAV (ccAAV) capsids, we adapted our structure-guided approach to evolve new variants in human kidney organoids. In addition, we developed an ex vivo rhesus macaque kidney perfusion using both ureteral and arterial routes to cycle AAV capsid libraries. By employing evolution schemes across different kidney systems (intravenous in mice and pigs, human organoid cultures and ex vivo organ perfusion), we discovered multiple new AAV variants. Notably, the ureteral and arterial perfusions yielded distinct capsid sequences, highlighting the importance of route of vector administration. High capsid protein sequence convergence was also observed in the case of several variants enriched from different approaches. Two novel AAV variants, AAV.k20 and AAV.k13, displayed robust transduction efficiency in murine kidneys following IV administration. Both variants revealed higher transgene expression compared to AAV9 and AAV.cc47, in particular, within the proximal tubules as indicated by immune-colocalization with lotus tetragonolobus lectin (LTL) staining. We also observed robust transgene expression using AAV.k20 and AAV.k13 vectors in human kidney organoids, corroborating murine data. The approach described here can also potentially be extended to ex vivo human kidney perfusion. Nephrotropic AAV variants represent promising delivery vehicles for therapeutic kidney gene transfer applications.

332 An Integrin-Targeting AAV Developed by a Novel Computational Rational Design Methodology Presents an Improved Targeting to the Skeletal Muscle and Reduced Tropism to the Liver

Ai Vu Hong, Laurence Seul-Petat, Alejandro Arco Hierves, Jérôme Poupiot, Isabelle Richard

GENETHON, Evry, France

Adeno-associated virus (AAV) have shown potential as a gene therapy vector due to its efficiency in delivering transgenes and low toxicity. However, its effectiveness can be limited by non-optimal tissue targeting and accumulation in the liver. High doses are often required to achieve therapeutic efficacy, particularly in the treatment of muscular diseases where the target tissue represents half the body mass. Such doses can lead to severe adverse effects, including hepatotoxicity as seen in recent clinical trials. With primary aim to lower treatment doses, we present here a novel methodology for AAV computational rational design targeting skeletal muscle, resulting in a new myotropic AAV variant. First, integrin alpha V beta 6 (AVB6) was selected from screening of potential receptors with high enrichment in skeletal muscle tissue compared to other organs. A liver-detargeting AAV capsid backbone, a hybrid between AAV-9 and -rh74 (AAV9rh74), was then engineered to specifically bind to AVB6. Inspired by recent successes of various protein design studies, we modified the entire loop of variable region IV from its predicted 3D structure in such way that the designed capsids acquire the RGDLxxL/I motif structure, which allows a high-affinity binding to AVB6 but remain stable thanks to low estimated energy. Five AAV variants from *in silico* design were experimentally tested. Compared to AAV9 or AAV9rh74, all designed AAVs showed similar productivity, better binding to AVB6, and greater infectivity towards human differentiated myotubes and murine skeletal muscles *in vivo* while entering poorly in the liver. One notable variant, LICA1, greatly increases transgene expression at 16.6/25.0-fold greater in human myotubes, and murine skeletal muscle at 13.7/129.3-fold greater than AAV9 and AAV9rh74, respectively. We further examined its efficacy, in comparison with AAV9, in delivering therapeutic transgenes in mouse models of Duchenne muscular dystrophy and limb-girdle muscular dystrophy R3 at a low dose of 5E12 vg/kg. At this dose, AAV9 is suboptimal where it can only infect 22.1-58.1% of total muscle fibers. In contrast, LICA1 effectively delivered and expressed transgenes in 74.8% myofibers in severely affected diaphragm, or at almost 100% in other tested muscles. Consequently, LICA1 corrected pathohistology by lowering centro-nucleation index and fibrosis, and restored global transcriptomic dysregulation. Interestingly, the anti-capsid antibody in LICA1 one-month treatment in DMD mice halves compared to AAV9 indicating lower immunogenic profile. Furthermore, compared to state-of-the-art myotropic AAVs identified by high-throughput screening, LICA1 is more specific since it targets skeletal muscle at similar level but accumulates less in liver. These results suggest the potential of our methodology for AAV engineering and our designed AAV for the gene therapy treatment of muscular diseases. The manuscript of this work is under preparation for submission.

Genome & Epigenome Editing Technologies II

333 A Novel Engineered U7 Small Nuclear RNA (snRNA) Scaffold Increases ADAR-Mediated Programmable RNA Base Editing

Susan M. Byrne, Stephen M. Burleigh, Robert Fragoza, Ricky Pabon, Yue Jiang, Adrian Briggs

Shape Therapeutics, Inc., Seattle, WA

RNA base editing presents a promising therapeutic approach for treating genetic disease, alleviating concerns of permanent DNA damage or immunogenicity from foreign bacterial proteins such as CRISPR/Cas. The naturally expressed human Adenosine Deaminase Acting on RNA (ADAR) enzyme can be directed to edit specific RNA targets by antisense guide RNAs (gRNAs), which anneal to a transcript and recruit ADAR to create targeted adenosine-to-inosine (effectively A>G) changes. For durable and potential one-time therapies, gRNAs can be delivered in genetically encoded form. However, a major challenge for RNA editing with gene-encoded gRNAs and endogenous levels of ADAR is achieving sufficient expression and function of the gRNA inside target cells, especially in

therapeutic situations where AAV delivery may be limited to around one viral genome per cell. Here we show that embedding antisense gRNAs into the framework of a natural small nuclear RNA (snRNA) design greatly increases the efficiency of custom RNA editing. We demonstrate that ADAR gRNAs coupled to an Optimal Sm-binding domain (SmOPT) and U7 snRNA hairpin sequence increased RNA base editing relative to ADAR gRNAs without the snRNA framework. Furthermore, robust editing was observed without the need for ADAR overexpression, demonstrating the recruitment of the cells' endogenous ADAR for programmable RNA editing. Adding an hnRNP A1 domain to the antisense guide RNA further improved editing. Importantly, no unwanted effects on transcript splicing or knockdown were detected. The increased editing efficiency provided by the SmOPT and U7 hairpin allowed for detectable RNA editing from a single genomically-integrated copy of gRNA construct per cell, which enabled us to further evolve the system by performing a pooled library screen of >700 gRNA variations against three separate gene transcripts in cell culture. This approach allowed us to identify critical residues required for RNA editing and revealed improved SmOPT and U7 hairpin variants that further boosted RNA editing relative to the original SmOPT and U7 hairpin. Coupling our improved SmOPT and U7 hairpin variants to gRNAs resulted in up to 76% targeted editing from a single integrated DNA copy of the gRNA construct, representing a 10-100-fold increase over previous approaches. Furthermore, our new SmOPT U7 variants also show promise for non-ADAR based therapies, increasing the efficiency of published antisense constructs for DMD exon skipping by several fold in differentiated myoblasts. In summary, our improved snRNA framework consistently enables high efficiency programmable RNA editing across many target sites under endogenous ADAR levels. These results demonstrate that our novel SmOPT and U7 hairpin variants provide great promise as a universal scaffold for ADAR-based RNA editing as well as other antisense RNA therapies.

334 Improving the Precision and Fidelity of Cas9 and PEn Mediated Gene Editing through Pharmacological Treatment

Marcello Maresca

Genome Engineering, AstraZeneca-Gothenburg, Moendal, Sweden

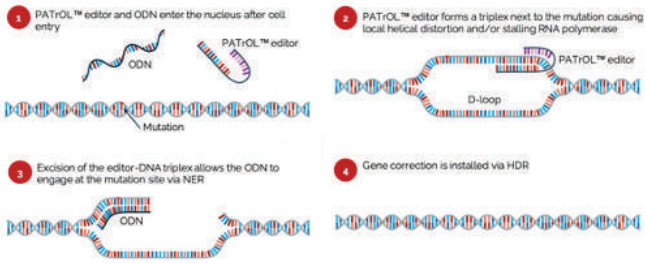
Genome editing tools, particularly CRISPR/Cas9-based methods, have revolutionized biomedical research and created possibilities for developing curative treatments for genetic disorders. Despite rapid advancements, low efficiency of targeted DNA integration and generation of unintended mutations remain significant barriers for genome editing applications. These issues stem from the interplay between Homology-Directed Repair (HDR), Non-Homologous End Joining (NHEJ), and Microhomology-Mediated End Joining (MMEJ) DNA Double-Strand Break (DSB) repair pathways. To enhance the efficiency of CRISPR-Cas9 genome editing, we developed pharmacological treatments to improve the efficiency of Cas9 and Prime Editing nucleases (PEn) mediated knock-in. Specifically, treatment with AZD7648 and Pol-Theta inhibitors (referred to as 2iHDR) significantly enhanced HDR-mediated insertion precision, with efficiencies of up to 80% and nearly no generation of unwanted Insertion-Deletions (InDels). AZD7648 treatment also increased PEn-mediated insertion precision and reduced InDels. Importantly, these strategies reduced Cas9-related off-target effects, significantly enhancing the performance and accuracy of CRISPR-Cas9 gene editing and primed insertions.

335 Nuclease-Free Gene Editing with Peptide Nucleic Acids: A New Class of *In Vivo* Gene Editors

Dani M. Stoltzfus, William Riedl, Lyuqin Chen, Lindsey R. Spiker, Steven M. Murphy, Nathan Tavenor, Barry Badeau, Jeremy W. Gleaton, Dietrich A. Stephan

NeuBase Therapeutics, Pittsburgh, PA

Gene editing promises permanent cures to genetic diseases. Early generations of gene editing technologies (e.g., generations of CRISPR/Cas and base editors) have suffered from fidelity (off-target and by-stander edits) and toxicity (including double stranded breaks) issues, which may limit their ability to be successfully administered *in vivo*. Additionally, these first-generation editors have a requirement for a protospacer adjacent motif (PAM) sequence directly adjacent to the causal variant of interest and are constrained to gene disruption or editing transition mutations, meaning the total addressable market of all such editors, combined, is ~20% of known genetic mutations in ClinVar. The introduction of prime editing (PE) resolves some of the limitations of these earlier technologies, by relaxing the PAM sequence constraint and allowing editing of transversions, insertions, and deletions such that an estimated 90% of all genetic mutations are now technically addressable. Challenges that remain include the ability to be flexible in delivery approaches such that editors can be delivered to a variety of tissues that manifest pathologies, improving fidelity to maximize safety, and overcoming the likely acquired immunogenicity of a bacterial nuclease which could limit the ability to re-dose a patient to address tissue turnover. We have developed a technology platform, PATrOL™, comprised of modified peptide nucleic acids (PNAs). These editors are PAM-sequence unrestricted, can address all mutational types, have fidelity rates on the order of background mutational rates in human cells, and which have additional advantages over PEs in that we have flexibility in delivery and do not elicit an acquired immune response. PATrOL™ editors engage the double-stranded genome with single base selectivity to recruit endogenous nucleotide excision repair (NER) and homology directed repair (HDR) enzymes which replace the disease-causing mutation with the correct sequence. This approach uses multiple layers of sequence selectivity for a locus of interest and relies on the body's own endogenous high-fidelity machinery to reduce off target editing to well below that reported for BEs. The editors themselves are on the order of 100 nucleobases in total length and are charge-tunable to allow use with various delivery technologies. Finally, due to the synthetic nature of the editors themselves, there has not been an acquired response reported to date. In combination with non-immunogenic lipid nanoparticle delivery, the PATrOL™ editors have the potential to unlock repeat dosing *in vivo* to address tissue turnover and achieve clinically relevant editing efficiencies. Data will be presented that describes the performance of our nuclease-free editing platform and how the technology in being applied to address several monogenic diseases that remain of high unmet need.



336 Compact Engineered Human Mechanosensitive Transactivation Modules Enable Potent and Versatile Synthetic Transcriptional Control

Isaac Hilton

Bioengineering, Rice University, Houston, TX

Gene and cell therapies can be broadly enabled using engineered transactivation domains (TADs) combined with programmable DNA binding platforms. Despite recent progress in programmable CRISPR/Cas-based transactivation (CRISPRa) technologies, the TADs used in these systems often contain viral elements and/or are prohibitively large for many applications. Here we defined and optimized minimal TADs built from human mechanosensitive transcription factors (MTFs). We used these components to construct potent and compact multipartite transactivation modules (MSN, NMS, and eN3x9) and to build the CRISPR-dCas9 recruited enhanced activation module (CRISPR-DREAM) platform. We found that CRISPR-DREAM was specific, robust across mammalian cell types, and efficiently stimulated transcription from diverse regulatory loci. We also showed that MSN and NMS were portable across Type I, II, and V CRISPR systems, TALEs, and ZF proteins. Further, as a proof of concepts, we used dCas9-NMS to efficiently reprogram human fibroblasts into iPSCs and demonstrated that MTF TADs are efficacious and well tolerated in therapeutically important primary human cell types. Finally, we leveraged the compact and potent features of these engineered TADs to build new dual and all-in-one CRISPRa AAV systems. Altogether, these compact human TADs, fusion modules, and new delivery architectures should be valuable for synthetic transcriptional control in a wide range of gene and cell therapy and assocated biomedical applications.

337 CRISPR Assisted Trans-Splicing of RNA Fragments

David N. Fiflis[1], Nicolas Rey[2], Sydney Milo[1], Aravind Asokan[3]

[1]Biomedical Engineering, Duke University, Durham, NC,[2]Biology, Duke University, Durham, NC,[3]Duke University, Durham, NC

We introduce a CRISPR-based RNA editing approach that hijacks the cellular spliceosomal machinery to promote trans-splicing between an endogenous target pre-mRNA and a recombinant RNA fragment. To achieve such, a catalytically dead Cas13 nuclease (dCas13) is paired with a recombinant trans-splicing RNA molecule. The latter is comprised of a Cas13 guide RNA linked to a hemi-intronic sequence and one or more recombinant exons. The resulting ribonucleoprotein complex is guided to an endogenous target pre-mRNA yielding a chimeric messenger RNA via trans-splicing. This approach, referred to herein as CRISPR Assisted Fragment Trans-splicing (CRAFT), can be utilized to replace one or more exons in the 5' or 3' region of any endogenous mRNA. We demonstrate robust CRAFT mediated mRNA editing across multiple targets within the transcriptome. Further, we describe a rigorous fluorescence-based screen to optimize guide selection. CRAFT is a broadly applicable and versatile RNA editing platform, with potential applications as a research tool for interrogating RNA biology and for therapeutic applications.

338 Precise Cut-and-Paste DNA Insertion Using Engineered Type V-K CRISPR-Associated Transposases

Connor Tou[1], Benno Orr[2], Benjamin P. Kleinstiver[3]

[1]MIT & Mass General Hospital, Cambridge, MA,[2]Massachusetts General Hospital & Harvard Medical School, Boston, MA,[3]Massachusetts General Hospital, Boston, MA

CRISPR-associated transposases (CASTs) enable recombination-independent, multi-kilobase DNA insertions at RNA-programmed genomic locations. However, the utility of type V-K CASTs is hindered by high off-target integration and a transposition mechanism that results in a mixture of desired simple cargo insertions and undesired plasmid cointegrate products. Here we overcome both limitations by engineering new CASTs with improved integration product purity and genome-wide specificity. To do so, we engineered a nicking homing endonuclease fusion to TnsB (named HELIX) to restore the 5´ nicking capability needed for cargo excision on the DNA donor. HELIX enables cut-and-paste DNA insertion with up to 99.4% simple insertion product purity, while retaining robust integration efficiencies on genomic targets. HELIX has substantially higher on-target specificity than canonical CASTs, and we identify several novel factors that further regulate targeted and genome-wide integration. Finally, we extend HELIX to other type V-K orthologs and demonstrate the feasibility of HELIX-mediated integration in human cell contexts.

339 *De Novo* Design of 26S Proteasome Recruiters with Language Model-Derived Guide Peptides

Vivian Yudistyra[1], Lauren Hong[1], Sophie Vincoff[1], Garyk Brixi[1], Tianlai Chen[1], Pranam Chatterjee[2]

[1]Biomedical Engineering, Duke University, Durham, NC,[2]Duke University, Durham, NC

The human proteome consists of around 20,000 proteins, many of which can acquire or present pathogenic consequences in disease states. A subset of these are considered "undruggable" by standard pharmacological techniques using small molecules, due to their unstable structural conformations, localizations, and/or post-translational modifications. Targeted protein degradation (TPD) represents a powerful modality to eliminate pathogenic proteins via the ubiquitin-proteasomal system. However, small molecule-based TPD platforms, such as PROTACs and molecular glues, rely on accessible binding sites on structured protein targets. In this study, we leverage robust protein language models, trained on millions of natural amino

acid sequences to grasp key biochemical, structural, functional features of input protein sequences, to generate target-specific "guide" peptides specific to pathogenic proteins of interest. As a genetically-encoded PROTAC analog, we fuse these guide peptides to 26S proteasome recruiters, and demonstrate robust degradation of diverse target proteins in human cells, including membrane proteins, transcription factors, and fusion oncoproteins. We further demonstrate that our constructs exhibit high specificity via whole-cell proteomics, and can effectively degrade oncogenic drivers, including β-catenin in colorectal cancer cells and EWS-FLI1 in Ewing sarcoma cellular models. Overall, our compact, programmable, genetically-encoded degradation strategy presents exciting opportunities for downstream in vivo studies and clinical translation.

Ophthalmic and Auditory Diseases

340 A Mutation-Independent RNA Replacement Approach Based on a RHO-Targeting Trans-Splicing Ribozyme for the Treatment of Autosomal Dominant Retinitis Pigmentosa (adRP)

Jihyun Kim[1], Ji-na Kim[1], Minyoung Cho[1], Archana Jalligampala[2], Maureen A. McCall[2,3], Seong-Wook Lee[1]

[1]R&D Center, Rznomics Inc., Seongnam-si, Korea, Republic of,[2]Ophthalmology and Visual Sciences, University of Louisville School of Medicine, Louisville, KY,[3]Anatomical Sciences and Neurobiology, University of Louisville School of Medicine, Louisville, KY

Retinitis Pigmentosa (RP) is the most common hereditary degenerative eye disease and caused by abnormalities in retinal photoreceptors (rods and cones) or the retinal pigment epithelium (RPE). Rhodopsin mutations account for about 25~30% of adRP. Although a single Pro23His (P23H) mutation in the rhodopsin (RHO) gene is currently known to be the most common cause of adRP in North Americans, over 150 autosomal dominant mutations also have been identified in the *RHO* gene. Group I intron-based trans-spicing ribozyme reprograms target RNA into a gene of interest through RNA replacement. In this study, we developed a specific trans-splicing ribozyme in a mutation-independent therapeutic strategy that can replace, and thus edit endogenous RHO RNA with exogenous functional RHO RNA and delivered it using adeno-associated virus (AAV). The most accessible target site of rhodopsin RNA was identified by RNA mapping, using a ribozyme library. Sequencing analysis of trans-splicing reaction sites revealed that the most efficient target site occurred at the base (U) in RHO RNA 5' UTR. To improve the trans-splicing specificity and efficiency of the ribozyme, we modified and optimized the structure of the ribozyme targeting the most accessible site of target RHO RNA. The candidate with the highest trans-splicing efficiency was then selected through comparative analysis in vitro using cells. Of note, we observed that various mutant RHO RNAs were trans-spliced with high fidelity and replaced with wild-type (WT) RHO RNA by the RHO-targeting ribozyme in cells. To verify in vivo function, an AAV vector, encoding the optimal RHO-targeting ribozyme, was constructed and bilaterally delivered by subretinal injection into the eye of P23H human RHO (hRHO) knock-in mice at postnatal week 5. Control groups are untreated or bilaterally PBS-treated knock-in mice. We evaluated rod isolated retinal function using the electroretinogram (ERG) in AAV-treated and control mice up to 26 week post injection (wpi). In contrast to controls, the b-wave amplitudes of AAV-treated eyes showed significant and dose-dependent increases which were maintained until 26 wpi. Molecular and cellular analysis of retina tissue showed that P23H RNA was replaced with WT RHO with high efficacy and fidelity and the outer nuclear layer (ONL) appeared significantly thicker in the RHO-targeting ribozyme treated areas in eyes. In addition, we delivered AAV encoding the RHO-targeting ribozyme via subretinal injection to both eyes of TgP23H hRHO pigs between postnatal days 3 to 7. From birth, untreated TgP23H hRHO pigs have no rod-isolated ffERG response. Eyes injected with AAV gained a significant rod-isolated ffERG response across all viral titers, first observed at 8wpi and lasting through 28wpi. Within the RHO-targeting ribozyme treated areas, Tg rods had elongated inner and outer segments (IS/OS) and thicker ONL compared with untreated areas in the same eye and the untreated/vehicle-treated eyes. Here, we proved that the ribozyme effectively prevents rod photoreceptor degeneration and preserves their function in both P23H hRHO knock-in mice and adRP TgP23H hRHO pig models through specifically targeting and trans-splicing of target RHO RNA. Taken together, these results suggest that RNA replacement based on RHO-targeting ribozymes could be a potential mutation-independent therapeutic strategy for RHO-adRP patients.

341 Massively Parallel and Systematic Engineering Platform for Highly Compact, Cell-Type Specific, and Potent Smart Sensor Promoters for Precision Retinal Gene Therapies

Joseph Draut[1], Thant Zaw[1], Myles MacEachern[1], Magdalena Cichewicz[1], Assen Roguev[1], Jang Hwan Cho[2], Daniel M. Cohen[2], Laura Barrio Real[2], Shreyasi Choudhury[3], Ali Nahvi[3], Jed Chatterton[2], Virginia A. Haurigot[2], Sean M. Armour[2], Federico Mingozzi[2], Rocky Chueng[4], Michelle Hung[1], Frances Liu[1], Rebecca Cottman[1], Nicholas Frankel[1], Tony Hua[1], Gary K. Lee[4], Curt Herberts[4], Philip Lee[1], Timothy Lu[1], Russell Gordley[1]

[1]Senti Biosciences, Inc., South San Francisco, CA,[2]Spark Therapeutics, Inc., Philadelphia, PA,[3]former employee of Spark Therapeutics, Inc., Philadelphia, PA,[4]former employee of Senti Biosciences, Inc., South San Francisco, CA

Adeno-associated viral (AAV) gene therapy is increasingly becoming an important therapeutic modality for ocular diseases, with demonstrated efficiency of gene delivery and relative lack of toxicity. However, a risk of toxic host-eye responses has been observed with some AAV vectors. A contributing factor may be promoter promiscuity that leads to AAV-mediated transgene expression in off-target cells, such as the retinal pigment epithelium (RPE). Ectopic expression of a therapeutic transgene may be a trigger for cell stress and/or inflammatory responses [5]. With the aim of satisfying the critical needs of both safety and efficacy, we generated compact, synthetic Smart Sensor promoters that are highly active in photoreceptor cells and relatively silent in RPE cells. We pursued two design approaches in parallel: 1)

high-throughput pooled screening of short, fully synthetic promoters and 2) clonal screening of longer elements derived from endogenous promoters and putative enhancers. For the first approach, we designed a pooled promoter library using transcription factor binding sites (TFBSs) identified through bioinformatics analysis of RNA-Seq datasets of primary cells. Tandem arrays of combinatorially arranged TFBSs were synthesized and screened as a pool in a Massively Parallel Reporter Assay (MPRA) in surrogate cell lines selected for both the ON target cell type (Y79 for photoreceptors) and the OFF-target cell type (ARPE-19 for RPE cells). For the second approach, differentially regulated promoters and enhancers, identified through bioinformatics analysis of RNA-Seq and DNase-Seq datasets, respectively, were cloned and screened individually by transient transfection. We developed a powerful analysis pipeline that leveraged the heterogeneity of individually transfected cells within a bulk population. Promoters and enhancers identified using this screen were systematically mutated to map core regulatory elements. The natural and synthetic core regulatory elements identified using these two approaches were combined to form chimeric promoters, yielding regulatory synergies that further boosted the strength and specificity of gene expression. This multi-pronged strategy yielded photoreceptor-specific synthetic promoters that achieve 100 to 10,000-fold specificity for the photoreceptor surrogate line Y79 over ARPE-19 (RPE), with expression levels equivalent to the strong constitutive CAG promoter currently in clinical use. All these potent synthetic promoters were 500 bp or less in length. Additionally, this effort uncovered highly compact promoters that retained strong selectivity for photoreceptors, albeit with reduced potency. Some of these compact promoters, as small as 130 bp, may be applicable to expression cassettes encoding large transgenes. These results validate our massively parallel and systematic workflow for designing highly compact, specific, and potent synthetic Smart Sensor promoters, which can be applied across various cell types and diseases of interest.

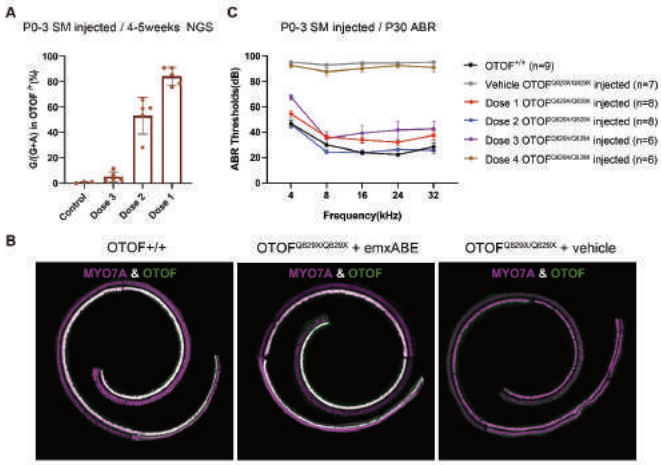
342 Rescue of *OTOF* Q829X Mutation-Induced Hearing Loss by *In Vivo* Delivery of Mini-dCas13X-Derived RNA Base Editor

Yuanyuan Xue[1], Xing Wang[1], Yuanhua Liu[2], Sifan Chen[1], Boou Yan[1], Yanwei Xie[1], Haitao Jia[1], Lanting Bi[1], Jingyu Zhang[1], Jinhui Li[1], Qingquan Xiao[1], Linyu Shi[1], Hui Yang[1,2]

[1]HuidaGene Therapeutics Co., Ltd., Shanghai, China,[2]Center for Excellence in Brain Science and Intelligence Technology, Chinese Academy of Sciences, Shanghai, China

Background: Hearing loss is one of the most common sensory disorders that affects approximately 5% of the world's population, which causes great burden to the society. Recessive deafness is mostly congenital and profound, and accounts for ~80% of all hearing impairment. Mutations in the otoferlin (*OTOF*) gene cause prelingual and profound recessive hearing loss. Nonsense mutation c.2485C>T (p. Q829X) in the exon22 of *OTOF* gene is responsible for about 3% of all cases of recessive prelingual deafness in the Spanish. Although hearing aids can provide significant benefits to patients and cochlear implantation is more suitable for severe-to-profound hearing loss to restore sound transduction, there is still unmet medical need for a one-time, precise, and permanent strategy to potentially cure the genetic hearing loss. Here we report a small size and low off-target RNA base editing tool (emxABE) to achieve high A-to-I conversion and restore hearing loss by *in vivo* AAV delivery of mini-dCas13X-derived RNA base editor (AAV-gOTOF-emxABE) to OTOF$^{Q829X/\ Q829X}$ mouse model. **Methods**: We constructed a humanized OTOF-Q829X mouse model, with part of the mouse *Otof* gene sequence replaced with human *OTOF* gene sequence containing the Q829X mutation. To achieve a better therapeutic effect, we first optimized and improved the editing efficiency of the mini-dCas13X-derived RNA adenine base editor (mxABE) on the premise of low off-target, and thus obtained the enhanced mxABE (emxABE) with higher editing efficiency. One AAV vector, comprising gRNA targeting *OTOF* (gOTOF) and emxABE, was constructed to develop a therapeutic strategy that restores the hearing function by conversing TAG to TGG, restoring the expression of OTOF protein by read-through of a premature stop codon. Postnatal day 0-3 (P0-3) humanized OTOF$^{Q829X/Q829X}$ mice were injected through scala media (SM). We further tested AAV-gOTOF-emxABE base editing strategy for the treatment of P30 humanized OTOF$^{Q829X/Q829X}$ mouse model by injecting AAVs through round window. The editing efficiency was tested by deep sequencing. The OTOF protein was detected by immunostaining and hearing function was measured by auditory brainstem response (ABR). The toxicity of emxABE tool was evaluated by hematoxylin-eosin staining of the cochlear. **Results**: emxABE achieved >80% A-to-I conversion efficiency at the RNA level in the P0-3 humanized OTOF$^{Q829X/Q829X}$ mice injected with AAV-gOTOF-emxABE (Fig. 1A), with >90% otoferlin expression restoration in inner hair cells (Fig. 1B). Auditory function was restored to the wild type range (Fig. 1C) and was observed up to 8 months post AAV-gOTOF-emxABE injection in OTOF$^{Q829X/Q829X}$ mice. In addition, no toxicity was observed in the treated OTOF$^{Q829X/\ Q829X}$ mice. Restoration of auditory function was also observed in OTOF$^{Q829X/Q829X}$ mice injected with AAV-gOTOF-emxABE at P5-7 and P30. **Conclusions**: Our findings not only provided a preferential clinical strategy for the treatment of OTOF-Q829X induced hearing loss, but also suggested that base editors as the promising toolkits may be a potential strategy for the treatment of genetic hearing loss or other kind of diseases in the future. To the best of our knowledge, we are the only group using base-editor strategy to potentially cure the genetic hearing loss caused by OTOF mutation.



343 Indirect Comparison of Lenadogene Nolparvovec Gene Therapy versus Natural History in m.11778mt-ND4 Leber Hereditary Optic Neuropathy Patients

Introduction: Lenadogene nolparvovec is a promising gene therapy for patients with Leber hereditary optic neuropathy (LHON) due to the m.11778G>A *MT-ND4* mutation. The purpose of this analysis was to compare the visual acuity of *MT-ND4* LHON patients treated with lenadogene nolparvovec in clinical trials to the spontaneous evolution of visual acuity in an external control group of untreated *MTND4* LHON patients. A previous analysis was performed on treated patients from three phase 3 studies. This updated analysis incorporates a fourth phase 3 trial, REFLECT, in which patients received lenadogene nolparvovec unilaterally or bilaterally. **Methods:** Individual visual acuity data of 174 *MT-ND4* LHON patients intravitreally injected in one or both eyes were pooled from four phase 3 trials: REVERSE, RESCUE, RESTORE and REFLECT. The external control group included 208 age-comparable (≥ 15 years old) untreated m.11778G>A *MT-ND4* LHON patients from 11 natural history studies. **Results:** Both cohorts were predominantly male patients (81.2%) with a median age at onset of vision loss of 26.0 years. Eyes treated with lenadogene nolparvovec had better visual acuity at all timepoints when compared to natural history eyes. Mean [95% confidence interval (CI)] difference versus natural history was 0.30 [0.39; 0.22] LogMAR (+15 EDTRS letters equivalent) at last observation ($p<0.01$) with a maximal follow-up of 3.9 years after treatment. When adjusting for covariates of interest (gender, age of onset, ethnicity, and duration of follow-up), the estimated mean [95% CI] difference was 0.43 [0.53; 0.33] LogMAR (+21.5 EDTRS letters) versus natural history at last observation ($p<0.0001$). Most treated eyes were on-chart (LogMAR ≤ 1.6) compared to less than half of natural history eyes at last observation (76.1% versus 44.4%; $p<0.01$). The treatment effect was larger in eyes of patients who received bilateral treatment than those of patients who received unilateral treatment. **Conclusion:** This comparison of treated patients with natural history patients confirmed a clinically meaningful and sustained improvement in visual acuity induced by lenadogene nolparvovec intravitreal injection in m.11778G>A *MT-ND4* LHON patients.

344 Development of a Mutation Independent Gene Therapy for Cone Reactivation in the Treatment of Retinitis Pigmentosa

Hanen Khabou[1], Cardillia-Joe Simon[1], Brix Mücher[2], Erin Livingston[3], Alain Quimbao[3], Phillip Vanlandingham[3], Rafal Farjo[3], Stefan Herlitze[2], Florence Lorget[1], Mehdi Gasmi[1], Deniz Dalkara[4]

[1]SparingVision, Paris, France,[2]Department of Zoology and Neurobiology, Ruhr-University Bochum, Bochum, Germany,[3]EyeCRO, Oklahoma City, OK,[4]Sorbonne Université, INSERM, CNRS, Institut de la Vision, Paris, France

We are developing genomic medicines for inherited retinal disorders and in particular adeno-associated virus-based gene therapies, independent of causative mutations. Our lead product SPVN06, aiming to improve cone outer segment renewal and viability at intermediate stages of the disease, has recently been approved for human clinical studies. SPVN20, currently in preclinical evaluation, is targeting cone photoreceptor cells at later stage of the disease when remaining cells have lost phototransduction function. Compared to other vision restoration strategies, SPVN20's mechanism of action would be compatible with restoration of color vision. GIRK1 is a G-protein gated inward rectifier potassium channel. This G-protein gated channel is originally found in the brain and the heart and controls neuronal excitability through hyperpolarization. This is achieved through co-expression of GIRK1 with other GIRK family members by forming heterotetramers. A mutant of GIRK1, referred to as GIRK1 F137S, forms functional homotetramers. In a human cell line (HEK), we first showed that when co-expressed with an opsin, human GIRK1 F137S (a G protein sensitive channel) generates a current upon light stimuli. These light-induced responses were measured by patch clamp recordings in vitro. We then asked whether GIRK1 F137S could be expressed in degenerating cones and improve their function in mouse models of RP. We optimized our expression cassette containing GIRK1 F137S transgene and chose PR1.7 cone specific promoter to control its expression. We treated rd10/rd10 mice, a rapid retinal degeneration mouse model. Subretinal administration of AAV8-GIRK1 F137S led to significant -but transient- functional improvements at 3 weeks after administration. Using immunohistochemistry, we detected GIRK1 F137S protein at the cell membrane of cones in AAV-treated rd10 retinas. Visual improvements were transient likely due to the low number of cones remaining at the later timepoints in this fast-progressing model. At advanced RP stages, retina is thinner and subretinal injection risky. Therefore, a desirable injection route in patients is the intravitreal (IVT) delivery, which is noninvasive to the retina. To determine whether GIRK1 F137S could be delivered to human cones, we used an engineered IVT-permissive AAV2 variant (AAVi), optimized for transducing retinal cells when delivered intravitreally. We transduced cone-enriched human retinal organoids using AAVi-PR1.7-GIRK1 F137S-GFP. GIRK1 F137S expression was found in human cones by immunohistochemistry, at the cell membrane, as observed in rd10 mice. Altogether, these encouraging in vitro and in vivo findings in mouse and human tissue

support exploring the potential of AAVi-GIRK1 F137S, with the aim of developing a noninvasive and restorative gene therapy product for late-stage RP patients.

345 Precise Targeting of GJB2 Cells Resulted in Safe and Efficacious Gene Therapy in a Rodent Model of Hearing Loss Due to GJB2 Deficiency

Kathryn Ellis[1], Yoojin Chung[1], Kasey Jackson[1], Theresa Abell[1], Joseph Goodliffe[1], Quynh-Anh Fucci[1], Chris Thompson[1], Madeline Barnes[1], Kevin Lebo[1], Sarah Cancelarich[2], Daniela Di Battista Miani[2], Leah Sabin[2], Meghan Drummond[2], Gabriela Pregernig[1]

[1]Decibel Therapeutics, Boston, MA,[2]Regeneron, Tarrytown, NY

Background: Mutations in Gap junction beta protein 2 (GJB2) are the leading cause of non-syndromic, prelingual deafness (DFNB1) worldwide. A major challenge in developing a gene replacement therapy is the ability to replicate the endogenous expression pattern in the cochlea, as GJB2 is expressed in a variety of cell types at different expression levels. A successful DFNB1 gene therapy must provide benefit by sufficiently targeting the diverse set of GJB2-expressing nonsensory cells but also must avoid toxicity by excluding expression from critical sensory cells. Here we demonstrate that selective targeting of GJB2-expressing cells results in robust and durable hearing restoration in a translationally relevant mouse model of GJB2 deficiency. Methods: Adult or neonatal mice were injected via the posterior semicircular canal with AAV encoding GJB2 or GFP driven by a ubiquitous promoter or GJB2 regulatory elements. Hearing was assessed using functional measures of auditory function (auditory brainstem response, otoacoustic emissions). Animals were sacrificed and immunohistochemistry was performed to assess cochlear morphology and transgene expression. Results: We leveraged integrative bioinformatic analyses of bulk and single cell epigenomic datasets to design combinations of GJB2 proximal promoter/enhancer regions that could mirror the endogenous GJB2 expression pattern. Candidates were screened in neonatal cochlear explants, identifying a series of combinations which drive expression in various groups of GJB2-expressing cells while excluding expression from hair cells and neurons. The expression profiles of the top candidates were confirmed *in vivo* in both mouse and non-human primates. Next, we evaluated the ability of our promoter/enhancer designs to restore hearing in a GJB2 deficiency mouse model. We demonstrate that several of our regulatory elements were able to drive hearing restoration in human GJB2 injected ears compared to contralateral ears and naïve controls. We show that our top candidate led to stable and durable hearing recovery in >75% of injected animals, achieving wildtype thresholds in the majority of animals. Finally, we also show that GJB2 overexpression under the control of these regulatory elements is safe in wild-type animals, compared to using a ubiquitous promoter, which leads to hair cell death and elevated hearing thresholds. This confirms that we successfully eliminated off-target toxicity by appropriately restricting GJB2 transgene expression. Conclusions: Our results underscore the importance of using the proper regulatory elements to drive GJB2 expression in AAV-based gene therapy for the most common form of genetic deafness and highlight the power of bioinformatics to achieve a successful design. The robust and durable recovery observed in mice with our vector represents significant progress towards the development of a gene therapy to restore natural hearing to DFNB1 patients.

346 A Novel Stem Cell Therapy for Treating Patients with Retinitis Pigmentosa

Deepti Singh[1], Pierre Dromel[2], Michael Young[3]

[1]Ophthalmology, Harvard Medical School, Boston, MA,[2]InGel Therapeutics, Allston, MA,[3]Schepens Eye Research Institute, Boston, MA

Stem cell therapies have shown great promise to restore vision in patients affected by retinal degenerative diseases. However, there are still challenges that remains due to the efficacy gap between *in vitro* studies and *in* vivo cell transplantation. This is partly due to the hostile microenvironments in which these cells are transplanted in. In a degenerative tissue, the host immune system and hostile conditions cause major challenges that need to be addressed.In retinitis pigmentosa (RP), the loss of vision is due to the death of both rod and cone photoreceptors. The absence of rods causes the loss of critical metabolic factors directly affecting cone survival and function. Therefore, cell therapies for RP are focusing on protecting, repairing, and replacing cone photoreceptors.To address this key issue, we have created a 3D hydrogel-based stem cell product that secretes neuroprotective factors in the vitreous to preserve cone photoreceptors. This biocompatible hydrogel mimics the *in vivo* extracellular matrix to offer a thriving environment for cellular proliferation and viability. Our biomaterial encapsulates a novel enriched target cell population that produces specific neurotrophic factors which are lost in RP: rod precursor cells. We have created a novel and proprietary protocol to isolate both rods and cones precursor cells in high purity and viability, allowing for high expansion capabilities.We have engineered this technology by combining material science and cell biology and have examined its effects *in vitro* on cone cells and *in vivo* with the rd1, and rd10 mice models along with a safety study in rabbits.Our studies show that our technology is a multimodal therapy that targets specific neurodegenerative pathways such as neuro-glycolysis and neuro-inflammation. The neurotropic factors present can enhance glucose uptake by cone photoreceptors and reduce the expression of W6/32 markers indicating a reduction in neuro-inflammation. Following the injection of our stem cell-matrix product in the vitreous of rd-1 mice (P26) we observed a 10-fold increase in cone survival (central retina) along with the presence of rods ay later time points (P60); these results translated into functional recovery in the rd-10 animal model. This technology is the first of its type to be gene agnostic and which can target multiple pathways that are affected in RP patients.

Gene Targeting and Gene Correction: CNS

347 High Efficiency *In Vivo* RNA Editing in the CNS with AAV-Delivered ADAR gRNAs

Stephen M. Burleigh, Jeffrey Huang, Herman Tung, Forrest Golic, Clay Patton, Nicole Enger, DuanKun Lee, Eric Chadwick, Yiannis Saava, Susan Bryne, Collin Hauskins, Melissa Works, Brian J. Booth, Adrian W. Briggs, David J. Huss

Research, Shape Therapeutics, Inc., Seattle, WA

RNA editing using guide RNAs (gRNAs) that recruit the endogenous adenosine deaminase acting on RNA (ADAR) enzyme has great potential as a versatile gene therapy approach, without the need to deliver a protein or protein-encoding transgene. ADAR deaminates adenosines into inosines, which are read as guanosines by the translational machinery, creating a functional A-to-G base change. The central nervous system (CNS) expresses high levels of ADAR1 and ADAR2, making it a particularly attractive target organ for therapeutic application of RNA editing. However, published results to date have relied on delivery of hyperactive forms of ADAR to achieve measurable in vivo RNA editing in the CNS. Here we demonstrate novel gRNA design combined with increased gRNA expression and stability that unlocks high efficiency RNA editing with endogenous ADAR in cell-based neuronal models and the CNS of adult mice. We began by applying our RNAfix gRNA discovery platform to CNS-relevant target adenosines. Briefly, RNAfix combines high throughput screening with generative machine learning to engineer gRNAs that interact with a target transcript, recruit endogenous ADAR and specifically edit the target adenosine. Therapeutic application of gRNAs requires sustained, high-level expression in target cells, leading us to choose a DNA-encoded delivery approach using AAV. We have previously shown that expressing gRNAs with elements of natural small nuclear RNAs (snRNAs) increases editing efficiency in multiple cell types. Importantly, in vivo delivery may only result in as low as one copy of the AAV genome per target cell, in contrast to in vitro systems that are amenable to high dose plasmid transfection or high AAV MOI transduction. Thus, maximizing gRNA expression and stability from each AAV genome is critical for high efficiency in vivo RNA editing. To this end, we undertook two engineering approaches: snRNA promoter engineering and AAV vector optimization. Initial experiments in HEK293 cells demonstrated that combining the enhanced promoters with improved vector designs resulted in up to 10-fold higher gRNA expression compared to starting designs. We then performed AAV transductions in differentiated SH-SY5Y cells, human NSC-derived neurons, mouse primary neurons and finally in adult mice. In vitro, the improved gRNA expression constructs increased target base editing efficiencies from <25% to >90%, with robust editing maintained at MOIs as low as one thousand viral genomes per cell. AAV vectors encoding the top construct designs were then injected into mice by intracerebroventricular delivery and bulk brain samples were collected four weeks post injection for RNA extraction and analysis. We observed up to 72% target adenosine editing in cortical tissue, far exceeding previously published data even with exogenous, hyperactive forms of ADAR. Given the potent and durable neuronal penetrance of AAV, our results support the delivery of RNAfix gRNAs in optimized expression constructs as a promising approach for treating a wide range of CNS diseases.

348 Targeting CX3CR1 Gene to Improve Microglia Reconstitution and Transgene Delivery into the CNS upon Hematopoietic Stem and Progenitor Cell Transplant

Annita Montepeloso[1], Davide Mattioli[1], Danilo Pellin[1], Pietro Genovese[1], Marco Peviani[1], Alessandra Biffi[1,2]

[1]Dana-Farber/Boston Children's, Harvard Medical School, Boston, MA,[2]Division of Pediatric Hematology, Oncology and Stem Cell Transplantation, University of Padua, Italy

Transplantation of hematopoietic stem/progenitor cells (HSPC) engineered by integrating vectors for expression of disease specific therapeutic transcripts has shown unprecedented curative potential in patients affected by monogenic neurometabolic diseases (NMD) when treated in early disease stages. This benefit is mediated by myeloid transplanted cell progeny in the central nervous system (CNS) that acts not only as vehicle for therapeutics, but also as modulator of neuroinflammation, possibly extending the application of this approach to a broader spectrum of neurodegenerative diseases (ND). Nonetheless, phenotypic effects after treatment are delayed likely due to the slow pace of CNS engraftment and differentiation of engineered HSPC into microglia like cells (MLC) compared to the rapid progression of neurodegeneration, that hampers the broad application of this approach. Here, we propose a novel gene addition strategy at CX3CR1 (CX) locus that may successfully address these limitations. CX gene encodes for a microglia chemokine receptor that regulates microglial recruitment to sites of neuroinflammation and microglia ontogeny. Firstly, we observed that transplantation of CX haploinsufficient (CXhaplo) HSPC resulted in a more robust engraftment and generation of MLC as compared to WT HSPC in competitive transplantations, where CXhaplo HSPC progeny prevailed over WT in the repopulation of hematopoietic organs (60% vs 40%) and brain (80% vs 20%). Next, to develop a therapeutic strategy combining the improved features of CXhaplo HSPC transplantation with a microglia specific transgene expression, we designed a CRISPR based gene addition strategy with a promoterless, splice trapping cassette encoding for a fluorescent reporter to be inserted into CX intron in a CX expressing cell line. We showed that targeted insertion allows regulated transgene expression and CX knockout only in HDR edited cells, while NHEJ indels did not impacted CX expression. We then used an established protocol based on Cas9/gRNA electroporation and AAV6 transduction to deliver the cassette in human HSPC (hHSPC), obtaining efficient integration (45% of the alleles) of the reporter gene, resulting in CX transcriptional and protein downregulation. Edited hHSPC were able to engraft into primary and secondary myeloablated immunodeficient mice, showing higher engraftment than AAVS1 edited hHSPC and increased transgene expression on human MLC compared to hematopoietic organs, as per physiologic CX expression. Interestingly, expression of the transgene driven by CX promoter in engrafted MLC was stronger than the expression driven by a conventional PGK promoter. Finally, a branching analysis performed on engrafted MLC revealed a greater extent of ramifications and

complexity of CXhaplo and CXedited *vs* WT and mock cells, both in the mouse- and human-into-mouse transplantation settings, suggesting a more rapid acquisition of a mature microglia like morphology and phenotype. To elucidate the biological mechanism underpinning this phenomenon, we performed a transcriptomic analysis at single cell resolution on FACS sorted MLC from competitively transplanted mice. Gene ontology analysis on signature genes revealed significant upregulation of Cdc42 signal transduction pathway in a cluster enriched with CXhaplo cells, that may account for greater activity in cytoskeleton rearrangement, cell motility and cell cycle progression explaining the quantitative and qualitative advantage observed. In conclusion, we identified and validated CX as a key target to enhance the ability of HSPC to generate MLC upon transplantation and allow specific and robust transgene expression in the CNS.

349 A Synthetic miRNA IFFL Circuit Module for Rett Syndrome Gene Therapy

Michael J. Flynn, Acacia Mayfield, Rongrong Du, Viviana Gradinaru, Michael Elowitz

California Institute of Technology, Pasadena, CA

The precise control of gene expression can enhance our ability to ameliorate or cure disorders that exhibit gene dosage sensitivity. Rett Syndrome gene therapy is a prototypical example of such a 'Goldilocks problem', where the delivered gene MECP2 must be expressed, but too much expression is harmful, as in MECP2 duplication syndrome. Multiple factors, including cell-cell variation in viral vector uptake and high expression from synthetic promoters, can cause expression levels to extend beyond the therapeutic window. An ideal gene therapy would adapt to these factors to maintain expression at an engineered, therapeutic setpoint. An incoherent feedforward loop (IFFL) circuit could perform this adaptive function. Here we show that an IFFL can be implemented using a compact synthetic miRNA module that can be placed within an adeno-associated viral vector (AAV) without severely constraining the other cargo in size, and confirm that it can be used to regulate MECP2-EGFP gene expression in cell culture. We packaged the circuit into an engineered, CNS-targeting capsid AAV-CAP.B22, and delivered it systemically to mice. We compared ectopic and endogenous MECP2 expression using hybridization chain reaction (HCR) analysis to count mRNA transcripts in brain slices. While an unregulated expression cassette overexpressed MECP2 relative to the endogenous MECP2, the regulated cassette matched ectopic and endogenous gene expression levels. Altogether, these results demonstrate how synthetic miRNA IFFL circuits allow the precise control of gene therapies.

350 CRISPR-SKIP 2.0: A Highly Efficient Base Editing Toolbox for Exon-Skipping That Enables a Therapeutic Approach for Alzheimer's Disease

Angelo Jay Miskalis, Shraddha Shirguppe, Gianna Elias, Devyani Swami, Wendy S. Woods, Maria Alejandra Zeballos, Hayden Moore, Thomas Gaj, Pablo Perez-Pinera

Bioengineering, University of Illinois at Urbana-Champaign, Urbana, IL

CRISPR-SKIP is a technology that utilizes base editors to install precise mutations in splice acceptor sites of exons, preventing their recognition by the spliceosome and inducing skipping of the exon. Exon skipping has also been accomplished with antisense oligo nucleotides (ASOs), which continues to be explored in clinical trials, and some products are approved for use. However, CRISPR-SKIP provides several advantages over ASOs including the ability to introduce permanent modifications that provide a long-term benefit with a single administration. Nonetheless, multiple challenges prevent the widespread application of CRISPR-SKIP. First, the use of wild-type SpCas9 can only edit splice sites flanked by NGG PAM motifs, limiting the number of targetable exons as well as the amount of sgRNAs that can be screened to maximize efficiency. Second, the editing rates installed at many sites are relatively low. Third, cryptic splice sites in exons can cause the spliceosome to recognize alternative splice sites, leading to partial skipping, which may not be desirable. These limitations have prevented the therapeutic efficacy for high-value targets, such as *APP* exon 17, which contains the cleavage site for β-secretases, and its disruption could prevent the formation of toxic β-amyloid plaques in Alzheimer's disease. Specifically, while we have edited the splice acceptor of *APP* exon 17 with CRISPR-SKIP at low rates, we have not been able to accomplish exon skipping. To overcome these limitations, we developed a new toolbox for exon skipping, named CRISPR-SKIP 2.0, that utilizes cytosine and adenosine base editors with relaxed PAM requirements fused with newer generation deaminases, which, in combination, enable editing of essentially any target site with high efficiency. Compared to our previous technologies, CRISPR-SKIP 2.0 can induce DNA modifications at splice acceptor sites that were previously refractory to editing. Furthermore, to reduce the probability of unwanted cryptic splicing events, we implemented a new strategy consisting of simultaneous targeting of splice donor and acceptor sites, which not only reduced cryptic splicing but also enabled higher skipping efficiencies of targeted exons. In multiple instances, this technique enabled skipping of exons that were refractory to splicing modulation when editing the splice acceptor or donor alone. Importantly, CRISPR-SKIP 2.0 enabled the skipping of *APP* exon 17 in multiple human cell lines, and it also effectively reduced Aβ42 *in vitro* in a cell line used to model Alzheimer's disease. We also demonstrated that CRISPR-SKIP 2.0 possesses *in vivo* therapeutic potential as we delivered AAVrh10-packaged split adenine base editors via stereotaxic injections to the hippocampus of four-week-old mice carrying the humanized *APP* gene. This system efficiently edited the splice acceptor and donor sites within *APP* exon 17 one month after injection and induced 25% exon skipping within unsorted hippocampus tissue without introducing unwanted cryptic splicing. These results demonstrate that CRISPR-SKIP 2.0 can edit splice donors and acceptors and skipping of exons that were previously resistant

to skipping. Moreover, the simultaneous targeting of splice acceptor and donor sites demonstrated improved exon skipping as well as *in vivo* therapeutic potential in a mouse model of Alzheimer's disease, highlighting the potential impact of CRISPR-SKIP 2.0 in biomedicine and gene therapy.

351 Rewriting *ABCA4* RNA for the Treatment of Stargardt Disease

Robert D. Bell, Shimyn Slomovic, Akiko Doi, Jesse Gray, Kirk Benjamin Burkhart, Rebekka Krumbach, John Bachmann, Bennett Bremer, Adam Clemens, Tayla Cormier, Conor Delaney, Lai Mung Fong, Xiaojin Liu, Savita Matapurkar, Julia Meredith, Justin Nelson, Akiko Noma, Anika Pavis, Lingtao Peng, Jason Thresher, Dennis Wu, Carrie Wager, Michael Ehlers, Romesh R. Subramanian

Ascidian Therapeutics, Boston, MA

Exon editing is a promising strategy for correcting disease-causing mutations by inducing trans-splicing between a therapeutic RNA Exon Editor molecule and an endogenous mutated pre-mRNA target, forming repaired mRNA and wild-type protein. Exon Editor RNA molecules can be designed to rewrite multiple contiguous exons carrying pathological mutations with the correct native sequence, thereby addressing the underlying genetic causes of disease. Potential applications include indications, such as Stargardt disease, which cannot be addressed by conventional gene therapies or gene editing approaches due to limited AAV packaging capacity, high mutational variance within gene targets, and/or narrow gene dosage indices. AAV-encoded RNA Exon Editors provide the durability of gene therapy, without the use of foreign enzymes, while maintaining endogenous gene expression patterns and thus, avoid many risks associated with direct DNA editing or gene replacement. Here we describe the process by which Ascidian's exon editing technology uses the endogenous spliceosome to rewrite mutated RNA resulting in full-length, correct mRNA molecules and protein rescue. We have applied this approach for the treatment of *ABCA4*-related retinopathies, including Stargardt Disease. We generated a high-throughput, multiplexed screening platform to design, evaluate, and optimize the RNA editing efficiency of thousands of Exon Editor molecules at a time. Here, we report on *ABCA4*-targeting Exon Editors that can efficiently replace 22 exons in the 5' half of the 7 kb *ABCA4* coding sequence, which covers 50-60% of known patient mutations, resulting in complete protein rescue *in vitro* in an engineered *ABCA4* mutant cell line. Next, we demonstrate durable and well-tolerated exon editing at therapeutically relevant levels in non-human primate retina following a single subretinal injection of AAV-encoded *ABCA4*-targeting Exon Editors. Moreover, we have recapitulated robust *ABCA4* exon editing in human donor-derived retinal explants following treatment with an AAV-encoded *ABCA4*-targeting Exon Editor. IND-enabling studies are underway to bring this program into the clinic, wherein we hope to demonstrate benefit to those living with *ABCA4*-related retinopathies. Finally, confirmation of the feasibility of Exon Editing has been further demonstrated in multiple other genetic targets *in vitro*. As we continue to work toward realizing the full potential of RNA exon editing and extending this approach to additional indications having high unmet medical need, this report demonstrates the translational viability of our therapeutic strategy.

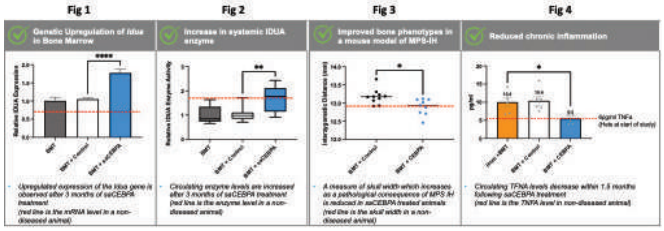
352 Transcriptional Upregulation of α-L-iduronidase Utilizing Small-Activating RNA Following Bone Marrow Transplant in a Murine Model of Hurler Syndrome

Michael J. Przybilla[1], Vikash Reebye[2], Konstantinos Vanezis[2], Konstantina Skourti Stathaki[2], John J. Rossi[3], Min-Sun Song[3], Laura Furness[4], Simon Jones[4], Nagy A. Habib[2], Chester B. Whitley[1]

[1]University of Minnesota, Minneapolis, MN,[2]MiNA Therapeutics Ltd, London, United Kingdom,[3]Beckman Research Institute of City of Hope, Duarte, CA,[4]Manchester University, Manchester, United Kingdom

Hurler syndrome, or MPS I, is a genetic disorder caused by a deficiency in the lysosomal enzyme α-L-iduronidase (IDUA), resulting in cellular accumulation of the glycosaminoglycans heparan and dermatan sulfate. While gene therapy and editing technologies are on the horizon for disorders like MPS I, the standard of care for patients is currently enzyme replacement therapy (ERT) and hematopoietic stem cell transplant (HSCT). To date, a significant percentage of MPS I patients have received HSCT but still present with aspects of the disease, including skeletal dysplasia, cognitive decline, and chronic pain. For the patients who have previously received or are currently receiving these treatments, the options are limited for improving these outcomes. One potential approach to address this limitation is to increase IDUA enzyme levels produced by the transplanted cells and their progeny through transcriptional upregulation of the IDUA gene utilizing a small-activating RNA (saRNA). saRNAs are short, double-stranded RNA oligonucleotides designed to target the regulatory region of a gene and activate or increase expression at the transcriptional and epigenetic level. Currently, a saRNA-based treatment is in a clinical trial for hepatocellular carcinoma, where the saRNA is designed to upregulate the transcription factor CEBPA, the master regulator of myeloid cells. Because CEPBA is a transcription factor, it has many genomic targets, one of which is the promoter region of the IDUA gene. In the current study, it was hypothesized that following bone marrow transplant, MPS I mice treated with an saRNA targeting CEBPA (MTL-CEBPA) would increase *Idua* expression, and thus enzymatic activity. To this end, 5- to 6-week-old MPS I mice were irradiated and transplanted with bone marrow from sex-matched, wildtype mice harboring two functional copies of the *Idua* gene. Following engraftment, mice began receiving weekly intravenous injections of MTL-CEBPA, or a sham saRNA targeting firefly luciferase (Fluc), for up to 14 weeks. Compared to Fluc-treated mice, *Cebpa* mRNA levels in the bone marrow were moderately increased in mice receiving 0.5 mg/kg MTL-CEBPA ($p<0.05$) and trending toward significance in mice receiving 2.0 mg/kg MTL-CEBPA ($p=0.07$). In both cohorts receiving MTL-CEBPA, *Idua* mRNA levels were nearly two-fold higher than Fluc-treated mice (Fig. 1). This increased mRNA level also translated to a significant increase in systemic IDUA enzyme activity compared to Fluc-treated mice (Fig. 2). Phenotypic analysis demonstrated normalization of the inter-zygomatic distance in mice receiving MTL-CEBPA (Fig. 3). Further, CEBPA activation resulted in a significant reduction of circulating

TNFα was in MTL-CEBPA-treated mice (Fig. 4). These results demonstrate the power and flexibility that saRNA-based therapies can provide for patients who have previously received HSCT by transiently over-expressing the therapeutic gene in the engrafted and derived cells. This targeted approach by saRNA opens a new avenue of therapeutic development for not only lysosomal disorders such as MPS I, but all disorders where transcriptional activation or enhancement of a gene could provide therapeutic benefits.



353 Epigenome Therapy Approach to Tune *SNCA* Expression in Parkinson's Disease: Pre-Clinical Proof of Concept in PD Mouse Model

Ornit Chiba Falek, Bernadette O'Donovan, Boris Kantor

Duke University, Durham, NC

Elevated *SNCA* levels are causative in Parkinson's Disease (PD) pathogenesis, while normal physiological levels of *SNCA* are essential to maintain neuronal function. Patients with *SNCA* triplication and duplication suffer from familial early onset from of PD, suggesting a therapeutics window of <30%. We aim to translate mechanistic knowledge of *SNCA* dysregulation towards the development of epigenome therapy for PD targeting *SNCA* expression. Towards this goal we developed *all-in-one* lentiviral vector (LV) carrying the deactivated CRISPR/(d)Cas9, a selected gRNA targeted at *SNCA*-intron1 and synthetic repressor molecules. Previously we provided *in vitro* proof-of-concept for the efficacy and efficiency of our LV-dCas9-repressor system in human iPSC-derived 'aged' dopaminergic neurons from a PD-patient with the *SNCA* triplication. We showed downregulation of *SNCA*-mRNA and protein levels that led to the rescue of disease-related pathological phenotypes including, mitochondrial dysfunction, neuronal-cell death, DNA damage and nuclear deficits. We now moved forward into *in vivo* validation studies. Our PD mouse model was generated by inducing the disease with an AAV-A53T-human SNCA vector that comprised of the mutated human-SNCA coding sequence fused with its native promoter/intron 1 region. We performed bilateral stereotactic injection of the AAV-A53T-human SNCA vector into the mouse substantia nigra (SN), the left SN was co-injected with the therapeutic LV-dCas9-repressor and the right SN was co-injected with the control inactive LV-dCas9 vector. Analysis of 10 mice demonstrated a significant reduction of 50% in human SNCA protein. Pathological examinations showed a significant robust reduction in Ser129-phosphorylated SNCA (nearly 80%) and in aggregated SNCA protein (70%). In addition, we observed significantly higher expression of tyrosine hydroxylase (TH +24%), suggesting a greater retention of dopaminergic neurons. We also collected safety measures. Monitoring daily behaviors showed no abnormalities in well-being criterions and no weight loss. In addition, safety measures demonstrated no issues for blood counts, serum chemistry and liver histology. In conclusion, our novel CRISPR/dCas9-based technology offers the unprecedented tool to modify a particular epigenetic mark resulting in effective fine-tuned reduction of *SNCA* expression levels sufficient for reversing PD-associated perturbations. This study provided an *in vivo proof-of-concept* for advancing our innovative epigenome editing-based system to a clinical trial as the next-generation PD epigenome therapy.

Gene and Cell Therapy Trials in Progress

354 Phase 1/2a Trial of Delandistrogene Moxeparvovec in Patients with DMD: 4-year Update

Jerry R. Mendell[1,2], Zarife Sahenk[1,2], Kelly Lehman[1], Linda P. Lowes[1,2], Natalie F. Reash[1], Megan A. Lammarino[1], Lindsay N. Alfano[1], Sarah Lewis[1,3], Kathleen Church[1], Richard Shell[1], Rachael Potter[1,3], Danielle Griffin[1,3], Eric Pozsgai[1,3], Mark Hogan[1], Larry Hu[3], Stefanie Mason[3], Eddie Darton[3], Louise Rodino-Klapac[3]

[1]Center for Gene Therapy, Nationwide Children's Hospital, Columbus, OH,[2]The Ohio State University, Columbus, OH,[3]Sarepta Therapeutics, Cambridge, MA

Delandistrogene moxeparvovec (previously known as SRP-9001) is an investigational recombinant adeno-associated viral (rAAV) vector-based gene transfer therapy designed to compensate for missing dystrophin in Duchenne muscular dystrophy (DMD) by delivering the SRP-9001 dystrophin transgene, which encodes a shortened, engineered dystrophin protein that retains key functional domains of the wild-type protein. The objective of this Phase 1/2a, single-dose, open-label clinical trial (NCT03375164) is to evaluate the safety of systemic delivery of delandistrogene moxeparvovec in patients with DMD. Four ambulatory patients with DMD (≥4 to <8 years old) were enrolled. Patients were given an intravenous infusion of delandistrogene moxeparvovec at a dose of $2.0x10^{14}$ vg/kg (supercoiled quantitative polymerase chain reaction, linear plasmid standard equivalent of $1.33x10^{14}$ vg/kg) and prednisone (1 mg/kg/day) 1 day pre- to 30 days post-gene delivery. The primary outcome measure is safety. The secondary outcome measures include micro-dystrophin expression in pre- and post-muscle biopsies (Week 12 post-infusion). Key efficacy outcome measures include North Star Ambulatory Assessment (NSAA) and timed function tests. Previously, data from 3 years post-treatment were presented. Treatment-related adverse events were mild to moderate, occurred mostly in the first 90 days of treatment, and all resolved. No serious adverse events, study discontinuations, or adverse events associated with clinically relevant complement activation were reported. All patients demonstrated a clinically meaningful improvement on NSAA. Patients treated with delandistrogene moxeparvovec generally maintained muscle strength (Time to Rise and 4-stair Climb) and showed improvement in ambulation

ability (10-meter and 100-meter walk/run) from baseline to Year 3. The observed safety profile and the enduring response following treatment provide proof-of-concept for continuation of clinical trials assessing delandistrogene moxeparvovec using single-dose gene therapy in patients with DMD. We present the latest long-term (4-year) safety and functional data from this study. This study is funded by Sarepta Therapeutics.

355 Autologous Stem Cell Transplantation in HIV Infected Recipients Using Zinc-Finger Nuclease-Based CCR5 Edited CD34+ Cells: Persistence of Hematopoietic Progeny and Stem Cells at 5 Year Follow-Up

Angelo A. Cardoso[1], Rodica Stan[1], Monica Torres-Coronado[1], Jay Lalezari[2], Ronald Mitsuyasu[3], Anthony Mills[4], Agnes Gardner[1], Diana L. Browning[1], Li Xiu-Li[1], Jonathan Chupka[1], Michael C. Holmes[5], Marina Falaleeva[5], Nancy Gonzalez[1], Teresa Kim[1], Amira Ahmed[1], Joycelynne Palmer[1], Jana Dickter[1], Nitya Nathwani[1], Stephen J. Forman[1], Dale Ando[5], Edward Conner[5], Amrita Krishnan[1], John A. Zaia[1]

[1]City of Hope, Duarte, CA,[2]Quest Clinical Research, San Francisco, CA,[3]UCLA CARE Center, Los Angeles, CA,[4]Mills Clinical Research, Los Angeles, CA,[5]Sangamo Therapeutics, Richmond, CA

We conducted the first clinical study in which gene-edited stem cells were administered to humans. A first-generation zinc-finger nuclease (ZFN) was used to edit CCR5 in mobilized autologous CD34+ stem cells (HSPC) and transplanted to persons living with HIV (PWH). A manufacturing process was qualified for HSPC selection and delivery of the ZFN mRNA by electroporation. In a feasibility and safety trial, eight healthy PWHs were infused with CCR5-edited (CCR5ed) HSPC, following non-myeloablative busulfan conditioning in two cohorts, cohort 1 targeted cumulative AUC 8,000 μM*min and cohort 2 12,000 μM*min. All manufactured CCR5ed-HSPC Drug Products met release specifications, with cell dosing of 2.2 - 11.5x10^6 CD34+ cells/Kg and CCR5 disruption of 8.0 - 43.3% (by miSeq assay). Sampling at the time of infusion showed high cell viability and purity, with presence of more primitive HSPC subsets. All patients engrafted, at 15 days for cohort 1 and 14 days for cohort 2. At 1 year (1Yr) post-transplant, CCR5 disruption was observed in peripheral blood (PB) mononuclear cells (MNC) in all patients (ranging from 0.07 - 2.95%), with levels stabilizing around month 6. Also, bone marrow (BM) analyses showed presence of CCR5 disruption in all patients, in purified CD34+ cells and in different cell subsets. Statistical analyses showed significant correlation between CCR5 disruption in BM CD34+ cells and busulfan exposure ($r=0.800$; $p=0.017$), which is particularly relevant considering the non-myeloablative conditioning. No significant correlation was seen between any features of the infused Drug Products and CCR5ed levels in BM CD34+ cells. Importantly, BM CD34+ CCR5 editing strongly correlated with CCR5ed levels in PB MNC ($r=0.968$; $p<0.0001$) and in total BM ($r=0.980$; $p<0.001$), and BM monocytes ($r=0.987$; $p<0.0001$) and other BM myeloid/immune cell lineages ($r=0.983$; $p<0.0001$), indicating successful engraftment of HSC carrying the CCR5 disruption. Also, significant correlation with CCR5ed levels in PB CD4+ T cells ($r=0.858$; $p=0.006$) was observed. Long-term follow-up demonstrated persistence of CCR5 editing in PB in all individuals at the most recent timepoint (years 4-5 post-infusion), maintaining significant correlation to the CCR5ed levels in BM CD34+ cells at 1Yr. In addition, in two individuals, BM studies were performed at ≥3 years post-infusion, and in both cases, again there was strong correlation between of CCR5ed levels in BM CD34+ cells and their frequency in PB MNC and CD4+ T cells and other BM cell subsets. Analysis of CD4 T cell recovery, immune function, memory subsets and TCR repertoire, as well as analysis of the HIV reservoir will be presented. In summary, we conducted the first long-term study in which HSPC were gene edited and infused in humans, without major adverse events. Engraftment of gene-edited stem cells was observed despite using a non-myeloablative conditioning and a first-generation editing construct. The persistence of CCR5ed progeny in all patients at 4-5 years post-infusion, with strong correlation to the levels of CCR5ed in the BM CD34+ cells post-transplant, supports the therapeutic use of ZFN gene-edited HSPC. With improved nuclease-based gene editing tools and transplant conditioning regimens, this strategy for gene editing in HIV warrants further research.

356 An Updated Follow-Up of BRL-101, CRISPR-Cas9-Mediated Gene Editing of the BCL11A Enhancer for Transfusion-Dependent β-thalassemia

Bin Fu[1], Xinhua Zhang[2], Li Wang[2], Jiaoyang Liao[3], Shuanghong Chen[3], Biao Zheng[4], Wei Li[4], Fei Wang[4], Dali Li[3,4], Mingyao Liu[3,4], Yuxuan Wu[3]

[1]Xiangya Hospital, Central South University, Hunan, China,[2]923rd Hospital of the People's Liberation Army, Guangxi, China,[3]Shanghai Frontiers Science Center of Genome Editing and Cell Therapy, Shanghai Key Laboratory of Regulatory Biology, Institute of Biomedical Sciences and School of Life Sciences, East China Normal University, Shanghai, China,[4]BRL Medicine Inc., Shanghai, China

INTRODUCTION: β-Thalassemia is an inherited hemolytic disease that is prevalent worldwide. Over 200 mutations in the HBB gene, which encodes adult hemoglobin (HbA), result in β-thalassemia. Hereditary persistence of fetal hemoglobin (HbF) can alleviate the symptoms of anemia. CRISPR-Cas9-mediated disruption of the BCL11A erythroid enhancer results in the reduction of BCL11A expression and the induction of fetal γ-globin, which is a practicable therapeutic strategy for treating transfusion-dependent β-thalassemia (TDT). **METHODS**: We conducted a nonrandomized, single-dose, open-label clinical trial of BRL-101 in pediatric patients with TDT at Xiangya Hospital (NCT04211480) and 923rd Hospital (NCTO4205435). The inclusion criteria included age 5-15 years, clinically diagnosed as β-thalassemia major, phenotypes including β0/β0, β+/β0, βE/β0 genotype, and subject's body condition eligible for autologous stem cell transplantation. CD34+ HSPCs were edited with CRISPR-Cas9 RNP at the +58 erythroid specific enhancer region of the BCL11A gene. Patients were monitored for routine blood test, editing frequency, total Hb, Hb fractions on HPLC, F-cell percentage (circulating erythrocytes with detectable levels of HbF) and AEs. **RESULTS**: All 6 patients, including 4 β0/β0 phenotype patients, received BRL-101 treatment and successfully achieved transfusion independence. The neutrophil engraftment occurred within 1 month

for all patients, the platelet engraftment and last pRBC transfusions occurred within 2 months for two-thirds of patients (table 1). The total Hb levels began to increase steadily until they reached healthy levels, and HbF levels were elevated sustainedly (figure 1). F-cell expression increased to more than 90% within 6 months (figure 2). The CRISPR-Cas9-edited HSPCs engrafted and differentiated into multiple lineages that retained the gene editing. Editing frequency of PBMCs from patients increased to more than 60% during the follow-up periods (figure 3). No drug-related AEs leaded to study withdrawal or death of patients during treatment. The majority of AEs were consistent with that of mobilization, apheresis, myeloablation, and autologous hematopoietic stem cell transplantation. All of these AEs have been resolved. Four SAEs were reported during treatment, including left cheek soft tissue infection, acute upper respiratory infection, infective fever and thrombocytopenia. Only thrombocytopenia was attributed to BRL-101 and was gradually relieved. **CONCLUSIONS**: All 6 patients with different genotypes achieved transfusion independence, including the patients with the most severe β0/β0 phenotype. After BRL-101 infusion, the levels of total Hb and HbF increased significantly, and gene editing is retained in multiple lineages of HSPCs. The safety profile of BRL-101 is generally consistent with mobilization, apheresis, myeloablation and autologous hematopoietic stem cell transplantation. This study demonstrate that BRL-101 is a safe, potential functional cure for the treatment of TDT.

Table 1. Characteristics of patients and gene-editing outcomes

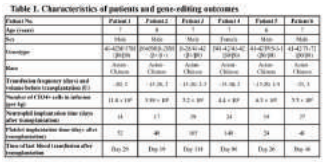


Figure 1. Substantial increases in total Hb and HbF level.

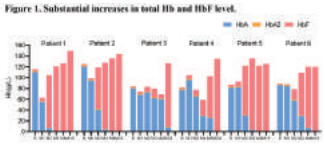

Figure 2. Durable increases in percentage of HbF.

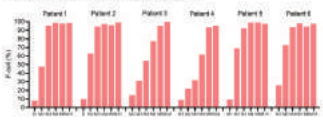

Figure 3. PBMCs from patients retained the gene editing.

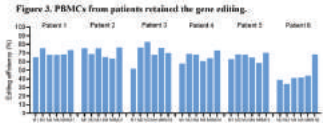


357 Supraphysiological Enzyme and Early Neurocognitive Outcomes after Autologous Hematopoietic Stem Cell Gene Therapy in Patients with Mucopolysaccharidosis IIIA

Brian W. Bigger[1], Jane Kinsella[2], Jane Potter[2], Rebecca Holley[1], Rachel Searle[1], Yuko Ishikawa Learmonth[1], Karen F. Buckland[3], Stewart Rust[2], Daniel Weisberg[2], Rebecca Bromley[2], Heather Church[2], Karen Tylee[2], K. Brammeier[2], H. Lee[2], L. Ford[2], Stuart M. Ellison[1], Adrian J. Thrasher[4], Claire Booth[5], Simon Jones[2], Robert F. Wynn[2]

[1]University of Manchester, Manchester, United Kingdom,[2]Manchester University NHS Foundation Trust, Manchester, United Kingdom,[3]University College London, London, United Kingdom,[4]UCL Institute of Child Health, London, United Kingdom,[5]UCL Great Ormond Street Institute of Child Health, London, United Kingdom

Ex vivo hematopoietic stem cell gene therapy (HSC-GT) provides a potential therapy for diseases with a single enzyme deficiency, where allogeneic HSC is ineffective. Mucopolysaccharidosis type IIIA (MPSIIIA) is a lysosomal storage disorder where pathogenic mutations in the *SGSH* gene result in the accumulation of heparan sulfate in all cells of the body. Build-up particularly affects the central nervous system, with devastating consequences. As the disease progresses, loss of previously acquired skills such as speaking and walking occurs, with profound behavioural disturbances and death between 10-20 years of age. There are no approved treatments. HSC-GT is expected to provide sufficient body-wide enzyme and potentially allow the trafficking of modified monocytes into the brain. Our phase I/II clinical trial (NCT04201405/EudraCT#2019-002051-42) has treated five children with severe MPSIIIA, aged 6-24 months. Recruitment to the trial is complete. Additional a patient was treated off-trial at 30 months old on a compassionate basis. Patient-specific HSCs were mobilised for transduction *ex-vivo* with a lentiviral vector expressing the *SGSH* gene under the myeloid CD11b promoter and cryopreserved. Patients received full myeloablative conditioning before product infusion. All trial patients had a vector copy number of 1.19-8.91 copies/cell/product, with a cell dose of 4.3-22.7x10^6 $CD34^+$/kg. Engraftment is sustained at >24 months (n=3), 18 months (n=1), or 9 months (n=1) follow-up, with supraphysiological expression of SGSH enzyme rapidly measurable in leukocytes (48 to 151-fold above median normal range by one month post-GT). Supraphysiological SGSH was also detected in $CD3^+$, $CD19^+$ and $CD15^+$ lineages and plasma. Cerebrospinal fluid (CSF) SGSH enzyme, previously undetectable, was within or above normal range by six months post-GT. Abnormal heparan sulfate storage at baseline was rapidly reduced in CSF, plasma and urine, with a normalization of urine glycosaminoglycan ratios. There has been no detection of replication competent lentivirus, and integration site analysis suggests a highly polyclonal product (9,771 to 70,686 unique integrations in leukocytes). No mappable unique integrations had a >1% contribution three-months post-GT or later, in samples analysed to date. Anti-SGSH IgG antibodies have been detected by one-month post-GT. However, there are no associated AEs and SGSH levels appear unaffected. Data from the off-trial patient (39 months post-GT) continues to show supraphysiological active SGSH, with neurocognitive outcomes suggesting an improved outcome compared to natural history. Neurocognitive assessments of trial patients are ongoing; early results show four out of five trial patients have gained skills in line with normal age equivalent development, one of whom shows an alteration in neurologic phenotype from natural history. In conclusion, treatment with *ex-vivo* autologous HSC-GT is well tolerated and delivers supraphysiological levels of enzyme throughout the body.

358 Initial Biomarker and Clinical Findings from the CAN*aspire* Canavan Disease Gene Therapy Trial: Exploration of Connections between NAA and Disease Severity

Florian Eichler[1], Amanda Nagy[1], Genevieve Laforet[2], Christine Burton[2], Kathleen M. Kirby[3], Bernard Kinane[1], Elise Townsend[1], Michael Kiefer[1], Beth Leiro[2], Rachel Williams[2], John Balser[4], Lisa Kratz[5], Adam Shaywitz[2], Annette Bley[6]

[1]Massachusetts General Hospital, Boston, MA,[2]Aspa Therapeutics, Palo Alto, CA,[3]Viridian Strategies, Barnstable, MA,[4]Veristat, Southborough, MA,[5]Kennedy Krieger Institute, Baltimore, MD,[6]University Medical Center Hamburg-Eppendorf, Hamburg, Germany

Background: Canavan disease (CD) is an ultra-rare white matter disorder caused by mutations in the *ASPA* gene leading to accumulation of N-acetylaspartate (NAA) and profound early-onset impairment of psychomotor development. Although NAA levels are used diagnostically in CD, longitudinal data are lacking and the relationship between NAA, disease severity and progression are not understood. **Methods:** CAN*aspire* (NCT04998396) is a first-in-human open-label study evaluating the safety, pharmacodynamic (PD), and clinical activity of BBP-812, a systemically administered recombinant AAV9 h*ASPA* vector for the treatment of CD. Data from the CAN*inform* CD natural history study (NCT04126005) will be used as a comparator. As a PD marker of ASPA activity, NAA levels are quantified in urine and cerebrospinal fluid (CSF) by gas chromatography-mass spectrometry (GC-MS) and in brain by magnetic resonance spectroscopy (MRS). Clinical outcome measures include the disease-specific Canavan Disease Rating Scale (CDRS) that ranks the severity of 11 characteristic neurological and developmental features of CD, as well as performance-based and parent-reported pediatric motor and developmental scales. Effects on white matter pathology and brain volumes are followed by magnetic resonance imaging (MRI). Preliminary exploration of a potential relationship between NAA levels and disease severity was conducted using CAN*inform* natural history data, baseline findings in CAN*aspire* participants, and literature reports on NAA levels and phenotypic severity. **Results:** All 4 CANaspire participants dosed to date (median age at dosing 20.7 months, range 11.0-29.2 months) have shown decreases in urine, CSF and brain NAA. Urine NAA reductions (42-87%) exceeded the natural variability seen in CAN*inform* over the same duration of follow-up. Robust NAA decreases in CSF (70-90%) and brain MRS (up to 75%) were also observed across all participants with a strong correlation between MRS and urine levels (Spearman r =0.927). Data to date demonstrate persistent reduction in NAA levels in all compartments compared to baseline followed for 3 to 12 months post-treatment. CAN*aspire* participants have shown stabilization or improvement in total CDRS scores compared to baseline up to Month 12. Our preliminary data in CAN*aspire* participants indicate an association between NAA levels and CDRS total scores at baseline. This observation is consistent with prior literature and aligned with CAN*inform* natural history data supporting an association between NAA levels and disease severity. BBP-812 has been generally well tolerated; most adverse events (AEs) have been mild to moderate and mostly managed with adjustments in steroid dosing, with no treatment-related serious AEs. **Conclusions:** Preliminary data have supported the overall tolerability of BBP-812 and demonstrated robust and durable post-dose NAA reductions in urine, CSF and brain along with initial suggestions of clinical stabilization. While the literature and the ongoing natural history study suggest an association between NAA levels and phenotype, whether these early signs of PD and clinical activity translate to clinical efficacy awaits confirmation with additional participant data and longer follow-up in CAN*aspire*.

359 First in Human RESKUE Phase 1/2 Clinical Trial of Intravenous FBX-101 (AAVrh10.hGALC) Administered after Immune and Myeloablation for Unrelated Umbilical Cord Blood Transplantation Prevented Immune Responses, Increased GALC Activity, Restored Normal Brain Development, and Normalized Motor Function in Patients with Infantile Krabbe Disease

Maria L. Escolar[1,2], Mark Vander Lugt[3], Michele D. Poe[1], Melissa Greco[2], Keith Werling[1], Erandi K. De Silva[1], Juan Ruiz[1], Paul Szabolcs[2]

[1]Forge Biologics, Grove City, OH,[2]Pediatrics, University of Pittsburgh, Pittsburgh, PA,[3]University of Michigan, CS Mott Children's Hospital, Ann Arbor, MI

Pre-immunity to AAV may be present in 50-60% of the population, which can lead to humoral and cellular responses against a capsid or therapeutic transgene. This has the potential to impact therapeutic efficacy and has recently been a focus for novel immune-modulation strategies to increase safety and possibly enable re-dosing approaches. Here we report clinical data utilizing a novel treatment regimen for patients with infantile Krabbe disease (IKD), a rapidly progressive demyelinating leukodystrophy due to deficiency of galactocerebrosidase (GALC). GALC deficiency leads to accumulation of psychosine which is toxic to oligodendrocytes and Schwann cells, resulting in demyelination and death by 2 years of age. IKD is currently treated with umbilical cord blood transplantation (UCBT), in which the immune system and the bone marrow are ablated to provide space for the UCBT, an immune stem cell source that is AAV naïve and can restore levels of GALC in the CNS. The approach avoids the antibody response to the capsid and transgene, allowing treatment of all patients including those patients who have no protein expression due to a null genotype. UCBT improves central nervous system (CNS) outcomes in asymptomatic infants, but motor function declines resulting in progressive peripheral neuropathy. The progression of peripheral neuropathy is presumed to be due to insufficient GALC as the patient grows. RESKUE is a first-in-human, open-label Phase 1/2 dose-escalating trial to evaluate safety and efficacy of FBX-101 after UCBT for the treatment of subjects with IKD. FBX-101 is an intravenously administered AAVrh10-hGALC vector designed to rescue peripheral nerve disease in patients with Krabbe disease that have previously received UCBT infusion. Nonclinical studies demonstrated that FBX-101 significantly increased survival and corrected peripheral neuropathy in Krabbe mice and dogs when given after HSCT. FBX-101 safety and biodistribution were established in a GLP rat toxicology study. Subjects (n=2) in cohort 1 received a single IV infusion of FBX-101

at a low dose ($3.0x10^{13}$ vg/kg) 25 and 29 days after UCBT infusion, respectively. FBX-101 was well tolerated, with no treatment-related serious adverse events (including no treatment-related liver enzyme elevations) observed up to Day 365 and Day 180, respectively. The subjects have engrafted with full chimerism. No antibodies to AAVrh10 have developed. We report a significant and sustained increase in plasma and CSF GALC enzyme activity following gene transfer and a reduction of psychosine levels. Subjects' motor skills, measured by PDMS-II, have improved and are within normal range. Finally, subjects have followed a normal white matter growth trajectory in the brain as measured by MRI-DTI. Administration of FBX-101 after UCBT represents a novel gene therapy strategy that leverages the immune- and myeloablation after UCBT, resulting in an immune environment that allows efficient AAV transduction. This administration strategy prevents antibodies against the transgene and capsid and ensures that sufficient GALC enzyme is delivered to sustainably support both brain and peripheral nerve development.

Wednesday Poster Session

361 Efficient Upper Motor Neuron Gene Delivery through AAV2-retro Spinal Cord Injection in Nonhuman Primate

Yuliya Lakhina[1,2], Nicholas Boulis[1,2], Thais Federici[1,2], Thomas Wichmann[3,4,5], Yoland Smith[3,4,5], Adriana Galvan[3,4,5]

[1]Neurosurgery, Emory University School of Medicine, Atlanta, GA,[2]Emory Translational Neuroscience Core, Atlanta, GA,[3]Neuropharmacology and Neurologic Diseases, Emory National Primate Research Center, Atlanta, GA,[4]Neurology, Emory University School of Medicine, Atlanta, GA,[5]Udall Center for Parkinson's Research, Emory University, Atlanta, GA

Introduction: Delivery of genetic payloads by viral vector administration into the spinal cord has significant potential to be of benefit for the treatment of diseases involving upper or lower motor neurons. For example, segmental neuroprotection delivered via virus injections into the C3-C5 of the spinal cord could result in preservation of diaphragmatic function and ventilation and protect upper motor neurons (UMN) in patients with Amyotrophic Lateral Sclerosis (ALS). Here we demonstrate efficient transduction of lower motor neurons (LMN) and UMN via direct delivery of AAVrg (also known as AAV2-retro) into the cervical spinal cord. Methods: Two adult male rhesus macaques (~5-8kg) that tested negative for pre-existing antibodies against AAV2 underwent multi-level cervical laminectomies at the C6-T1 segmental levels. Each animal received multiple (8-10) bilateral intraparenchymal injections of AAVrg vectors with engineered peptide insertion for opposite changes in binding of heparin and AAV receptor towards retrograde incorporation in motor neural circuit carrying different fluorescent reporter genes (mCherry or GFP) and the hSYN promoter. Head stabilization and a custom stereotaxis system were used for the procedures. Injections (2 ul deposit , delivered at 2 ul/min) were performed at a depth of 3mm, targeting the ventral horn of the spinal cord with a floating cannula. Euthanasia was performed six to eight weeks after the injections. Immunohistochemistry analysis was performed using antibodies against mCherry or GFP to demonstrate transduction of these proteins at terminal fields in the targeted area in the spinal cord and in neurons projecting to the injected areas.Results: All animals tolerated the procedures well and had no neurological deficits in the postoperative period. Injections resulted in robust transduction of neurons within the injected segments of the spinal cord with spread to the contralateral side. In addition, extensive neuronal transduction of correspondent corticospinal pyramidal neurons could be observed in the primary motor cortex, supplementary motor area and the pre-motor cortex, indicating retrograde axonal transport to the upper motor neurons projecting to the spinal cord.Conclusion: We found that pairing optimal promoter and viral vector serotype can result in efficient gene expression in the spinal cord and brain following direct delivery to the ventral horn of the cervical spinal cord. Delivery of protective genes to the upper motor neurons presents a challenge given their laminar distribution throughout the motor homunculus. The present study demonstrates that retrograde delivery of AAVrg to the primate upper motor neurons is a feasible and safe approach with critical advantages over diffuse delivery methods, such as the need for considerably lower doses of vector, convenient surgical access as well as the precise gene expression in a specific anatomical location. Characterization of retrograde transport and its limitations is important for increased understanding of the possibility of UMN restoration, which also provides contribution to trunk muscles function as a part of overcoming life-threatening respiration failure. Gene delivery into the spinal cord parenchyma is still an undervalued approach for segmental gene therapy, particularly in the cervical spinal cord, is a therapeutic outcome that could justify clinical translation in diseases such as ALS.Acknowledgement / Funding:This work was supported by the grants P50NS123103-01 and P51OD011132.

362 Limitations of Marmosets as an Animal Model for AAV Mediated Liver Gene Transfer

Bryan Mastis[1], Kevin Olivieri[1], Cara West[1], Charles Gualtieri[1], Tyler Ironside[1], Cynthia T. Pryce[1], Kimberly Le[1], Douglas N. Sanders[2], Laura K. Richman[1], Roberto Calcedo[1]

[1]Affinia Therapeutics, Waltham, MA,[2]formerly at Affinia Therapeutics, currently at AVROBIO, Cambridge, MA

Nonhuman primates are commonly used as an animal model to evaluate biodistribution and safety of Adeno-Associated Viral vectors (AAV). Cynomolgus macaques (*Macaca fascicularis*), an old-world monkey, and marmosets (*Callithrix jacchus)*, a new-world monkey species, have been used extensively in these preclinical studies. There are notable differences between these two species, especially in body weight, social behavior, and absence of CMAH (Cytidine monophosphate-N-acetylneuraminic acid hydroxylase) which has an important effect on the tropism of AAVs using sialic acid as the primary receptor. Marmosets are significantly lighter animals, making this species a desirable model especially for systemic administration of AAV due to reduced manufacturing cost. Here we compare the biodistribution profile of an AAV9.CAG.GFP vector intravenously (IV) administered in cynomolgus and marmoset monkeys. Prior to vector administration and during the course of the study, animals were immunosuppressed to limit immune responses to AAV capsid and GFP transgene. Animals

were sacrificed 28 days post vector administration and liver, cardiac and skeletal muscle tissues were collected and analyzed by ddPCR, RTddPCR and immunohistochemistry (IHC). Samples collected for IHC analysis were evaluated by a pathologist and percent of cells transduced reported. In addition, the prevalence of neutralizing antibodies (NAbs) to AAV in serum was evaluated in both species. The biodistribution data showed comparable transduction efficiency in cardiac muscle between species. Interestingly, liver transduction was significantly reduced in marmosets. Lower distribution in the liver of marmosets was also associated with lower gene expression of GFP measured by both RTddPCR and IHC. In addition, skeletal muscle transduction and gene expression in marmosets was greater than in cynomolgus macaques. Seroprevalence analysis showed that AAV NAbs in marmosets was significantly lower than in cynomolgus macaques. Most marmosets screened for AAV NAbs were seronegative. In contrast and as expected, high level of NAbs were detected in cynomolgus macaques. Although our study included a small number of animals (n=7) and a single vector dose (1e14 vg/Kg), our data indicate that marmosets may not be an ideal translational animal model to evaluate liver gene transfer and safety with administration of AAV vectors. AAV seroprevalence and liver transduction are significantly higher in cynomolgus macaques. The low levels of liver transduction observed in marmosets may not be predictive of toxicity observed in humans, especially with a high dose systemic AAV administration. Therefore, macaques may be a more representative translational model to evaluate liver transduction and safety for systemically administered AAV.

363 Dose-Dependent Cardiac Responses to Intravenous AAVrh.10hFXN Treatment of the MCK Murine Model of Friedreich's Ataxia

Dolan Sondhi[1], Alessandria Greco[1], Nicholas C. Gorman[1], Bishnu P. De[1], Isabelle Wilson[1], Melissa Yost-Bido[1], Rachel Spokony[1], Neil R. Hackett[1], Stephen M. Kaminsky[1], Richie Khanna[2], Ronald G. Crystal[1]

[1]Department of Genetic Medicine, Weill Cornell Medicine, New York, NY,[2]LEXEO Therapeutics, Inc., New York, NY

Friedreich's ataxia (FA) is a life threatening autosomal recessive disorder for which there is no effective therapy. Most FA patients are homozygous for a GAA trinucleotide expansion in the first intron of the frataxin (FXN) gene, resulting in transcriptional silencing and reduced FXN mRNA and protein levels. While heterozygotes are normal, homozygotes develop neurological dysfunction from 5 to 15 years of age and cardiac dysfunction at 20 to 25 years of age. Two thirds of FA patients die from cardiac dysfunction at an average age of 37.5 years. Average cardiac frataxin levels in FA homozygotes are estimated to be ~9.4 ng/mg protein and heterozygotes ~32.5 ng/mg compared to normal ~59 ng/mg. This provides the target level for vector-derived frataxin expression mediated by gene therapy using intravenous administration of AAVrh.10hFXN, a rh.10 capsid expressing the normal human FXN coding sequence driven by the CAG ubiquitous promoter. We assessed AAVrh,10-FXN function in the MCK mouse model, a severe disease model which has Cre-mediated knockout of the frataxin gene mediated by the MCK promoter confined to cardiac and skeletal muscle. A dose of 1.8 x 10^{12} gc/kg resulted in cardiac FXN levels in MCK mice of 33.7 ng/mg, equivalent to the FXN level in FA heterozygotes. Assessment of mice at this dose resulted in a modest 21.5% improvement in survival from 72 to >88 days ($p<0.01$ compared to PBS controls), with echocardiogram parameters lower than those of wildtype mice ($p<0.001$). To determine if there was additional benefit from higher doses and higher frataxin expression levels, we administered to 7-week-old MCK mice doses of AAVrh.10FXN increasing by half-log increments of 5.7 x 10^{12}, 1.8 x 10^{13} and 5.7 x 10^{13} gc/kg. With the reference of the original dose (1.8 x 10^{12} gc/kg) based on heterozygous cardiac FXN levels as the target, we refer to these as 3.3X, 10X and 33X dose cohorts. Following vector administration, health and behavioral assessments, echocardiograms, and cardiac and liver human FXN levels were obtained. All of the higher dose cohorts had human cardiac FXN levels in excess of the target based on non-FA human heart rising to 20,800 ± 3,200 ng/mg protein in the 33X dose cohort. There was an increase in survival increasing from a median of 87.5 days at the reference dose (1.8 x 10^{12} gc/kg) to 119 days in the 3.3X cohort, plateauing at 128 days in the 10X cohort. At the 33X dose, there was a varied impact on survival, with some animals surviving over 200 days but with some deaths earlier than those in the 10X cohort, likely representing toxicity at this very high dose. Assessed by echocardiogram, compared to the untreated control mice, there was a significant, dose-dependent increase in ejection fraction at 11 weeks from 18.9 ± 4.5% to 31.9 ± 2.9% in the reference dose cohort, increasing to 54.5 ± 9.8% in the 10X dose cohort. At the 33X dose, there was a decrease in ejection fraction, consistent with cardiac toxicity. In summary, there is a substantial survival and cardiac benefit in AAV-mediated expression of frataxin above the normal physiological level achieved at the 10X reference dose in the MCK mouse model of Friedrich's ataxia, but toxicity at high doses. This provides a rationale for ascending the dose in human clinical studies, but with caution regarding toxicity.

364 Development of AAV-Expressed C5 Inhibitor to Locally Suppress Complement Pathway Activation in the Eye as a Potential Treatment for Dry Age-Related Macular Degeneration

Wei-Hua Lee, Mi Shi, Ryan Clarke, Alex Dong, Jessica Gumerson, Vitaliy V. Bondar, Benjamin Heithoff, Zhuo Wang, Jared B. Smith, Subha Karumuthil-Melethil, Olivier F. Danos, Ye Liu, Joseph T. Bruder, Brendan Lilley

REGENXBIO Inc., Rockville, MD

Age-related macular degeneration (AMD) is the leading cause of blindness in the elderly population. Multiple lines of evidence suggest that dysregulation of the complement pathway plays an important role in AMD pathophysiology. Results from recent clinical trials demonstrate that monthly intravitreal injections with biologics that suppress complement pathway activation significantly delay lesion growth and disease progression in patients with geographic atrophy (GA), the dry form of late-stage AMD. Despite these encouraging results, monthly eye injections for the duration of a patient's life impose considerable treatment burdens. A single treatment with a gene therapy expressing complement pathway inhibitors in the eye represents an alternative approach that could both reduce the treatment burden and

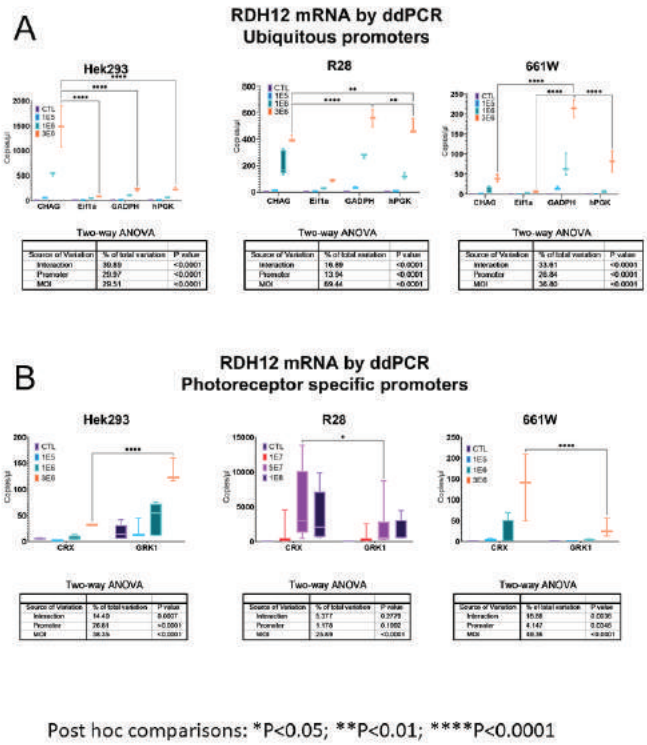
deliver therapeutic molecules for localized inhibition. Here we develop multiple AAV-expressed inhibitors that target human or mouse C5. We evaluated expression and potency using *in vitro* assays and *in vivo* murine models. We generated AAV constructs expressing C5 inhibitors in multiple formats, including anti-human C5 IgG (150 kDa), Fab (50 kDa), scFV (25 kDa), anti-mouse C5 IgG (150 kDa), Fab (50 kDa), scFV (25 kDa). A tick C5 inhibitor (17 kDa) was also tested in parallel. Media collected from transfected HEK293 cells were examined for transgene expression and for suppression of complement pathway activation in hemolysis inhibition assays. In addition, we generated recombinant purified proteins of each C5 inhibitor to compare their IC_{50} values in the classical and alternative complement pathways using hemolysis inhibition assays. The binding kinetics and affinity of each C5 inhibitor to human, cynomolgous macaque, and mouse C5 were measured with the Octet^{RED}384 system. All three formats of human C5 inhibitor demonstrated K_D values for human C5 in the low to high picomolar range, whereas the tick C5 inhibitor bound less strongly with a low nanomolar affinity constant. We next developed an *in vitro* model of complement overactivation by inducing the formation of the end-product of the complement pathway, membrane attack complex (MAC) on ARPE and iPSC-RPE cells, which are a target for complement deposition in AMD. Treating the cells with purified or vectorized C5 inhibitors prevented C5 cleavage and reduced MAC formation on the cell surface. The anti-C5 factors potently suppressed MAC formation in both systems tested with IC_{50} values in the nanomolar range. The ability of the C5 inhibitors to block C5 cleavage into C5a was also examined in media from the ARPE and iPSC-RPE cells. Dose-dependent reductions in C5a generation were observed with multiple formats of C5 inhibitors. AAV8 encoding C5 inhibitors were injected into wild-type mouse eyes via subretinal administration to determine the distribution, level, and bioactivity of the transgene products (TP) in the mouse eyes. All TPs tested showed high levels of expression and bioactivity. Collectively, our data support the potential of vectorized C5 inhibitors as a treatment for dry AMD.

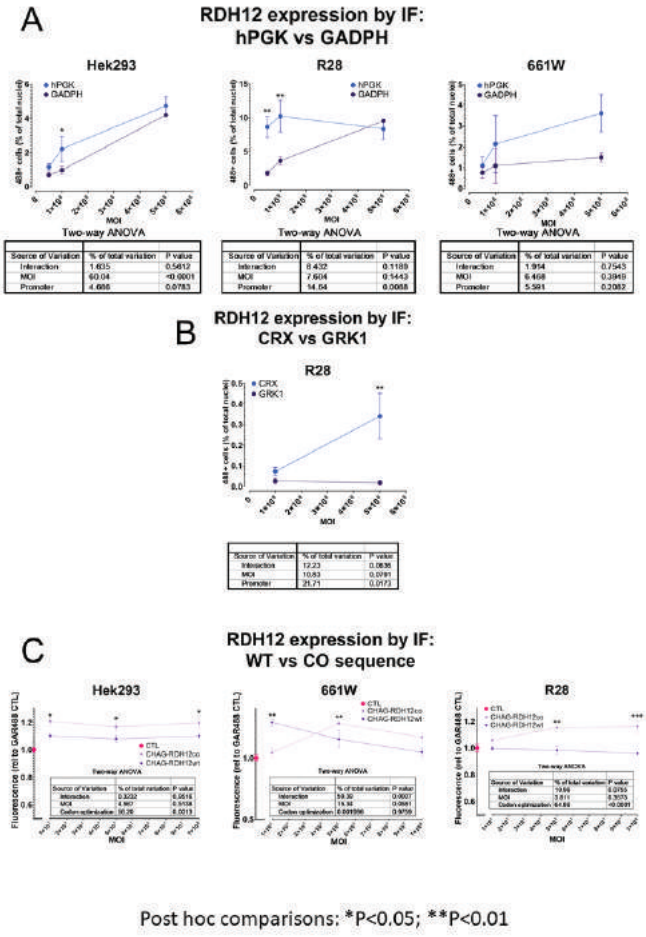
365 Comparison of *In Vitro* and *In Vivo* Potency of AAV8 Constructs to Correct RDH12 Deficiency

Manuel Solino, Mark Champe, Dwaipayan Sen, Fabrizia Urbinati

Vector Biosciences, Astellas Gene Therapies, South San Francisco, CA

Inherited retinal degeneration may lead to blindness and is caused by mutations in over 200 genes. One of them, *RDH12*, codes for an enzyme involved in the visual cycle; its deficiency leads to early onset blindness in humans. In preclinical studies, RDH12 deficiency causes a susceptibility to light damage in mice. There have been some published successful efforts in producing AAV gene therapies capable of restoring RDH12 expression; however, these did not produce a phenotype that showed morphological changes in the retina or correction of the phenotype using a murine version of RDH12. We aimed to find an AAV construct to express human RDH12 in RDH12 KO mice and protect them from light induced degeneration. To achieve this, we compared the strengths of different ubiquitous and photoreceptor-specific promoters (hPGK, GADPH, Eif1a, CHAG, GRK1, CRX) driving a wild type or a codon optimized RDH12 sequence in vitro and in vivo. Data was analyzed with Graphpad Prism using 2 way - ANOVA tests and the two-stage linear step-up procedure of Benjamini, Krieger and Yekutieli for post-hoc comparisons. To compare promoter potency, human (HEK293) and murine retinal progenitor (R28 and 661W) cell lines were transduced with AAV8 with the different constructs at multiplicity of infection (MOI) 1 x 10^5 to 5 x 10^8 virus particles per cell; ddPCR and immunofluorescence were performed to quantify RDH12 mRNA and protein expression, respectively. Considering results from Hek293, R28 and 661W cells, CRX and hPGK were selected as the best performing photoreceptor-specific and ubiquitous promoter, respectively (Fig. 1 & Fig. 2A, B; most significant comparisons and MOI ranges shown). To select between the codon optimized and the wild type sequence of RDH12, the same cell lines were transduced with AAV8 with CHAG as promoter at MOI 1 x 10^7 to 1 x 10^8 virus particles per cell. The codon optimized sequence produced more fluorescence in all cell lines (Fig 2C; most significant comparisons and MOI ranges shown). Finally, to select between hPGK and CRX, we will compare their effects in vivo. RDH12 KO C57BL/6N mice will be injected subretinally with AAV8 carrying the codon optimized RDH12 under CRX or hPGK promoters at doses ranging from 1E8 to 1E10. RDH12 mRNA will be quantified by qPCR. RDH12 protein will be quantified in photoreceptor cells by immunofluorescence and flow cytometry. These results are pending. In a follow up study, the best performing construct will be tested as a potential therapeutic for light induced retinal degeneration in C57BL/6N RDH12 KO mice.



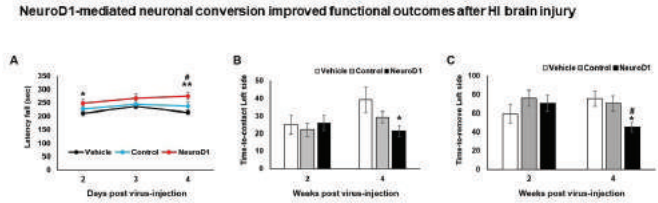


366 *In Vivo* Neural Regeneration via AAV-NeuroD1 Gene Delivery to Astrocytes in Neonatal Hypoxic Ischemic Brain Injury

Jeong Eun Shin[1], Miri Kim[1], Il-Sun Kim[1], Seungsoo Chung[2], Songyeon Kim[3], Seokmin Oh[3], Kook In Park[1], Jae-Hyung Jang[3]

[1]Department of Pediatrics, Yonsei University College of Medicine, Seoul, Korea, Republic of,[2]Department of Physiology, Yonsei University College of Medicine, Seoul, Korea, Republic of,[3]Department of Chemical and Biomolecular Engineering, Yonsei University, Seoul, Korea, Republic of

Neonatal hypoxic-ischemic (HI) brain injury is a major cause of massive neuronal loss and neonatal mortality and long-term neurodevelopmental disability. Current therapeutic approaches for HI brain injury have been limited to general supportive therapy because of the lack of methods to compensate irreversible neuronal loss. Recently, i*n vivo* direct neuronal reprogramming technology, which can avoid exogenous cell supply and immune suppression, has emerged as a powerful approach to compensate for the loss of neurons. We report an neuroregenerative therapy through *in vivo* transdifferentiation of astrocytes to neurons based on AAV-NeuroD1 gene delivery in neonatal HI brain injury mouse models, that have shown anatomical and functional recovery. The AAVShH19 vector, which has a higher rate of gene transfer to astrocytes than parent AAV2, and the a Cre-FLEx system for astrocyte-specific and long-term tracking of infected cells were used. AAVShH19-mediated ectopic expression of NeuroD1 in an HI brain injured mouse model converted astrocytes into GABAergic neurons and the converted cells had electrophysiological properties and synaptic transmitter. Additionally, we found that NeuroD1-mediated *in vivo* direct neuronal reprogramming protected injured host neurons and altered the host environment, represented as reduced number of activated microglia and reactive astrocytes, reduction of toxic A1-type astrocytes, and reduced expression of proinflammatory factors. Furthermore, NeuroD1-treated mice significantly improved their motor functions. Together, this study demonstrates that NeuroD1-mediated *in vivo* direct neuronal reprogramming technology through AAV gene delivery as a novel regenerative therapy for neonatal HI brain injury.



367 Translational Volumetric Capacity of the Cerebrospinal Fluid Compartment between Humans *and* Nonhuman Primates

Stephanie Korszen, Kelli Hancock, Michael DiBalsi, Geary Smith, Dennis Choi, Noelle Claycomb, Jeremy Stigall, Ernesto Salegio

ClearPoint Neuro, Inc., Solana Beach, CA

The cerebrospinal fluid (CSF) plays a crucial role in the homeostasis of the central nervous system (CNS) and has also been known to provide protection from exogenous trauma. Exploration of different routes of administration (RoAs) as potential avenues for gene therapy delivery have led to the reaffirmation that adeno-associated viral (AAV) vectors can indeed infect nervous tissue following CSF administration. Using magnetic resonance (MR) images acquired on a 3T scanner, donor scans from adult cynomolgus (N=10), pediatric human (N=10) and adult human cases (N=10), were analyzed using ClearPoint's Navigational Software, ITK-SNAP and OsiriX for corresponding volumetric values for CSF compartments. Interestingly, volumetric analysis of the cisterna magna lumen revealed a clinical variation of 7-fold in adult humans, versus a 5-fold variation in both pediatric humans and in nonhuman primates (NHPs). Comparatively, the difference in the averaged volume of the cisterna magna between human adults versus NHPs was 10-fold, whereas it was 9-fold between pediatric MRIs and those of NHPs. Examination of fourth ventricular lumens evinced a lower intra-subject variation clinically, as opposed to a greater inter-species variability between NHPs and humans. The volumetric data, in addition to measurements collected along a 3-dimensional axis, provide important translational considerations when designing *in vivo* animal studies and clinical trials aimed at delivering gene products to the cisternal and fourth ventricular lumen.

368 Barogenetic Gene Therapy for Modulating Blood Pressure

Subrata Batabyal, Darryl Narcisse, Adnan Dibas, Houssam Alsaad, Sanghoon Kim, Samarendra K. Mohanty

Nanoscope Technologies LLC, Bedford, TX

Introduction: Cells of different organs in the body undergoes exposure to range of pressures which changes in various diseases including neurological, cardiovascular, ophthalmological, and renal diseases. Clogging of arteries leads to hypertension and related injury. In case of hypertension, blood exerts pressure against the walls of blood vessels that can lead to severe health complications and increase the risk of heart disease, stroke, and sometimes death. We have engineered a mechanosensitive channel from bacteria that acts as pressure sensing and actuating molecule (SAM) and shown that heterologously expression of SAM in targeted cells leads to reduction of hypertension. **Methods and Mechanism of Action:** To investigate the effect of SAM-gene therapy for reduction of blood pressure, mouse model of hypertension (BPH/2J, Jackson lab) was used. The mice were injected with 175 µl of rAAV-SAM in tail vein. After 2 weeks of injection, tail cuff blood pressure measurement via Volume Pressure Recording (Kent Scientific) was carried out. Blood pressure was also recorded for non-injected BPH/2J mice (positive control) and wildtype mice. After these measurements, the mice were sacrificed, and tissues from various vital organs were collected. Immunohistology was performed on tissue sections to visualize the reporter (mCherry) expression. SAM expression in the endothelial cells of the glomerulus or the excretion apparatus in the kidney is expected to sequester fluid from the vasculature into the interstitial spaces or the glomerular space for later excretion from the body. Auto-regulating activity of the SAM molecule may induce an overall volume loss from the systemic vasculature, leading to a decrease in overall blood pressure.**Results:** Systemic injection of rAAV-SAM led to robust expression in the endothelial cells of the glomerulus in kidney. SAM expression in hypertension mouse model led to significant reduction of elevated Systolic and diastolic blood pressure to a level similar to that of the wildtype mice. Thus, SAM therapy demonstrated to have the same end physiological effect as diuretics but with the added benefit of self-regulation and permanence (as it would activate as soon as elevated blood pressure induced tension in the blood vessels reaches a pre-determined threshold). **Conclusions:** The engineered sensing and actuating molecule (SAM) is activated at physiological pressures, thereby enabling significant reduction of blood pressure in hypertension mice model. The SAM-gene therapy approach has potential to be transformative in maintaining health and physiological functions of various organs in a gene-agnostic manner for chronic diseases involving hypertension.

370 Exploring Gene Addition of a Single Unit within the Multi-Subunit Enzyme Complex of Serine Palmitoyl Transferase

Yi Gong[1], April Qian[1], Kenneth Gable[2], Casey A. Maguire[3], Teresa Dunn[2], Florian Eichler[1]

[1]Massachusetts General Hospital, Boston, MA,[2]Uniformed Services University of the Health Sciences, Bethesda, MD,[3]The Massachusetts General Hospital, Charlestown, MA

Sphingolipids (SLs) are lipid molecules that play essential structural and signaling functions in eukaryotes and have been linked to many neurological diseases. Serine palmitoyl transferase complex (SPT) mediates the first and rate-limiting step in the de novo sphingolipid biosynthetic pathway. The larger subunits SPTLC1 and SPTLC2/SPTLC3 together form the catalytic core with a smaller third subunit either SSSPTA or SSSPTB propelling the catalytic efficiency and providing substrate specificity for the fatty acyl-CoA substrates. Recently, the SPTSSA^{T51I} mutation was discovered in two girls with stagnant neurodevelopment, and both showed substantially elevated levels of several SLs. To further investigate the pathophysiology of this disease-causing mutation and explore therapeutic approaches, we developed a mouse model T51I knock-in mouse using targeted introduction of the T51I allele into exon 2 of the *SPTSSA* gene by CRISPR technology in fertilized eggs and further assessed the sphingolipid biochemistry and behavior in these mice. While the Sptssa^{T51I} heterozygous mice had minimal neurological deficits (sensory, motor or cognition) up to 5 month of age, biochemical analysis revealed an elevation in SL levels. Surprisingly, supplementation with 10% L-serine for 2-3 months further increased SL levels and now worsened the hind limb clasping behavior, suggesting a critical threshold in lipid chemistry impacting motor behavior. *In vitro* data in patient fibroblasts demonstrated successful transduction with adeno-associated virus (AAV) vector encoding wildtype SPTSSA (AAV-SPTSSA) and improvement in lipid chemistry. This has provided the justification for ongoing *in vivo* studies of AAV-SPTSSA gene therapy in Sptssa^{T51I} heterozygous mice. In conclusion, our studies demonstrate the feasibility of adding a single unit of a multisubunit enzyme complex to confer functional benefit. Our preliminary studies in mouse suggest the functional importance of the small subunit variant in Sptssa^{T51I} heterozygous mice by demonstrating the association of hind limb clasping with SL elevations. AAV-mediated delivery in human fibroblasts suggests that addition of SPTSSA can combine with other native subunits and impart its specific catalytic efficiency and restore the normal homeostasis of SPT. This may warrant further *in vivo* therapeutic development in mice and humans.

371 Prosaposin Gene Therapy Improves Features of Gaucher Disease in Preclinical Studies but Does Not Reverse the Neuropathology in Mouse Models of Alzheimer's Disease and Amyotrophic Lateral Sclerosis

Prosaposin is a highly conserved glycoprotein and the precursor for four lysosomal activator proteins called saposins. These saposins have distinct roles in regulating lysosomal hydrolysis of sphingolipids. Dysfunction of saposins results in an assortment of lysosomal storage disorders (LSD), such as Gaucher Disease (GD) with severe neuropathology. Mutations in the *PSAP* gene can cause a deficiency of either full-length prosaposin or any of the individual saposins, resulting in the accumulation of nondegradable, toxic glycolipids. Secreted full-length prosaposin has been shown to exert neuroprotective and glioprotective effects in cell culture systems but its in vivo application has not been examined. We hypothesized that increasing prosaposin levels might be useful therapeutically for LSDs and neurodegenerative disorders. Using a gene therapy approach, we administered AAV-hPSAP to two established mouse models of GD, the CBE and 4L/PS-NA mouse models via intracerebroventricular (ICV) injections. AAV-hPSAP improved neuroinflammation, and glycolipid levels in the brain with a trend towards improved motor function. To examine the neuroprotective role of prosaposin, we used two mouse models of Alzheimer's disease (AD), APP-PS1 and rTg4510 and a mouse model of Amyotrophic Lateral Sclerosis, TAR6/6. ICV delivery of AAV-hPSAP had no effect on memory dysfunction, phospho-Tau or neurofilament light chain (Nf-L) levels in AD mouse models. In the TAR6/6 model, ICV delivery of AAV-hPSAP did not improve motor dysfunction, Nf-L or TDP-43 levels. In summary, we demonstrate the therapeutic potential of prosaposin in LSD but further work is warranted to understand whether the protective effect of prosaposin can be extended to other neurodegenerative disorders.

372 Antibody Gene Therapy for Rabies Encephalitis

Jyoti Yadav[1,2], Amanda L. Gross[1], Giovanna Panepinto[1], Ywh-Min Tzou[1], S. Satheshkumar Panayampalli[3], L. Claire Godino[3], Kent R. Van Kampen[4], Miguel Sena-Esteves[5,6], Henry J. Baker[1,7], Douglas R. Martin[1,2]

Introduction. Rabies virus is one of the most crippling neurotrophic viruses with almost 100% fatality rate worldwide. Vaccination strategies that are currently used to prevent rabies infection primarily rely on the generation of the host serum neutralizing antibodies against rabies virus. The major caveat of serum neutralizing antibodies-based therapy is that while the rabies virus can easily breach blood-brain barrier, the antibodies cannot, making them largely ineffective in the treatment of symptomatic brain encephalitis. There is a need for antibody-induced protection in the central nervous system, independent of the host immune system. We propose to use the recombinant AAV9 (rAAV9) viral vector to traverse the blood-brain barrier and express a neutralizing human immunoglobulin against rabies glycoprotein in the brain. **Methods**. rAAV9 vector expressing a broadly neutralizing human antibody against rabies (CR57) was used to treat C57BL/6J mice intravenously for dose escalation study ($1x10^{10}$ to $1x10^{13}$ vg/kg) and longitudinal study ($6x10^{13}$ vg/kg dose and monitored for 60 days). We analyzed the expression of human CR57 in blood samples and brain tissue by Rapid Fluorescent Focus Inhibition Test (RFFIT), ELISA, and IHC. Additionally, 4-month-old cats were treated with low ($2x10^{12}$ vg/kg) or high ($1x10^{13}$ vg/kg) doses of rAAV9 intravenously and tissues were further analyzed. **Results.** The rabies neutralizing antibody level in mouse serum was >200 times higher than the protective titer suggested by the World Health Organization (WHO; 0.5 IU/ml) 1-3 months after the administration of $1x10^{12}$, $1x10^{13}$ and $6x10^{13}$ vg/kg rAAV9 vector. The expression of rabies neutralizing antibodies was further confirmed in neurons and brain endothelial cells by IHC. The level of CR57 was persistent in mouse serum for 60 days post-injection. However, neutralizing antibodies were absent in the lowest dose treatment group ($1x10^{10}$vg/kg). In rAAV9-treated cats, the high-dose treatment group showed significant levels of rabies neutralizing antibodies in serum for at least 15 months and in CSF for 3 months post-injection. Antibodies were also observed in cat serum of the low-dose cohort for 15 months after treatment. The decline in rabies neutralizing antibodies in feline serum of both high and low-dose treatment groups after 15-months is attributed to the development of cat immune response against human CR57. Nonetheless, rabies neutralizing antibodies were detected in the feline brain of the high-dose treatment group at endpoint (25-months post-treatment) by IHC.

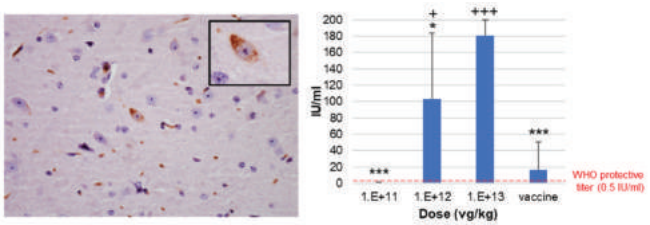

*Fig. Left: Antibody in mouse brain after IV injection of rAAV9 vector (brown staining). Insert represents the magnified neuron. Right: Recombinant AAV9 doses produced rabies neutralizing antibody >200 times above the protective titer (WHO) in mouse serum. ***p<0.0001 or *p<0.05 v. 1e13; +++p<0.0001 or +p<0.05 v. standard rabies vaccine*

Conclusions. An AAV9 vector injected intravenously in two species expresses broadly neutralizing antibodies in brain cells and thereby may provide protection against, or treatment of, viral encephalitis.

373 Development of a Gene Therapy for Alzheimer Disease by Lowering Toxic APOE While Simultaneously Overexpressing a Protective APOE Variant

Amila Zuko, Lisa Hentschel, Madhurima Chatterjee, Hendrina Wattimury, Lorenzo Boggiani, Angga Kusuma, Fiona Moreno, Bas Bosma, Javier Villamil, Lisa Spronck, Shrijana Tripathi, Ines Lopes Pereira, Ana Nogueira, Sara Gimeno Peris, Lukas Schwarz, Lieke Paerels, Elena de Miguel, Greg Dobrynin, Ying Poi Liu

uniQure biopharma B.V., Amsterdam, Netherlands

Alzheimer Disease (AD) is the most common form of dementia in people over 65 years (~50 million), manifesting as progressive memory loss and decline in cognitive function. The strongest genetic risk factor for late onset AD (LOAD) is the Apolipoprotein E4 (APOE4) variant. This lipoprotein is expressed in the liver and brain, facilitating lipid transport and homeostasis. APOE3 is the most common variant in the population, followed by APOE4 and APOE2 (79>13.3>7.3%). APOE4 is present in 45-60% of all AD cases and is associated with increased risk and decreased age of onset, while APOE2 is deemed neuroprotective. APOE4 depletion in humanized (h) APOE-AD mouse models prevented neurodegeneration in previous studies. We are developing an AAV gene therapy approach to treat patients with LOAD by silencing toxic APOE4 and overexpressing a protective APOE variant simultaneously. To identify the best candidates, a number of APOE silencing miQURE® molecules and protective APOE-variants were first screened in vitro and in vivo separately. We previously demonstrated that microRNAs against APOE using our silencing miQURE platform effectively suppressed APOE expression *in vitro*. APOE-targeting miQURE molecules were tested by intrastriatal delivery of AAV vectors in a *hAPOE4*-transgenic mouse model. Expression of miQURE molecules resulted in potent reduction of hAPOE4 mRNA and protein in the brain. Additionally, various protective APOE-variants were screened *in vitro* for transgene expression and secretion. The best protective APOE-variants were examined *in vivo* by intrastriatal AAV delivery in a human Tau overexpressing transgenic model; P301S Tau-transgenic mice. The expression of the protective APOE-variants and the impacts on pathological phenotypes will be analyzed on post-mortem material seven months post-injection. Finally, the most potent miQURE molecules and protective APOE-variants were selected and implemented into a combined construct to function in concert. The combined constructs that simultaneously encode miQURE and protective APOE-variant transcripts were validated in an *in vitro* screen to demonstrate miQURE efficacy as well as APOE-variant expression. A subset of these constructs was selected for *in vivo* testing via intrastriatal delivery of AAV vectors, whereafter the expression of the transcripts will be examined. In conclusion, simultaneous silencing of toxic APOE and overexpressing a protective APOE variant warrants further investigation as a gene therapy approach for AD. *miQURE is a registered trademark in the US and other jurisdictions.*

374 An Adeno-Associated Virus-Based Combination Gene Replacement Therapy for Parkinson's Disease

Qian Zhang, Pengjuan Ma, Jing Ma, Liang Lu, Xi Zhu, Xiaoping Zhao, Shin-Shay Tian, Yezheng Tao

Vitalgen BioPharma Co, Shanghai, China

Parkinson's disease (PD) has an incidence rate as high as 1%-2% among people over 60 years old, and is the second largest neurodegenerative disease in the world. In China, it is estimated that there are more than 2 million PD patients. The pathogenesis of PD is hypothesized to be the combined effects of gene mutations and the environmental factors. The main pathological changes of PD are the loss of dopaminergic neurons in the substantia nigra, and the appearance of Lewy bodies (mainly the aggregation of α-synuclein protein) in the cytoplasm of the remaining neurons, leading to the irreversible neurodegeneration of dopaminergic projections from the substantia nigra to the striatum. With the reduction of dopamine in the striatum, typical motor symptoms (Parkinsonism) appear, including resting tremor, muscle rigidity, slow movement, posture and gait disorders, and when degeneration affects other brain regions, obvious non-motor symptoms such as sleep disturbance, depression, cognitive impairment, *etc*., will also appear. The currently available treatments are mainly to increase dopamine levels in the brain by providing dopamine derivatives, like levodopa. These treatments have limited efficacy for non-dopaminergic symptoms, especially in advanced stage of PD and are unable to change the disease progression. Moreover, as the disease progresses, the side effects, for example escalating dose of levodopa induced dyskinesia, gradually become intolerant. New therapies that could not only effectively improve motor symptoms, but also slow the disease progression and delay the onset of disability of other brain functions are urgently needed for PD patients. In the normal brain, dopamine is converted from tyrosine to dopa catalyzed by tyrosine hydroxylase (TH), and then into dopamine by dopa decarboxylase (AADC). The progressive decrease of AADC expression in the striatum of advanced PD patients has been hypothesized to be one of the reasons for reduced responses to levodopa. Therefore, supplementing AADC in the striatum could effectively increase the conversion efficiency of levodopa into dopamine and reduce the side effects induced by levodopa overdose. Meanwhile, to stop the progressive degenerative changes in patient's brain, neuroprotective intervention like overexpressing neurotrophic factors has shown to be a promising strategy. Based on the above hypothesis and our knowledge of PD pathologies, we have developed a combination gene therapy to address simultaneously the different aspects of PD pathologies to provide a disease modifying long-term

treatment option for PD patients. In the current study, VGN-R09b, as a recombinant AAV9, delivers genetically modified human AADC and a neurotropic factor genes, which are directly distributed in the striatum, to infect nerve cells through brain parenchymal injection. The AADC delivered by VGN-R09b will increase dopamine levels in the synaptic cleft to improve motor symptoms. The neurotropic factor delivered will be secreted extracellularly, act on the synaptic terminal of dopaminergic neurons to promote axonal sprouting and produce neuroprotection effects. In preclinical mouse studies, intra-striatal injected VGN-R09b appeared to be well-tolerated at doses up to 2×10^{12} vg/kg. Intra-striatal injection of VGN-R09b could dose-dependently improve the motor impairments, increase the striatal AADC activity, and protect the dopaminergic terminals in PD rodent and monkey models. Our preclinical data demonstrated the safety and efficacy of VGN-R09b and indicated its potential as an effective long-term treatment for PD.

375 A New Minimally Invasive Endovascular Approach to the Cerebello-Pontine Cistern Enables Improved AAV Biodistribution Compared to Cisterna Magna Injection

Hector Ribeiro Benatti[1], Vania Anagnostakou[1], Erin Frances Hall[1], Adel M. Malek[2], Carl B. Heilman[2], Brandon M. Beneduce[3], Anita Leporati[1], Robert King[1], Matthew Gounis[1], Heather L. Gray-Edwards[1]

[1]UMass Chan Medical School, Worcester, MA,[2]Neurosurgery, Tufts Medical Center, Boston, MA,[3]CereVasc, Auburndale, MA

Introduction: Delivery of viral vectors to target brain tissue remains an unsolved challenge due to the blood brain barrier. Parenchymal brain injections or cerebrospinal fluid delivery to the cisterna magna (CM) can improve CNS delivery, but with unfavorable risk profile. A novel approach that leverages advances in catheter intervention, imaging technology, and operator workforce could improve safety and efficacy, and resolve the challenge of delivering clinically useful gene and cell-based therapies to the brain. We have previously presented a percutaneous endovascular CNS access system to the cerebello-pontine angle (CPA) cistern located in front of the brainstem. Considering the characteristics and limitations of current techniques, here we determine how biodistribution of scAAV9-CB-GFP administered into the CPA compares to that of the same vector into the CM. **Methods:** Eight sheep were allocated into CPA (n=4) and CM (n=4) cohorts. Lumbar puncture was performed into the lumbosacral intervertebral space (L7-S1). A 1.7F braided microcatheter with 0.014" micro-guidewire was introduced into the subarachnoid space and navigated into either the CPA cistern or CM under fluoroscopic guidance. Cone-beam computed tomography fused with MR imaging was used to confirm accurate final placement of the catheter. scAAV9-CB-GFP (1.0×10^{14} vg in 3mL) was injected at 200µl/min. Animals were sacrificed 3 weeks post-procedure. Anti-GFP antibody immunohistochemistry was performed with (Abcam ab290). Vector genome biodistribution was determined by qPCR using primers and probes for the BGH poly (A). **Results:** Immunohistochemistry targeting GFP shows a stronger transduction profile in the parietal cortex in the CPA cohort compared to CM (Fig 1). In the dorsal midbrain, a modest increase of GFP immunoreactivity was observed in the CPA cohort. Strong immunoreactivity was also observed in the ventral aspect of the cingulate gyrus. Vector genome quantification of the occipital cortex and midbrain tissues revealed comparable vector genomes between CPA and CM injection routes at approximately 10,000 vg/100ng (Fig. 2). Only modest biodistribution to peripheral liver tissue was observed with both injection routes. **Conclusions:** CPA delivery of AAV9 resulted in increased transduction of the parietal and cingulate cortex, compared to that observed with CM injections. These results suggest that the clinically safer percutaneous endovascular minimally invasive method of delivery to the CPA cistern may offer a more effective approach than cisterna magna injection for diffuse delivery of gene and cell-based therapies to the CNS.

376 Ocular Biodistribution of AAVHSCs across Species and Routes of Administration

Sumeet Sarin[1], Nancy Avila[1], Jason Lotterhand[1], Laura Silk[1], Monicah Kivaa[1], Laura J. Smith[1], Hillard Rubin[1], Jeff Ellsworth[2], Omar Francone[1], Albert Seymour[1], Jacinthe Gingras[1]

[1]Homology Medicines, Inc., Bedford, MA,[2]Stellar Research and Development, LLC, Lexington, MA

A current challenge for ocular gene therapy is choosing an appropriate delivery vehicle and route of administration to target diseased cells precisely and robustly. Although several options of dosing routes have emerged, cell-type selective delivery vehicles are limited. Adeno-associated viruses (AAVs) show promise for gene therapy in the eye due to their stable transgene expression in non-dividing cells. We have reported the discovery of 15 novel, naturally occurring, Clade F AAVs derived from human hematopoietic stem cells (HSCs). Here, we present the complete ocular biodistribution of 11 AAVHSCs to demonstrate their utility as delivery vehicles for a variety of indications. We evaluated tropism of each AAVHSC capsid for individual ocular cell types by packaging one of two transgenes: single-stranded enhanced green fluorescent protein (ss-eGFP) transgene driven by the CMV promoter or self-complementary enhanced green fluorescent protein (sc-eGFP) driven by the chicken beta actin (CBA) promoter. We first targeted the posterior segment of the mouse (C57Bl6/J) eye by three dosing routes, subretinal, intravitreal (IVIT) and suprachoroidal. We then extended subretinal dosing to two larger mammals, non-human primates (NHPs, cynomolgus macaque) and Gottingen pigs. To target the anterior segment of the mouse eye, we dosed each capsid by one of two routes, IVIT or intracameral. Finally, we dosed human retinal explants with ss.AAVHSC15.eGFP. In all species, biodistribution of each AAVHSC was assessed by multiplexed immunostaining with anti-eGFP along with cell-type specific markers. Key observations include: 1) Across all species tested, including in human cells and in NHPs, AAVHSCs transduced photoreceptors (PRs) and retinal pigment epithelial (RPE) cells, both targets for inherited retinal disease; 2) A subset of AAVHSCs transduced murine PRs and RPE by the preferred IVIT dosing route; 3) Other murine retinal cells of therapeutic interest, Müller glia and retinal ganglion cells, were also transduced in a capsid-selective manner; 4) AAVHSCs exhibited capsid-specific tropism for trabecular meshwork cells, a cell type key to the onset of glaucoma; 5) Specific AAVHSCs exhibited the ability to cross the blood-retina barrier following a suprachoroidal dose, the least invasive ocular route of administration. These data demonstrated that AAVHSCs transduced several clinically relevant cell types across multiple species, allowing potential for gene therapy application in treating ocular diseases affecting both the front and back of the eye.

377 Development of an AAV-Based Gene Therapy for Dermatosparaxis Ehlers-Danlos Syndrome

Abby McElroy[1], Jillian Gallagher[1], Toloo Taghian[2], Erin Frances Hall[1], Hector Ribeiro Benatti[1], Elizabeth Parsley[3], Laura Dupont[4], Miguel Sena-Esteves[5], Alain C. M. A. Colige[4], Heather L. Gray-Edwards[2]

[1]Horae Gene Therapy Center, University of Massachusetts Chan Medical School, Worcester, MA,[2]Horae Gene Therapy Center; Department of Radiology, University of Massachusetts Chan Medical School, Worcester, MA,[3]Cummings School of Veterinary Medicine at Tufts University, North Grafton, MA,[4]Laboratory of Connective Tissue Biology, University of Liège, Liège, Belgium,[5]Horae Gene Therapy Center; Department of Neurology, University of Massachusetts Chan Medical School, Worcester, MA

Introduction Dermatosparaxis Ehlers-Danlos syndrome (dEDS) is an autosomal recessive connective tissue disorder caused by a loss of function mutation in ADAMTS2 encoding for procollagen I N-proteinase. The mutation impairs the cleavage of the N-propeptide from type I procollagen chains resulting in mature collagen fibrils with aberrant morphology and lower tensile strength. Patients with dEDS present with severe skin fragility and redundant skin, hernias, craniofacial deformities, short stature, easy bleeding and bruising, visceral fragility, and premature placental rupture of the membranes. This type of EDS was selected for development of a gene therapy, because 1) it is caused by a loss of function of a secreted protein (ADAMTS2), 2) it is encoded by a 3.6kb cDNA, and 3) ADAMTS2 is ubiquitously expressed throughout the body. Due to the extracellular action of ADAMTS2, AAV9 was selected with the goal of transducing liver and skeletal muscle to provide stable long-term expression. The knockout mouse model of ADAMTS2 (*Adamts2*^{KO}) also develops skin fragility, loss of surface contour of the molar teeth, abnormal lungs with a pseudo-emphysematous appearance, and sterility of male mice.
Methods Four AAV9 vectors encoding for various elements to optimize expression and secretion were screened for toxicity in 6-week-old C57BL/6J mice. Mice in each group (n=4) were treated via intravenous tail vein injection at a dose of 1E12 vg/mouse. Mice were sacrificed one month later. Subsequently, *Adamts2*^{KO} (n=6) and normal littermate controls (n=6) at 1E12 vg/mouse were injected via intravenous tail vein injection post-symptomatically at 2 months of age. Two endpoints, 2 months and 1 year, will be employed for each group.
Results The wild type mouse study produced no adverse clinical outcomes in any mice, and tissues appeared grossly normal at necropsy. Histology, transmission electron microscopy, qPCR, and western blot are underway. *Adamts2*^{KO} mice will be evaluated based on clinical signs, skin fragilty, necropsy findings, transmission electron microscopy, biochemical electrophoretic analysis of procollagens, qPCR analysis of ADAMTS2 expression and vector genomes to select the best vector. Following this, a clinical trial will be initiated using a naturally occurring dog model of dEDS.

378 Significance of Pre-Existing Antibodies to Multiple Serotypes of AAVs in NHPs Serum, Measured by NAb and TAb Assays

Javier Mota, Lisa Tomanek, Victoria Flores, Beverly Gondo

VRL, San Antonio, TX

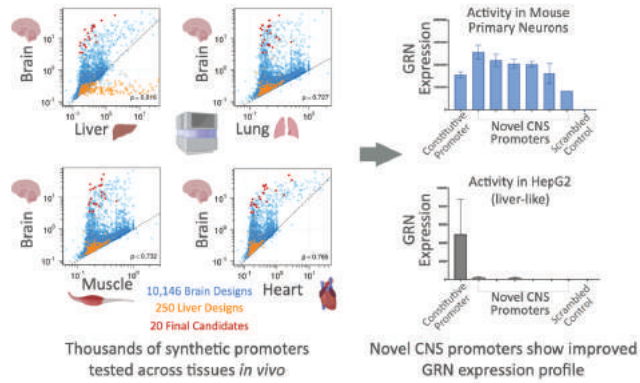
The presence of pre-existing neutralizing antibodies (NAb) against adeno associated viruses (AAVs) has the potential to negatively impact the transduction efficiency when they are used as delivery vectors in gene therapy studies. With AAV emerging as one of the most efficient viral vectors, it is now more relevant to have effective and consistent tools to measure anti-AAVs antibodies. Cell-based assays to measure NAbs, and ELISA to measure total antibodies (TAbs), are the most commonly used methods to enumerate anti-AAV antibodies. In this work we used both techniques to correlate and determine the significance of having antibodies to several serotypes. We investigated what could be the impact of the presence of multi reactive antibodies measured by TAb-ELISA in their capacity to neutralize a specific AAV serotype. To this end we tested a panel of 171 NHP serum samples. Five different AAV serotypes, AAV1, AAV2, AAV5, AAV8 and AAV9 were used for the analysis. For the NAb assay, the AAV reporter for each serotype, encodes for the green fluorescent protein and was used to measure the percentage of neutralization inhibition. For the TAb assay, virus-like particles of the five serotypes were used to measure total IgG in the serum samples by an indirect ELISA. The implications of multi-reacting samples in the neutralization of the corresponding serotype and other serotypes of AAV will be further discussed.

379 Rational Engineering of Novel Synthetic Promoters for Specific AAV-Delivered GRN Expression in the CNS

Jacob M. Tome, Hussein Al-Asadi, Sandra B. Shannon, Stephanie R. Kall, Michael A. Koday, Samantha R. Edwards, Lillian J. Bussema, Timothy G. Johnstone, Yue Jiang, Jonathan H. Wang, Robyn J. Laing, Eric M. Chadwick, Ronald James Hause, Adrian W. Briggs, Richard T. Sullivan

Shape Therapeutics, Inc., Seattle, WA

Safe and effective gene therapies using adeno-associated viruses (AAVs) require payload expression at high levels in target cells with minimal expression in undesirable tissues, especially for therapies targeted outside the liver. Promoter sequences are key levers to control gene therapy transgene expression, but most "off-the-shelf" promoters are not sufficiently strong, or tissue-specific, or compact enough for use in AAV-based gene therapy. To address these challenges, we developed a synthetic biology platform that enables discovery of highly specific and tunable promoters that are tailored to a desired target product profile (e.g., central nervous system (CNS-specific). We employ Massively Parallel Reporter Assays (MPRAs) to screen thousands of promoters or promoter components in each experiment. Our approach is based on the modular framework of a highly optimized core promoter combined with a cell-type-sensing enhancer region, whereby the final promoter is of a consistent and small size (~200 bp). Here we demonstrate the development of brain-specific promoters for a Progranulin (GRN) gene replacement transgene for the treatment of frontotemporal dementia (FTD). We aimed to engineer a synthetic promoter that provides robust CNS-specific expression of a GRN transgene with minimal expression in other AAV-transducible tissues such as liver, heart, and skeletal muscle. We first performed a 3,600-candidate MPRA screen that identified an improved core promoter yielding three-fold higher expression than industry-leading standard core promoters like ybTATA and minP and no loss in dynamic range. We then engineered 10,000 candidate CNS-specific enhancers by mining human functional genomic databases and screened by MPRA in both in vitro cell and in vivo mouse models. Final candidates were selected for high expression in CNS models including mouse brain and the human neuronal LUHMES cell line, with low expression in mouse liver, heart, skeletal muscle, kidney, and lung, and a human liver-derived HepG2 cell line. The top performing CNS-enhancers were combined with the core promoter to yield final promoter constructs that displayed improved strength, specificity, and size profiles compared with currently available constitutive or CNS-specific promoters. In addition to identifying CNS-specific, liver-inert promoters, our modified core promoter plus enhancer discovery approach can be adjusted rapidly for other desired tissue expression profiles, as the underlying genomic datasets already exist body-wide. In particular, the combination of specific and tunable promoters with emerging novel tissue-specific AAV capsids promises to accelerate the development of safe and effective gene therapies.



380 Cell Class-Specific Gene Therapy for Dravet Syndrome

John K. Mich[1], Jiyun Ryu[2], Bryan B. Gore[3], Aguan D. Wei[2], Refugio A. Martinez[1], Rong Guo[3], Michelle Bard[4], Yemeserach Bishaw[1], Jan Ramirez[5], Jonathan T. Ting[1], Ed S. Lein[1], Boaz P. Levi[1], Franck Kalume[1]

[1]Allen Institute for Brain Science, Seattle, WA,[2]Seattle Children's Research Institute, Seattle, WA,[3]Allen Institute, Seattle, WA,[4]Seattle Children's Research Institute, Seattle, WA,[5]Seattle Children's Research Institute and UW Dept. of Neurological Surgery, Seattle, WA

Dravet syndrome (DS) is a devastating developmental and epileptic encephalopathy marked by treatment-resistant seizures, developmental and motor deficits, and a high rate of premature death. In over 80% of patients with DS, the disease is caused by heterozygous loss-of-function mutations in SCN1A, the gene encoding Nav1.1 channels. SCN1A mutations impair GABAergic interneuron excitability, and mouse models recapitulate key DS

phenotypes when SCN1A mutations are targeted to GABAergic interneurons. Taken together these observations suggest interneurons constitute a promising target for precision gene therapy in DS. Here we developed a GABAergic interneuron-targeted AAV SCN1A gene replacement therapy using highly validated cell class-specific enhancers. Using these tools we circumvented AAV carrying capacity limitations and achieved full-length SCN1A expression in forebrain GABAergic neurons with high efficiency and specificity. These constructs produce functional Nav1.1 protein as evidenced by patch-clamp recordings and western blot in cell lines. After packaging these vectors into AAV and administration in mice, immunohistochemical analyses showed dose-dependent biodistribution of the therapeutic cargo in targeted cells and brain regions. Remarkably, these vectors conferred strong dose-dependent protection against mortality and thermally induced seizures to DS mouse models carrying nonsense alleles of Scn1a. We observed protection in two independent model mouse lines and at two independent research sites, with no overt toxicity observed in littermate control mice. Immunohistochemistry on these testing cohorts allowed us to directly correlate vector biodistribution with functional rescue. Furthermore, we also tested additional vectors for pan-neuronal expression of Nav1.1, and these vectors provided weaker protection from DS symptoms, and also showed safety concerns including preweaning lethality. As a whole these findings suggest that cell class specificity might not only boost effectiveness of gene therapy in DS, but could also make therapy safer. In summary these findings demonstrate proof-of-concept that cell class-specific AAV-mediated SCN1A gene replacement therapy could provide an effective precision therapy in DS.

381 ICV Administered AAV9-NGLY1 Gene Replacement Therapy (GS-100) Improves Motor Function and Biomarker Outcomes in Ngly1 Deficient Rats

Lei Zhu, William F. Mueller, Jennifer W. Cook, Brandon Tan, Alicia Newton, Selina S. Dwight, Brendan Beahm, Matt Wilsey, Brett E. Crawford, Becky Schweighardt
Grace Science LLC, Menlo Park, CA

GS-100 is an AAV9 gene therapy for the treatment of N-glycanase 1 (NGLY1) Deficiency, an ultra-rare, debilitating recessive disorder due to loss-of-function mutations in the NGLY1 gene. Symptoms include global developmental delay, intellectual disability, hyperkinetic movement disorder, elevated liver enzymes, (hypo)alacrima, and peripheral neuropathy. There are no approved therapies for this disease. Preclinical route of administration and dose-finding studies with GS-100 demonstrated positive treatment effects starting at 6.2e11 vg/animal in Ngly1-/- rats following intracerebroventricular delivery. We evaluated the dose-dependent efficacy and safety of GS-100 in a 6-week pharmacology/toxicity study in Ngly1-/- rats at three dose levels (6.2e11, 6.7e12, and 1.1e13 vg/animal). Widespread dose-dependent biodistribution of GS-100 vector DNA was detected in the brain and spinal cord, which positively correlated with hNGLY1 mRNA and protein expression. Treatment with GS-100 resulted in a dose-dependent improvement in motor function (rotarod) and reduction of the NGLY1 disease biomarker, GNA, in the cerebrospinal fluid (CSF) and brain tissue. The low dose of GS-100 was associated with non-significant trends in rotarod improvement and GNA reduction in the Ngly1 deficient rats, whereas the mid-dose was associated with statistically significant improvement in motor function to near wild-type levels that correlated with a statistically significant reduction in GNA (42.5%). Similar rotarod findings were detected at the high dose, with slightly more reduction in the GNA biomarker (45.9%). GNA levels in the CSF were found to correlate with GNA levels in brain tissue, supporting the use of CSF GNA levels as a surrogate measurement for brain tissue GNA levels. Importantly, an inverse correlation was observed between motor improvements and the GNA biomarker in CSF and brain tissue, supporting the use of CSF GNA as a surrogate marker of clinical endpoint improvement in a clinical setting.GS-100 was well tolerated at all dose levels tested in this study. There were no systemic toxicities, significant increases in liver transaminases, or macroscopic pathology attributed to GS-100. Histopathology analysis revealed dose-dependent, mild to moderate neuronal loss and gliosis in the hippocampal region of the brain near the injection site, at all dose levels. Statistical analysis found no correlation between the severity of the neuropathologic findings and motor performance within individual animals. Correlations between vector biodistribution, hNGLY1 expression, GNA biomarker reduction, and motor function improvement in Ngly1 deficient rats indicate that ICV administration of GS-100 results in the expression of functional hNGLY1 that ameliorates the underlying disease pathology, resulting in positive disease modification.

382 Crossing the Non-Human Primate Blood Brain Barrier with Machine-Guided AAV Capsid Design

Megan Elizabeth Bailey, Dan Bloodgood, Ina Chen, Jeff Gerold, Jerrah Holth, Rishi Jajoo, Eric Kelsic, Kathy S. Lin, Patrick McDonel, Aashu Vihani, Sam Wolock
Dyno Therapeutics, Watertown, MA

AAV capsids that efficiently cross the blood brain barrier and transduce the brain are necessary to facilitate gene therapy for many neurological disorders but remain a major unmet need. Here, we describe the discovery and characterization of a novel capsid exhibiting substantially improved transduction of the CNS when delivered intravenously in non-human primates (NHPs). In high throughput screens, this capsid consistently demonstrated large improvements in transduction efficiency relative to AAV9, including an 80-fold improvement in African green monkeys and a 100-fold improvement in cynomolgus macaques. Moreover, in an NHP validation study at modest dose (1e13 vg/kg), histology analysis showed that the selected capsid transduced >10% of all cells, and up to 25% of neurons in therapeutically relevant brain regions including the hippocampus, basal ganglia, cerebellar cortex, and substantia nigra. The capsid exhibited 5-fold reduced biodistribution and 10-fold reduced transduction in the NHP liver relative to AAV9, and produced comparably to AAV9. The discovery of this capsid leveraged machine-guided design to identify an AAV capsid sequence with greatly improved CNS transduction properties over AAV9 as well as additional properties of therapeutic interest. The sequence changes include a novel motif relative to all known engineered capsids that is not a peptide insertion. Iterated application of machine-guided design has identified further-improved capsids that warrant additional characterization given the high concordance between our discovery and validation studies demonstrated here.

383 A Multiplexed Barcode Approach to Simultaneously Evaluate Gene Delivery by AAV Capsid Variants Across Multiple Non-Human Primate Tissues

Daniel Stone[1], Nadja Meumann[2], Anne-Sophie Kuhlmann[3], Christopher W. Peterson[3], Hong Xie[4], Pavitra Roychoudhury[4], Michelle A. Loprieno[1], Vu Xuan-Khang[2], Daniel Strongin[4], Elizabeth Kenkel[5], Anoria Haick[1], Laurence Stensland[4], Willimark Obenza[3], Jacob Parrott[3], Veronica Nelson[6], Robert Murnane[6], Meei-Li Huang[4], Martine Aubert[1], Hans-Peter Kiem[3], Hildegard Buning[2], Keith R. Jerome[1]

[1]Vaccine and Infectious Disease Division, Fred Hutchinson Cancer Center, Seattle, WA,[2]Hannover Medical School, Hannover, Germany,[3]Clinical Research Division, Fred Hutchinson Cancer Center, Seattle, WA,[4]Department of Laboratory Medicine and Pathology, University of Washington, Seattle, WA,[5]Bristol Meyer Squibb, Seattle, WA,[6]University of Washington, Seattle, WA

Adeno-associated virus (AAV) vectors have been widely used to deliver therapeutic transgenes to many distinct cell populations or tissues across countless studies. Both naturally occurring and engineered AAV capsids have been independently investigated as AAV vectors, and extensive studies have been performed in mice and other species to determine their *in vivo* tropisms. However, studies in mice are not always predictive of vector performance in other animal models or humans, and differences in tissue tropisms have been observed between different mouse strains. Considering the increasing interest in AAV vectors for human gene therapy, an increasing number of studies are being performed in large animals such as non-human primates (NHP), yet studies in large animals have also shown that significant species-to-species, and often within-species variation exists. To optimize the process of AAV capsid selection and keep animal numbers to a minimum, we developed a multiplex barcoding approach that allows the simultaneous evaluation of *in vivo* vector performance for multiple different capsids. We assessed vector biodistribution and gene transfer in male and female rhesus macaques that were simultaneously administered a combination of 8 or 11 naturally occurring and capsid engineered barcoded AAV vectors intravenously. Animals were immune suppressed with rapamycin and tacrolimus for 2 weeks prior to AAV administration and for the duration of the experiment to suppress pre-existing anti-AAV immune responses, and then followed longitudinally post AAV administration to determine which AAV capsids were able to successfully transduce different tissues using a combination of qPCR, qRT-PCR, vector DNA Illumina amplicon sequencing (vDNAseq), and vector mRNA Illumina amplicon sequencing (vRNAseq). We analyzed vector biodistribution and gene transfer in PBMCs at 1-, 3-, 7-, 14- and 23-days post AAV administration, in BAL, in axillary lymph node and colonic biopsies at 7-days post AAV, and in a panel of 8 lymphoid and 10 non-lymphoid tissues at 23-days post AAV. We also determined the levels of neutralizing antibodies (NAbs) against each capsid within our AAV-inoculum at the time of injection to evaluate the degree to which pre-existing humoral immunity can influence vector biodistribution and gene transfer. Our findings show that there is significant animal-to-animal variation in both the biodistribution and tissue transduction of different AAV vector capsids, and that pre-existing serotype-specific neutralizing antibodies can play a significant role in the outcomes for each capsid once administered systemically. They also allowed us to identify capsids that were enriched in several different tissues of interest for the development of gene therapeutics including liver, heart, and muscle. In summary, this method offers a robust approach to vector optimization that can be used to identify and validate vectors for gene delivery to potentially any anatomical site or cell type.

384 E-Selectin/AAV Gene Therapy Promotes Myogenesis and Skeletal Muscle Recovery in a Mouse Hindlimb Ischemia Model

Antoine J. Ribieras, Yulexi Y. Ortiz, Yan Li, Nga T. Le, Carlos T. Huerta, Francesca A. Voza, Hongwei Shao, Roberto I. Vazquez-Padron, Zhao-Jun Liu, Omaida C. Velazquez

Surgery, University of Miami, Miami, FL

Introduction: Chronic limb hypoperfusion due to systemic atherosclerosis in peripheral artery disease (PAD) can lead to life-limiting claudication and limb-threatening ischemia. Identifying novel targets regulating neovascularization and regeneration of ischemic tissues is key to developing nonsurgical treatment adjuncts for PAD. E-selectin is an adhesion molecule that mediates recruitment of endothelial progenitor cells during neovascularization. Therapeutic priming of ischemic limb tissues with intramuscular E-selectin gene therapy promotes angiogenesis and reduces tissue loss in a mouse hindlimb gangrene model. In this study, we further evaluated the effects of E-selectin gene therapy on skeletal muscle recovery, specifically focusing on exercise performance and myofiber regeneration. **Methods:** C57BL/6J mice aged 10-12 weeks were treated with a total of $1x10^{11}$ viral genome of either E-selectin/adeno-associated virus serotype 2/2 gene therapy (E-sel/AAV) or LacZ/AAV as control. Hindlimb ischemia was induced by unilateral femoral artery and vein coagulation. Recovery of hindlimb perfusion was measured by laser Doppler perfusion imaging and skeletal muscle function assessed by treadmill exhaustion and grip strength testing. On postoperative day (POD) 21, gastrocnemius muscles were harvested for immunofluorescence analysis of myogenic precursors and fiber-type distribution. Expression of *E-sel* transgene was confirmed by real-time reverse transcription quantitative polymerase chain reaction (RT-qPCR). **Results:** After induction of hindlimb ischemia, both E-sel/AAV- and LacZ/AAV-treated mice experienced a similar reduction in perfusion (0.08 ± 0.01 *vs* 0.08 ± 0.01, $P = .64$). Hindlimb perfusion progressively recovered in both groups but was significantly enhanced by E-sel/AAV gene therapy as early as POD 3 (0.21 ± 0.02 *vs* 0.14 ± 0.01, $P = .002$) and at all time points through POD 21 (0.58 ± 0.02 *vs* 0.33 ± 0.02, $P < .001$). In parallel with recovery of hindlimb perfusion, mean grip strength was significantly greater in mice treated with E-sel/AAV compared to LacZ/AAV starting on POD 7 (1.89 ± 0.08 *vs* 1.57 ± 0.07 gf/g, $P = .009$) and through POD 21 (2.36 ± 0.08 *vs* 1.93 ± 0.09 gf/g, $P = .001$). E-sel/AAV-treated mice also outperformed LacZ/AAV controls during treadmill exhaustion testing on POD 7 (264 ± 26 *vs* 157 ± 23 m, $P = .009$) and through POD 21 (354 ± 27 *vs* 232 + 30 m, $P = .009$). On POD 21, RT-qPCR confirmed that *E-sel* mRNA levels were 322-fold higher in muscle treated with E-sel/AAV compared to LacZ/AAV. Immunofluorescence analysis demonstrated enhanced proliferation of myogenic precursors as measured by number of $MyoD^+$ cells (10.3

± 2.1 *vs* 1.5 ± 0.4 cells/mm^2, P = .003), Ki-67$^+$ cells (5.7 ± 0.9 *vs* 1.7 ± 0.2 cells/mm^2, P = .002), and MyoD$^+$/Ki-67$^+$ co-staining cells (1.8 ± 0.7 *vs* 0.03 ± 0.03 cells/mm^2, P = .040), as well as a greater proportion of Myh7$^+$ myofibers (21.0 ± 0.7% *vs* 4.9 ± 1.5%, P <.001) in ischemic muscle treated with E-sel/AAV compared to LacZ/AAV. **Conclusion:** First, this study confirms the efficacy of intramuscular E-sel/AAV gene therapy for therapeutic angiogenesis in a mouse hindlimb ischemia model. In addition to improving perfusion, E-sel/AAV also enhances proliferation of myogenic precursors and is associated with increased proportion of type I/slow-twitch myofibers in regenerating ischemic muscle. Altogether, these effects correlate with improved exercise capacity and suggest a potential role for E-sel/AAV gene therapy as a nonsurgical option in patients with life-limiting PAD.

385 *In Silico* Prediction and *In Vivo* Testing of Promoters Targeting GABAergic Inhibitory Neurons

Robert Duba-Kiss[1], Yosuke Niibori[2], Joseph T. Bruder[3], Jared B. Smith[3], David R. Hampson[2]

[1]Dept. of Pharmacology & Toxicology, University of Toronto, Toronto, ON, Canada,[2]Faculty of Pharmacy, University of Toronto, Toronto, ON, Canada,[3]REGENXBIO, Inc., Rockville, MD

Impairment of GABAergic inhibitory neuronal function is linked to epilepsy and other neurological and psychiatric disorders. One therapeutic strategy for treating disorders where GABAergic inhibition is impeded, is to enhance GABA neuronal activity in the brain. Recombinant adeno-associated virus (rAAV)-based gene therapy targeting GABAergic neurons is a promising treatment for GABA-associated disorders. However, there is a need to develop rAAV-compatible gene regulatory elements capable of selectively driving expression in GABAergic neurons throughout the brain. Here, we designed several novel GABAergic gene promoters. *In silico* analyses, including evolutionarily conserved DNA sequence alignments and transcription factor binding site searches among GABAergic neuronal genes, were carried out to reveal novel sequences for use as rAAV-compatible promoters. rAAVs (serotype 9) were injected into the CSF of neonatal mice, and into brain parenchyma of adult mice to assess promoter specificity. In mice injected neonatally, transgene expression was detected in multiple brain regions with very high neuronal specificity, and moderate to high GABAergic neuronal selectivity. The GABA promoters differed greatly in their levels of expression, and in some brain regions, showed strikingly different patterns of GABAergic neuron transduction. This study is the first report of rAAV vectors that are functional in multiple brain regions using promoters designed by *in silico* analyses from multiple GABAergic genes. These novel GABA targeting vectors may be useful tools to advance gene therapy for GABA-associated disorders.

386 Preclinical Studies with HMI-104, an AAVHSC Vectorized C5 Monoclonal Antibody, for the Treatment of PNH

Yogeshwar Sharma, Meghan Scarpitti, Hillard Rubin, Nancy Avila, April Hayes, Jason Lotterhand, Jose Israel Rivas, Fermin Lopez, Stephen Woodcock, Thomas Klem, Lindsay Hyde, Teresa Wright, Jenn Newman, Omar Francone, Albert Seymour, Carmen Maria Barnes

Homology Medicines, Inc., Bedford, MA

Adeno-associated virus (AAV) gene therapy has the potential to offer a long-term resolution for diseases that rely on chronic dosing of therapies such as monoclonal antibody-based drugs. Our Gene Therapy-mAb (GTx-mAb) platform is focused on using the liver to express a C5 mAb with a one-time dose. HMI-104 is an AAVHSC vector designed to elicit hepatic expression of a C5 monoclonal antibody (C5mAb) for the treatment of paroxysmal nocturnal hemoglobinuria (PNH) and other complement-mediated disorders. HMI-104 is delivered via a single intravenous (I.V.) injection and the expression of C5mAb can inhibit C5-mediated lysis of red blood cells. We have previously shown that a platform GTx-mAb construct achieved dose-dependent and sustained expression of functional C5mAb in two immunocompromised models: NOD SCID mice, which lack murine C5, and FRG® liver-humanized mice, which express physiological levels of human C5 (Sharma et al, ASGCT-2021). Here, we present the results from two nonclinical studies with HMI-104 for the treatment of PNH. The 16-week dose range-finding study of HMI-104 in NOD SCID male mice was designed to determine the relationship between dose levels, liver vector genomes (vgs), mRNA levels, C5mAb serum concentrations, and *ex vivo* hemolysis over time. In the study, HMI-104 led to sustained antibody levels with serum C5mAb concentrations steadily increasing through Week 5 and plateauing thereafter to Week 16 (end of study). A dose-dependent increase in liver vg concentrations and liver transcript levels were shown for all doses and time points. The 4-week, dose range-finding study in the humanized liver FRG KO mouse xenograft model was designed to evaluate HMI-104 transduction (vgs) and mRNA levels in human hepatocytes, and to assess C5mAb levels in the presence of human C5. In the study, HMI-104 transduced human hepatocytes *in vivo* and expressed sustained serum C5mAb levels in the presence of human C5, achieving antibody levels by Week 3 that were comparable to those obtained at steady state in the NOD SCID mouse model. Finally, we established that C5mAb following HMI-104 administration in the humanized liver FRG and NOD SCID models is functional, as determined by complete inhibition of *ex vivo* hemolysis. In conclusion, we present nonclinical data with HMI-104 demonstrating sustained expression of functional C5mAb levels in NOD SCID and humanized liver FRG KO mice. These results support the development of HMI-104, which is currently in IND-enabling studies, for the treatment of PNH and complement-mediated disorders. Given the severity of PNH and the unmet need associated with available therapies, HMI-104 aims to provide, with a single treatment, sustained serum C5mAb sufficient to inhibit C5 complement-mediated lysis and reduce breakthrough and residual intravascular hemolysis associated with insufficient C5 antibody levels in PNH patients.

387 Anticodon-Engineered Transfer RNA for the Treatment of Nonsense-Associated Cystic Fibrosis

Wooree Ko, Joseph J. Porter, John D. Lueck
Pharmacology and Physiology, University of Rochester, Rochester, NY

Cystic fibrosis (CF) is an autosomal recessive disorder caused by loss-of-function mutations in the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene encoding CFTR anion channel. CFTR dysfunction disrupts chloride and bicarbonate transport across epithelia and results in the buildup of thick and sticky mucus in multiple organs. Among different CF-causing mutations, nonsense mutations, which result from single nucleotide conversion of a sense codon into a nonsense or premature termination codon (PTC), account for ~10% of CF cases. PTCs lead to significant reduction in steady-state transcript expression through nonsense-mediated mRNA decay (NMD) process and production of a truncated, nonfunctional protein. Because CF patients with nonsense mutation have a problem with protein synthesis, they are not responsive to the FDA-approved CFTR modulator drugs that target the malfunctioning CFTR protein. Anticodon-engineered transfer RNA (ACE-tRNA) is a gene therapy approach being investigated in our lab for this patient population. We previously reported that liposome-based delivery of ACE-tRNA encoding cDNAs efficiently suppresses PTCs, inhibits NMD and rescues >70% of functional CFTR channel encoded from its endogenous gene. In this study, we tested the efficiency of adenovirus (Ad)-delivered ACE-tRNAs to rescue endogenous CFTR mRNA and protein expression and determined the benefit of ACE-tRNA delivery in combination with NMD inhibitor and the FDA-approved CFTR modulators. Further, we wanted to determine the ability of one ACE-tRNA sequence to rescue multiple nonsense-associated CF mutations. ACE-tRNAs delivered to 16HBEge cell lines with common CF-causing nonsense mutations significantly increased CFTR transcript level, which was measured by quantitative reverse transcription PCR. Significant ACE-tRNA-dependent rescue of functional CFTR channels was also measured by Ussing chamber recordings. NMD inhibitor treatment improved CFTR transcript expression, but rescue of CFTR channel function was only demonstrated when combined with ACE-tRNAs. In contrast, treatment with CFTR modulators had no effect on CFTR mRNA level but had synergistic effects on CFTR channel activity with ACE-tRNAs. Excitingly, we discovered the possibility of advancing one ACE-tRNA sequence as a platform therapy for several nonsense CF variants. In summary, ACE-tRNAs, especially in combination with other small molecule drugs targeting the overall transcript level and/or protein stability and function, hold great promise as a novel therapeutic option for CF patients with nonsense mutations.

388 Sensor-Actuator-Modulator Gene Therapy for Glaucoma

Samarendra K. Mohanty, Subrata Batabyal, Houssam Al-Saad, Darryl Narcisse, Sanghoon Kim, Michael Carlson, Adnan Dibas
Nanoscope Technologies LLC, Bedford, TX

PURPOSE Glaucoma is characterized by overexpression of fibrous proteins in glaucomatous trabecular meshwork (TM) leading to increased stiffness of TM and associated poor drainage of Aqueous humor (AH) through the conventional outflow pathway. Glaucoma is recalcitrant to treatment and the resulting optic nerve damage is irreversible. The currently available pharmacological and surgical treatments for glaucoma have significant limitations and side-effects, which include, systemic reactions to medications, patient non-compliance, eye infections, surgical device failure, and damage to the eye. Here, we put forth a novel commission for sensor-actuator-modulator (SAM) channel as a virally delivered transgenic pressure modulator in the impaired TM of glaucomatous eyes. **METHODS** Pressure-clamp electrophysiology was conducted to evaluate SAM functioning in cells in-vitro. Different glaucoma mice models were used to evaluate the therapeutic efficacy of SAM gene therapy. AAV-SAM was delivered to TM via intracameral injection. Intraocular pressure (IOP) and outflow measurements were carried out at baseline and different post-injection time points. Structural changes were monitored via optical coherence tomography (OCT), and QPCR was used for biodistribution. The safety was analyzed via ELISA and immunohistochemistry. **RESULTS** Our results demonstrate that SAM is: (i) functional in cultured TM cells, (ii) successfully transduced *in vivo* in TM cells; and (iii) effective in lowering the IOP in a mouse model of ocular hypertension without (i) non-targeted expression (measured by QPCR); (ii) ocular damage (assessed by OCT); (iii) inflammatory cytokines in plasma (detected by ELISA); or (iv) immune cell response and (v) loss of viability of targeted cells expressing SAM over long period. **CONCLUSION** The use of heterologously expressed engineered SAM channel, acting as macromolecular pressure sensor and outflow actuator in TM cells, led to regulation of IOP. The development of a safe effective long-lasting single dose therapeutic for the treatment of Primary Open Angle Glaucoma would be transformative in ophthalmology and would improve the lives of millions of people worldwide.

389 Extracellular Vesicles for Delivery of AAV Vectors

Ines Colic[1], Giulia Massaro[1], Amy Geard[1], Julie A. Watts[2], Anne Benedikt[3], Gareth R. Williams[1], Ahad A. Rahim[1]
[1]School of Pharmacy, University College London, London, United Kingdom,[2]School of Pharmacy, Nottingham University, Nottingham, United Kingdom,[3]Evonik Operations GmbH, Darmstadt, Germany

Introduction: Adeno-associated viral (AAV) vectors are a leading platform for gene therapy however, the biggest hindrance to their clinical application is the host immune response that generates neutralizing antibodies (NAb) following AAV administration. The presence of NAb prevents re-administration of AAVs, but also their application in seropositive patients. The estimate is that 40 - 80 % of the adult population is seropositive due to natural exposure to the wild-type virus. During standard AAV vector production, a portion of AAV particles released into the cell culture media is associated with extracellular vesicles (EVs) - membrane-bound vesicles released into the extracellular environment by cells. We hypothesize that these EV-associated AAVs (EV-AAVs or exoAAVs) will provide complete or partial protection from NAbs, allowing for repeated administration and treatment of seropositive patients. However, due to the similar physical properties of EVs and AAVs (i.e size and density) separating exoAAVs from free AAV particles present in the cell culture media is

quite challenging. Therefore, we aimed to assess different protocols for the isolation/purification of exoAAVs to determine which one is the most effective in removing the free AAV particles from final exoAAV samples. Moreover, exoAAVs obtained using the most and the least successful purification protocol were tested in vivo to assess their transduction efficiency and immunogenicity. ***Methods:*** Standard AAVs and exoAAV vectors were produced by triple transfection of HEK293T cells and isolated 72h post-transfection from harvested cell lysates and culture media, respectively. Standard AAVs were isolated using iodixanol gradient centrifugation. For isolation of exoAAVs five different protocols were tested: differential ultracentrifugation (UC), size exclusion chromatography (SEC), differential gradient centrifugation (DGC), and two combined protocols using two isolation methods, combined protocol 1 and 2 (CP1 and CP2). 7 weeks old male CD-1 mice were injected IV with standard AAV, UC exoAAV, and CP2 exoAAV samples, dosed at $3*10^{11}$ genome copies per animal. 2 weeks post-injection animals were sacrificed and different organs and plasma samples were collected for assessment of transduction efficiency and presence of NAb, respectively. ***Results:*** The presence of EVs and AAV particles was confirmed in all exoAAV samples using different characterization methods. AAV capsids enveloped by lipid membranes were observed in all exoAAV samples using cryoTEM however, the contamination of samples with free AAV particles was the highest in samples purified using UC (most often used for isolation of exoAAVs) while it was the lowest in the samples isolated using combined protocols. Tested in vivo, exoAAVs purified using CP2 showed lower transduction efficiency compared to standard AAVs and exoAAVs purified using UC. On the other hand, cell-based NAb assay indicated lower levels of NAb in the plasma of animals injected with exoAAV sample isolated by CP2. ***Conclusions:*** The combined protocols outperform the UC protocol in separating exoAAVs from free AAV particles present in starting cell culture media. Tested in vivo, exoAAVs isolated by CP2 display lower transduction efficiency but also lower immunogenicity compared to standard AAV and UC isolated exoAAVs.

390 Purification of a Broad Range of Adeno Associated Virus Serotypes from HEK293 Cell Lysates via the Peptide Based Affinity Adsorbents

Wenning Chu[1], Shriarjun Shastry[2], Eduardo Barbieri[1], Raphael Prodromou[1], Stefano Menegatti[1]

[1]Department of Chemical and Biomolecular Engineering, North Carolina State University, Raleigh, NC,[2]N C State BTEC, Raleigh, NC

Cell and gene therapies (CGTs) are at the forefront of innovation to treat rare degenerative & dysregulation diseases, immunological disorders, and genetic defects diseases, such as A1AT deficiency. To support the manufacturing of Cell and Gene Therapies, we have developed innovative peptide-based affinity ligands, specifically designed to capture a wide-ranging Adeno-Associated Virus serotypes (AAVs) from HEK293 cell lysate with excellent yield and binding capacity. This work presents the development of short synthetic AAV-binding peptides and demonstrated their binding reactivity towards a set of AAV serotypes that includes AAV1, AAV2, AAV4, AAV5, AAV6, AAV8, AAV9, and AAVrh10, as well as synthetic serotypes. Candidate AAV-targeting peptides were identified by screening a solid-phase peptide library against a mixture of AAVs spiked in HEK293 lysate via microfluidic screening technology. Twelve promising AAV-binding ligands were investigated, some of which showed high binding capacity toward AAVs with good salt-tolerance ($>1x10^{13}$ genome copies/mL of resin), mild elution (pH 6.0, 0.4 M $MgCl_2$) with excellent recovery (>38%), comparable purity ($LRV_{HCPs} > 1$), good chem-stability (over 20 runs) and low immunogenicity caused by ligand leakage. Notably, the AAVW2 ligand can currently purify the AAV2, AAV6, AAV8 and AAV9 serotypes from TFF-treated HEK293 cell lysate with excellent yield of 63.2%, 57.7%, 58.1%, and 38.2%, respectively. In sum, affinity peptide ligands enable a robust, fast, and platformable purification process for a broad range of AAV serotypes with excellent yield in one chromatography step.

391 Downstream Purification: A Toolbox Approach for Adaptive Multi-Serotype AAV Solutions

Helene Trottin

Pharmaron, Liverpool, United Kingdom

There are several key attributes to consider when developing a process for purification of AAV viral vectors. At Pharmaron, we have successfully developed a downstream platform process for the purification of such vectors but with an adaptive toolbox to manage these varying attributes. Through careful selection of the best techniques, we can handle a wide range of serotypes, genes of interest, harvest yields, impurity profiles and titres of different gene therapy products. We utilise our high throughput DSP robotics platform to conduct an early assessment of a products fit to our platform process with speed and accuracy. Once assessed, we can focus on a targeted optimisation approach to determine, the best resin, elution conditions, chromatography approach or filter type to maximise process yield. We continue to develop our process through evaluation of new technologies, offering significant improvement on standard 'one platform fits all' approaches. Our flexibility to employ different tools from the toolbox, allows us to develop advanced technical solutions to a wide range of gene therapy product needs.

392 Advancing AAV: Novel Sequencing Solutions for Quality Control in Gene Therapy

Andrea O'Hara[1], Haythem Latif[1], Chris Mozdzierz[1], Laure Turner[2], Ginger Zhou[3]

[1]Azenta Life Sciences, Burlington, MA,[2]Genewiz From Azenta Life Sciences, South Plainfield, NJ,[3]Genewiz, Inc./Brooks, South Plainfield, NJ

Interest in cell and gene therapy-based disease prevention and treatment has grown rapidly over the last decade, however there are still hurdles to overcome and progress to be made in the field. Recombinant adeno-associated viruses (rAAV) have become the vector of choice for virus-mediated gene therapy due to their non-replicating nature, high-titers, low immunogenicity, and low genotoxicity. Extensive quality control (QC) throughout the entire development and manufacturing process is essential. A robust QC process expedites safe and effective commercialization of the final product. Next-generation sequencing (NGS) offers an effective high-throughput approach for monitoring AAV quality, from initial construct assembly to analysis of the encapsulated product. Both Illumina® short-read and PacBio® long-read

sequencing technologies offer distinct advantages including sequencing of the entire AVV genome and inverted terminal repeat (ITR) regions, with detection of potential mutations, truncations, and contaminants. Both platforms require conversion of the single-stranded genome to double-stranded DNA prior to library preparation; however, high-fidelity protocols for this step are lacking. Additionally, an efficient bioinformatics pipeline is needed to generate interpretable results from massive amounts of NGS data. Here we describe our novel proprietary workflows, starting with sequence confirmation and correction of AAV plasmid, through QC results using both NGS platforms with supported from a regulatory-compliant Sanger assay. Sanger ITR sequencing and sequence correction upstream alleviates potential downstream issues in viral packaging. The combined NGS approach alleviates current constraints for high throughput AAV sequencing and thereby enhance the overall QC process. Our Good Laboratory Practices (GLP) Sanger sequencing method extends read lengths through the entire ITR regions, allowing for rapid sequence confirmation of the final AAV product. The combination of these approaches enables a comprehensive solution, ideal for sequence confirmation of both transfer plasmid and final packaged product for improved AAV manufacturing in advance of FDA IND and BLA filings.

393 Bioanalytical Evaluation of Single-Stranded DNA for Gene Therapy Applications: A Reference Standard for Quality Control Workflow

Zhi-xiang Lu, Michael Miller, Anis Khimani, Ying Valcour, Yanhong Tong

PerkinElmer Health Science Inc., Waltham, MA

For research use only. Not for use in diagnostic procedures. **Background:** Single-stranded DNA (ssDNA) is a DNA donor template in adeno-associated virus (AAV)-based gene therapy. For CRISPR Homology-Directed Repair (HDR) mediated gene knock-in, ssDNA has lower rates of random or off-target integration and lower toxicity compared to double-stranded DNA. In addition, ssDNA-based aptamers with high specificity and affinity for their targets provide a new tool for drug delivery and targeted cancer therapy. Rapid growth in the use of ssDNA in biotherapeutics underscores the importance of quality control to ensure the integrity and purity of ssDNA. **Method:** RNA Pico reagent (Part#: CLS960012), and DNA 5K/RNA/CZE HT LabChip (Part#:760435) were used in the study. A novel ssDNA ladder (Part #: CLS157950, from PerkinElmer) ranging from over 1000 to over 7000 bases was evaluated on PerkinElmer's LabChip® GXII Touch™ (Part# CLS138160). Flow control in microfluidics was further optimally configured for better size resolution. **Result and Conclusion:** This report provides a reliable, higher throughput reference standard, and bioanalytical screening solution for ssDNA samples (workflow in **Figure 1**). The novel ssDNA ladder is suitable for analyzing 1.1kb to 7.2kb ssDNA samples **(Figure 2).** In addition, double-stranded DNA (dsDNA) can be efficiently detected by the new assay, with different migration speed compared to ssDNA. **Discussion:** The availability of ssDNA ladder as a reference standard is of significant value for the identification, evaluation, and characterization of ssDNA-based payloads either via viral (e.g., recombinant adeno-associated virus, rAAV) or non-viral vehicles (e.g., Lipid nanoparticles, LNPs) in gene therapy or gene editing applications. Hence, the novel size standard we report here, will be beneficial for molecular bioanalytical and quality control workflows across gene therapy and other ssDNA-related applications. For instance, it can be used effectively to evaluate critical quality attributes (CQAs) such as relative titer quantification, purity, and integrity of ssDNA from rAAV preparations (~4.7kb length).

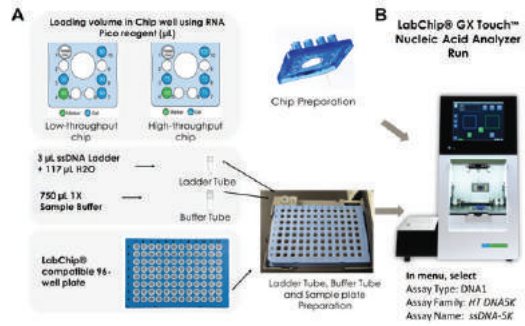


Figure 1: A workflow of ssDNA analysis assay. (A) Chip, Ladder and sample preparation. (B) Program selection on instrument.

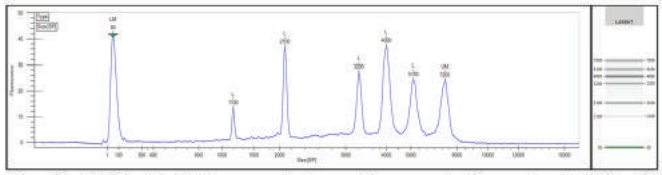

Figure 2. ssDNA Ladder Performance. Ladder working concentration used on LabChip® GXII Touch™ here is 2ng/µL diluted by nuclease-free water.

394 rAAV Produced by Sf9-Baculovirus System Shows Different Product Quality Profile Throughout the Production Cycle

Zeynep Guillemin, Hannah Murphy, Varshini Venkatesan, Shamik Sharma

Voyager Therapeutics, Inc., Cambridge, MA

The Sf9/baculovirus expression system for rAAV production offers advantages such as higher yields and lower costs of raw materials, compared to other production systems. Generally two baculovirus expression vectors - containing either the Rep/Cap elements or the gene of interest - are utilized to co-infect Sf9 cells. The infection may occur at Low or High Multiplicity of Infection (MOI) and each process has its advantages and challenges. High MOI infection results in a high percentage of cells simultaneously co-infected so that cell division stops very rapidly. This synchronous infection could generate rAAV with more homogeneous product quality; however, high MOI infection can be costly due to large quantity of baculovirus needed. In low MOI infection a much lower quantity of virus is added to the culture and cells continue to divide until the baculovirus completely infects the culture, so that co-infection happens during secondary or consequent infection cycles.. However low MOI infection yields rAAVs that are produced over a longer period in the culture, raising the question of whether the quality of the rAAV produced is homogenous throughout the culture. In this study we evaluated the quality of the rAAV produced throughout the culture process in 12 hour intervals. ddPCR is performed to analyze

the rAAV productivity. The quality is assessed by examining VP ratios, percentage of full particles and integrity of the vector genome. rAAV productivity and product quality showed different patterns by hour and the MOI utilized, shedding light on the optimal harvest time for rAAV production.

395 Process Development Considerations for Ultrafiltration & Diafiltration of Viral Vectors

Anand Alembath, Rosario Cervellere, Jonathan Steen, Jacob McCoskey, Joseph Hersey

Filtration R&D, MilliporeSigma, Bedford, MA

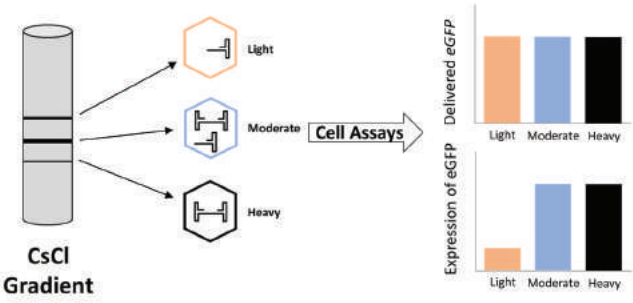
Compared to monoclonal antibody downstream processing, viral-vector manufacturing is less standardized, which can result in lower yields and throughputs in unoptimized processes. A critical part of the downstream purification process addressed within this work is the ultrafiltration/diafiltration (UF/DF) steps which can be optimized through the proper selection of molecular weight cutoff and operating mode. Properly designed tangential flow filtration (TFF) operations can provide concentration, buffer exchange, and impurity reduction through UF/DF in the downstream manufacturing of viral vectors. Viral vectors can be retained while also removing impurities like endonucleases using a 100 or 300 kDa membrane cut-off. The preferred membrane cut-offs fall between the tighter UF (30 kDa) and high permeability microfiltration applications (>1000 kDa). TFF with tighter membrane cut-offs operate by transmembrane pressure (TMP) control where the flux and TMP are controlled by adjusting the retentate-side pressure. High permeability microfiltration applications use permeate control and rely on a pump or a flow-controlled valve on the permeate side to control the flux. This study evaluated both control modes using 100 and 300 kDa membranes by evaluating performance for a 10X concentration and 5 diavolume diafiltration of a clarified adeno-associated virus (AAV2) stream. TMP control had a flux (or processing time) advantage over permeate control, while permeate control had an impurity clearance advantage. Both control modes had similar yields (>85% recovery) of AAV2. Initial process development and optimization of parameters were performed with laboratory-scale 50 cm^2 cassette using 50-200 ml volume. Lab-scale parameters were then utilized to scale-up to larger area devices demonstrating a successful 300-fold scale-up of the operation.

396 Partial Genome Content within rAAV Impacts Performance in a Cell Assay Dependent Manner

Bryan Troxell[1,2], Sarah L. Jaslow[2], I-Wei Tsai[2], Chelsea Sullivan[2], Benjamin E. Draper[3], Martin Jarrold[4], Kate A. Lindsey[2], Levi Blue[2]

[1]AjaxBio, Holly Springs, NC,[2]StrideBio, Research Triangle Park, NC,[3]Megadalton Solutions, Bloomington, IN,[4]Indiana University, Bloomington, IN

Recombinant adeno-associated viruses (rAAV) deliver DNA to numerous cell types. However, the packaging of partial genomes into the rAAV capsid is of concern. Although empty rAAV capsids are studied, there is little information regarding the impact of partial DNA content on rAAV performance in controlled studies. To address this, we characterized and tested vectors containing varying levels of partial, self-complementary *eGFP* genomes. Density gradient cesium chloride ultracentrifugation was used to isolate three distinct rAAV populations: 1) a lighter fraction, 2) a moderate fraction, and 3) a heavy fraction. Alkaline gels, SEC-MALS, and CD-MS were used to characterize the genome size of each population and ddPCR to quantify residual DNA molecules. Cell assays demonstrated opposing results depending on the endpoint measurement. Both live cell imaging and eGFP ELISA assays demonstrated reduced expression following transduction with the light fraction compared to the moderate and heavy fractions. However, PCR-based assays showed that the light density delivered DNA to cells at a similar efficiency as the moderate and heavy fractions. These data support the growing evidence that the genome purity impacts vector performance. Moreover, these results highlight the benefit of combining expression data with quantification of delivered DNA in cell assays.



397 Use of the GH329 Cell Line for Adeno-Associated Virus Production

James W. Brown, Amber Chevalier Plambeck, Santo Anto, Andrzej K. Noyszewski, Michael Chambers, John Ballantyne, Alex Deiulio, Jagadish Loganathan

Agathos Biologics, Fargo, ND

Human adenovirus derived vectors are a frequently used delivery vehicle for human gene therapy and vaccination. Much effort has been devoted to improving E1 complemented cells by limiting homology between E1 deleted adenoviral vectors and thus preventing the formation of replication-competent adenoviruses (RCA). In pursuit of this strategy PER.C6, SL0003 and GH329 were among the cells derived from the parental cells human embryonic retinoblast, A549 and HeLa respectively, that stably express E1 locus and avoid RCA formation. No reported attempts have been made to prove these cells can produce adeno-associated viruses. We demonstrate that GH329 cells enable the production of rAAV (recombinant AAV) by the three plasmid transfection method. FIG. 1 shows rAAV viral genomes measured in GH329 compared to parental HeLa cell (measured value below limit of detection) after triple transfection. We are investigating ways to improve the properties of GH329 cells and will present our ideas and relevant results. The resulting cell line could improve production methods and address yield, scalability, and ethical concerns in rAAV production.

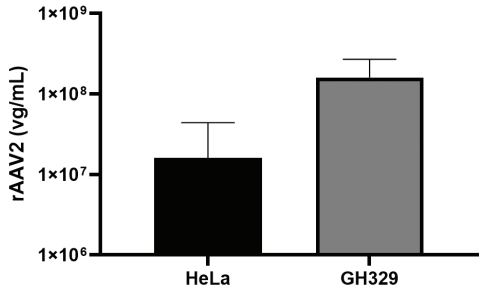


FIG. 1 Digital PCR (QIAcuity, Qiagen) measurements of rAAV2 viral genomes. GH329 $1.6x10^8$ +/- $1.10x10^8$, HeLa below level of detection.

398 Development of Chromatography Based Separation of Empty and Full Capsids in rAAV Manufacturing Process

Corben J. Davis, Keerthana Subramanian, Smita Menon, Blake Gursky, Ganesh Krishnamoorthy, Frank Agbogbo, David J. Dismuke

Process Development, Forge Biologics, Grove City, OH

Recombinant adeno-associated virus (rAAV) vectors are one of the most promising technologies to deliver therapeutic transgenes for gene therapy. For optimal potency and safety, rAAV vectors must be purified from cellular and process contaminants during the downstream purification steps. During production of AAV vectors, two distinct predominant species of vector are formed, one being capsid that does not contain the therapeutic target gene, referred to as 'empty' vector, and the other being capsid that contains the therapeutic target gene, referred to as 'full' vector. Large amounts of empty or partially-filled capsids are known to cause a negative immune response in patients and reduce infectivity of full AAV. It is therefore necessary to remove the 'empty' vector from the final drug product through full capsid enrichment. Historically, gradient based empty and full capsid separation utilizing ultracentrifugation has been the industry standard, however this process is difficult to scale and perform robustly at larger scales in an end-to-end closed process that are typically performed during commercial manufacturing. A common gradient based ultracentrifugation process utilizes cesium chloride, which requires additional testing for residual cesium and toxicity levels in the final drug product. Chromatography based purification allows for a rapid and cost-efficient process for scale-up while both decreasing processing time and increasing product purity. At Forge Biologics, we have developed a robust anion exchange (AEX) chromatography method for the Full Capsid Enrichment. The AEX process can accomplish this separation by utilizing the slight difference in capsid charge between empty capsid and full capsid. Through systematic screening of 4 different AEX columns in conjunction with different elution buffer matrices, Forge has successfully developed and scaled an AEX process for several serotypes such as AAV9, AAV8, rH10, and AAV6. The rAAV purified by AEX was analyzed for vector titer by ddPCR, and for empty capsid and full capsid ratio by Analytical Ultracentrifugation (AUC) and orthogonal techniques. The data from this study will be presented, which emphasizes the need to explore the use of chromatography-based enrichment techniques in rAAV purification.

399 Single-Use Capsule versus Hollow Fibers for Ultrafiltraion/Diafiltration (UF/DF) in Viral Gene Therapy Manufacturing

Rosario Cervellere, Alembath Anand, Jonathan Steen, Jacob McCoskey, Joseph Hersey

Filtration R&D, Applications, MilliporeSigma, Bedford, MA

Recent advances in novel modalities, such as viral gene therapies (VGT), are driving the implementation of single-use manufacturing technologies to improve speed-to-market and manufacturing flexibility. Maximizing viral yield at each downstream purification step while also minimizing processing time is critical as VGT streams are expensive and can be sensitive to shear and exposure to ambient conditions. Tangential flow filtration (TFF) modules (e.g. hollow fibers, cassettes, and spirals) with appropriate molecular weight cutoffs (e.g. 100 and 300 kDa) for retaining viruses (e.g. AAV, Lentivirus) while removing impurities (e.g. host cell protein, DNA, and endonuclease) are an attractive purification technology if properly implemented. Single-use TFF modules address the need to reduce process complexity and increase manufacturing flexibility while minimizing product and operational risks. Herein, we compare traditional single-use TFF hollow fiber modules to a new pre-sterilized, holder-less and linearly scalable spiral module design. Using model and real AAV streams, concentration and diafiltration performance characteristics including scalability, process efficiency/time, and viral yield are compared. At the same feed flow rate, the single-use capsule has a higher and more stable operating flux with comparable virus yield compared to hollow fiber modules, resulting in smaller systems and/or faster TFF operations. As such, the capsule provides a more productive single-use TFF process than hollow fiber modules, enabling high concentration and/or diafiltration targets in less time while maintaining the same high viral yields.

400 A Streamlined Downstream Purification Platform Process for Adeno-Associated Viral Vectors

F. Michael Haller[1], Leila N. Kondo[1], Chien-Ting Li[1], Tam Duong[1], Peng Wang[1], Jacob Mardick[1], Jiasong Jiang[1], Peng Lu[2], Shuo Lu[2], Neda Maleki[2], Senthil Ramaswamy[1], Wenling Dong[2], Bingnan Gu[1]

[1]Research & Development, Lonza, Houston, TX,[2]Process Development, Lonza, Houston, TX

One major obstacle to achieving shortened development times and reduced costs of adeno-associated gene therapy products is the lack of standardized and cGMP-compliant downstream purification platforms. Besides providing high yields and purities, such platforms should be applicable to a wide variety of AAV serotypes as well as being customizable with minimal process modifications to allow rapid development of scalable downstream purification processes for clinical testing. Previously, we developed a comprehensive AAV production platform consisting of a proprietary high-producer suspension HEK293 cell line, a high-performing packaging plasmid system and an optimized triple transfection-based upstream process. In this study, we developed a streamlined downstream purification process using a GFP-encoding AAV9 construct (AAV9-GFP) as model. The applicability of the process was subsequently verified for several

other AAV serotype/GOI combinations. For AAV9-GFP, the total process recovery was up to 38 %, starting from unclarified cell lysate at 3 L bioreactor scale, with post lysis titers of ~1.0 E+15 vg per liter cell culture by ddPCR titer assay. After affinity capture, circa 60 % full capsid content were obtained, which could be further enriched to up to 74-90% full, based on AUC capsid only quantification and/or SEC-MALS or mass photometric analyses. For an AAV9 model construct encoding a therapeutically relevant protein (AAV9-GOI1), a post-lysis intact genomic titer by 2D ddPCR of 4.1E+14 vg per liter production scale was achieved. After affinity capture, a Full:Empty ratio of 1.1 was obtained which increased to 11.5 for the BDS, with the final product containing 86 % full and less than 8 % empty capsid (AUC capsid only quantification). Starting from crude cell lysate, an overall downstream process yield of 33 % was obtained, while residual host cell DNA was reduced to below 2.5 ng/E+12 vg and HCP levels below the assay's lower limit of quantification. In conclusion, we developed a streamlined AAV downstream purification process with high total recovery and full% capsid content of the final product at high levels of purity.

401 Sensitivity of AAV to Chemical and Physical Changes from Different Degradation Pathways

Robert Damitz, Victoria Dowling, Wayne Yount
Kriya Therapeutics, Inc., Research Triangle Park, NC

Gene therapy has been successfully applied in the clinic using adeno-associated virus (AAV) vectors to treat genetic diseases. AAV vectors are exposed to a variety of conditions which may cause product degradation over the product lifecycle, but the sensitivity of vectors to these different conditions remains poorly understood. Improved understanding of these degradation modes will allow us to design better manufacturing processes and formulations to maximize the safety and efficacy of AAV vectors. Formulated AAV2 drug product was subjected to various physical, thermal and chemical stresses for multiple durations of time to generate a library of degraded samples. Samples were characterized and product quality attributes relevant to stability were measured. The impact of each stress on the product quality was assessed.

Degradation Conditions and Durations		
Stress	**Condition**	**Duration**
Physical	-80°C/Room Temperature (RT), Freeze-thaw, small volume	Up to 10x cycles
	-80°C/RT, Freeze-thaw, large volume	Up to 3x cycles
	Photooxidation, fluorescent laboratory light at RT	Up to 7 days
Thermal	40°C	Up to 7 days
Chemical	Acidic, pH 2.0 at RT	Up to 7 days
	Acidic, pH 4.0 at RT	Up to 7 days
	Alkaline, pH 8.0 at RT	Up to 7 days
	Alkaline, pH 10.0 at RT	Up to 7 days
	Chemical oxidation, 1 ppm H_2O_2 at RT	Up to 24 hours
	Chemical oxidation, 3% H_2O_2 at RT	Up to 24 hours

Changes in product quality were detected from nearly all evaluated conditions. Some conditions caused only physical changes to the product (particle size distribution or precipitation) while other conditions caused additional chemical changes (both protein and genome). Decreases in potency were observed along with physical and chemical changes to the product. AAV2 was most sensitive to extreme acidic conditions and high concentrations of chemical oxidants. High temperature also caused physical and chemical changes. AAV2 was less sensitive to alkaline conditions, although very high pH caused notable product degradation. Freeze-thaw cycling caused physical changes to the product, but these changes were much more notable with larger fill volumes. AAV2 was not highly sensitive to photooxidation or low concentrations of chemical oxidants. Notably, the capillary electrophoresis sodium dodecyl sulfate (CE-SDS) method used to quantify vector proteins was not capable of detecting any changes to the product from any of the degradation modes evaluated and the effectiveness of size exclusion chromatography (SEC) to measure aggregation was limited. These results identify the extremes and limits which AAV2 can be exposed during manufacturing and product handling and may also help diagnose future product stability issues. This work further established whether analytical methods used to measure quality attributes are stability indicating.

402 Fit-for-Purpose Assay Characterization of GS-100 Potency Assay

Jennifer W. Cook[1], Brandon Tan[1], Alicia Newton[1], Jake Pritchett[2], Victoria Gruhn[2], William F. Mueller[1]
[1]Grace Science, LLC, Menlo Park, CA,[2]Integrated Analytical Solutions, Inc, Berkeley, CA

Introduction: N-glycanase 1 (NGLY1) Deficiency is an ultra-rare autosomal recessive disorder caused by the loss of NGLY1 function. GSL is developing GS-100, an AAV9 gene replacement therapy designed to deliver a fully functional copy of the human NGLY1 gene, for the treatment of NGLY1 Deficiency. NGLY1, a cytosolic enzyme, catalyzes the hydrolysis of the amide bond between N-linked glycans and proteins. When NGLY1 is not sufficiently functional its substrate GlcNAc-Asn (GNA) accumulates. Thus, GNA serves as a critical biomarker of pharmacodynamic response to GS-100. The GS-100 potency assay precision, accuracy, linearity, range, and specificity were assessed and described here. Aggregation and potency were assessed to determine if higher concentrations of GS-100 were associated with decreased potency. Methods: *GNA Quantification Methods* NGLY1 Knock Out (KO) cells overexpressing the AAV receptor were transduced in low serum conditions at various multiplicities of infection (MOI), incubated, harvested, frozen, homogenized, extracted, and analyzed by hydrophilic interaction chromatography (HILIC) and MS/MS against a standard curve. Detection and accuracy controls were assessed in a wild type control (low GNA) or untransduced KO control (high GNA). The Activity is reported as % reduction (%R) of GNA relative to untreated NGLY1 KO cells per log (MOI). The Mean Activity is determined by averaging the %R/log(MOI) across two or more MOIs per experiment. Accuracy was confirmed by WB and qRT-PCR. *Sample Concentration and Aggregation Testing:* Manufacturing batch samples were titered by ddPCR targeting NGLY1. Samples were concentrated using

ultra- or centricon centrifugation and then re-titered to confirm the concentration. Samples were analyzed via Stunner-DLS or HPLC-SEC. Results: The GS-100 assay passed all performance parameter criteria.

Performance Parameters	Acceptance Criteria	Result
Inter-Assay Precision	Activity ≤ 30% CV for each MOI Mean Activity ≤ 30% CV	0.23% to 18.5% 8.21%
Intra-Assay Precision	Activity ≤ 30% CV for each MOI	1.79% to 12.76%
Accuracy to mRNA expression	Correlation between mRNA fold change and Activity should have an $r^2 > 0.9$	$r^2 = 0.9510$
Accuracy to Western blot analysis of protein expression	Dose dependent response of NGLY1 protein band in Western blot analysis	0 >10k > 100k > 1MM
Linearity of LC-MS/MS	$r^2 > 0.9$ across GNA range spiked into WT background (GNA ng/mL)	$r^2 = 0.9932$
	GNA ng/mL ≤ 30% CV at each concentration	1.2% to 9.2%
Linearity of KO/WT Cell Mixing	$r^2 > 0.9$ across 0-100% KO cells	$r^2 = 0.9886$ and 0.9632
Range	Transduced *NGLY1*$^{-/-}$ cells should have GNA concentration values that do not exceed the KO cells, but reach or exceed the GNA concentration in WT cells	KO Untreated: 148.33 ng/mL KO Treated Cells: 24.30 - 104.17 ng/mL WT Untreated: 50.23 ng/mL
	Activity ≤ 30% CV at each MOI	2.61% to 23.86%
Specificity	AAV9-GFP should not significantly decrease GNA ng/mL	AAV9-GFP did not statistically decrease GNA ng/mL

Aggregation and Potency Assessments

Virus	DLS (nM)	SEC HPLC		GOI Titer (vg/mL)	Activity %R/log(MOI)
		% Aggregate	% Monomer		
Vendor 1 – Lot 1	29.25	0	100	2.00E14	15.14
Vendor 1 – Lot 2	33.96	0	100	1.87E14	13.34
Vendor 2 – Lot 1	31.57	3.2	96.8	9.70E12	12.17
Vendor 2 – Lot 1, concentrated	27.41	NT	NT	5.37E13	13.82
Vendor 2 – Lot 1, concentrated	32.37	11.35	88.65	9.22E14	14.62

NT = Not tested

Conclusions: The GS-100 potency assay showed acceptable assay performance and was deemed suitable for use in fit-for-purpose analysis of GS-100 potency comparability across manufacturing batches. GS-100 was concentrated from 9.70E12 - 9.22E14 vg/mL and potency and aggregation was determined for each lot. There was no loss in potency, suggesting that GS-100, an AAV9-hNGLY1 gene therapy, is potent at a wide range of concentrations.

403 A Leading Engineered Capsid Harboring a 7-mer Peptide Insertion Yields Low Titers and Packages Heterogeneous Vector Genomes

Mengtian Cui[1], Qin Su[1], Mitchell Yip[1], Shun-Yun Cheng[1], Jackson McGowan[1], Claudio Punzo[1], Guangping Gao[1,2], Phillip WL Tai[1,2]

[1]UMass Chan Medical School, Worcester, MA,[2]Co-correspoding Authors, Worcester, MA

Recombinant adeno-associated virus (rAAV) vectors have become the ideal human gene therapy vehicle. However, there are still some barriers hindering their expanded application. For example, rAAV administration via intraocular injection can trigger vasculitis or uveitis in response to foreign agents. These adverse events can typically be suppressed by anti-inflammatory drugs, but they remain leading factors in negatively impacting safety and therapeutic efficacies. AAV2.7m8 is an engineered capsid that carries a unique seven amino acid insertion at each of the three-fold spikes of AAV serotype 2 (AAV2). AAV2.7m8 is considered a leading capsid for transducing photoreceptor cells; however, we have consistently observed that it packages with low titers irrespective of the transgene cassette used. To illustrate this phenomenon, we packaged via plasmid transfections of HEK293 cells, multiple transgene cassettes in self-complementary (scAAV) or single-stranded AAV (ssAAV) vectors with AAV2.7m8 or AAV2 capsids. We found that during the purification of vectors by CsCl density gradient ultracentrifugation, preparations using AAV2.7m8 capsids consistently yielded undefined bands. This finding indicated that AAV2.7m8 preparations package a high degree of non-unit length genomes. To validate this interpretation, we subjected purified vectors to AAV-GPseq analyses. We found that AAV2.7m8-packaged vector genomes were consistently more heterogeneous than AAV2-packaged genomes, regardless of the vector transgene cassette used. Multi-dimensional Droplet Digital PCR analysis also confirmed these trends. In order to understand the impact of delivering heterogeneous vectors, we administered AAV2 or AAV2.7m8 vectors into mouse eyes by intravitreal injection. We found that AAV2.7m8-mediated transduction substantially stimulates infiltration of microglia, while the response to AAV2 was much milder. Further investigation into the mechanisms underpinning the delivery of heterogenous vector genomes into retinal tissues and its resulting contribution towards retinal inflammation is ongoing. Our work uncovers for the first time that differences in AAV capsid designs can directly impact vector genome heterogeneity, which in turn, can possibly trigger immune responses. We are currently exploring whether the specific group of capsids classified by 7-mer peptide insertions have a greater penchant for compromised vector genome packaging, and whether they are more immunogenic following intravitreal administration.

404 Developing a Scalable Full Empty Separation Step for an AAV Capsid by Anion Exchange Chromatography in Step Gradient Elution Mode

Regina Staffler[1], Eleni Tsiaousi[1], Johanna Weizenegger[1], Jared Babic[1], Bilal Alkharrat[2], Christina Weiss[1], Matthias Boscher[1], Johanna Wagner[1], Sinisa Petrik[1], Sebastian Ritter[1], Christine Zach[1], Marie Lott[1], Tobias Kloetzer[1], Anita Heinlein[1], Matthias Gora[1], Ahmed Youssef[1], Alexandra Schoberth[1], Melanie Langhauser[1]

[1]Ascend GCTx, Martinsried, Germany,[2]Roche, Planegg, Germany

Packaging heterogeneity in recombinant adeno-associated virus (rAAV) manufacturing may lead to potential product-related impurities like 'empty' capsids, capsids containing partial vector genomes, and capsids containing different DNA impurities. It is technically very challenging to reduce or eliminate 'empty' capsids in down-stream processing, especially in a scalable manner. Here we describe a fully scalable method to efficiently enrich the percentage of full capsids by anion exchange chromatography. An anion exchange (AEX) chromatography step was established in isocratic elution mode and optimized by design of experiment (DoE) studies. After an initial screening of different resins, a strong anion exchanger was selected for further development in step gradient mode.

DoE data were evaluated using chromatography UV and Stunner® (Unchained Labs) data. The DoE center point run results were confirmed by qPCR (recovery data) and mass photometry analysis (enrichment and percent full data). Based on the DoE studies it was determined that the capsid load and salt concentration during the empty particle elution phase are the most critical process parameters to achieve a high percentage of full particles and a satisfactory yield. The scalability of the AEX step was demonstrated by polishing material from an entire 50-liter scale run applying the optimized step gradient conditions. The enrichment factor was dependent on the proportion of 'full' and 'empty' capsids in the load material. We obtained an up to 3-fold enrichment of full capsids compared to input material, or about 75% 'full' determined by mass photometry at a vector genome step recovery of ~70%. The AEX chromatography process is designed to be optionally plugged into downstream processing depending on required product specifications. It is readily scalable and represents a tool that can be adapted for specific expression cassettes or capsids.

405 Design of Experiment (DoE) Based High Throughput Process Optimization for rAAV Manufacturing Development

Rupert Derler, Kathrin Breunig, Sandra Lange, Martina Ohme, Markus Hörer, Florian Sonntag, Andreas Schulze

Ascend GCTx, Martinsried, Germany

Recombinant adeno-associated virus (rAAV) is among the most widely used viral vectors for gene therapy. However, vector manufacturing remains a challenge as the choice of upstream production systems represents a trade-off between flexibility, scalability, and quality. Currently, adherent or suspension cell-based rAAV manufacturing processes are used by the industry. While different large-scale adherent production systems, such as the iCELLis® 500, are in use, there are several reasons to switch to suspension cell-based rAAV production processes. Suspension processes allow for better scalability (scale-up instead of scale-out) resulting in lower operational costs. Furthermore, suspension-based processes eliminate the need for animal-derived component supplementation. Resource- and labor-intensive approaches for process development and optimization, such as the use of shake flasks or bench-top bioreactors, limit the throughput required to efficiently improve rAAV production processes. Furthermore, these systems do not easily allow for changing of multiple parameters at a time (e.g., DoE - design of experiment) to determine the individual and combined effects of these changes on rAAV production. Therefore, high-throughput, automated microbioreactor systems represent ideal tools for effective bioprocess development and optimization. We previously presented that we successfully developed a microbioreactor system using the Ambr® 15 system that can be used as a suitable scale-down model for our suspension cell-based rAAV production processes. Furthermore, high throughput microbioreactor systems facilitate utilization of a DoE methodology to analyze multiple variables at a time, which enables optimization of rAAV production in our HEK293 suspension cell production platform. Here, we present the results of a DoE-based study evaluating the impact of process parameters, such as cell seeding density, total DNA per cell at transfection, and pH setpoint of the bioreactors on rAAV yield and quality. We applied a full-factorial central composite orthogonal (CCO) design allowing for quadratic modelling of vector yields as well as plasmid- and host cell-derived impurity packaging. These results allowed for the definition of key parameters and their set-points to enable efficient up-scaling of the rAAV production processes to larger-scale suspension manufacturing systems. Furthermore, the study provided insight into opportunities to optimize rAAV quantity and quality by adjusting these parameters. Overall, application of the DoE methodology to improve rAAV quantity and quality parameters allows for usage of the Ambr15® system as a superior tool for future manufacturing process development, optimization, and starting material development.

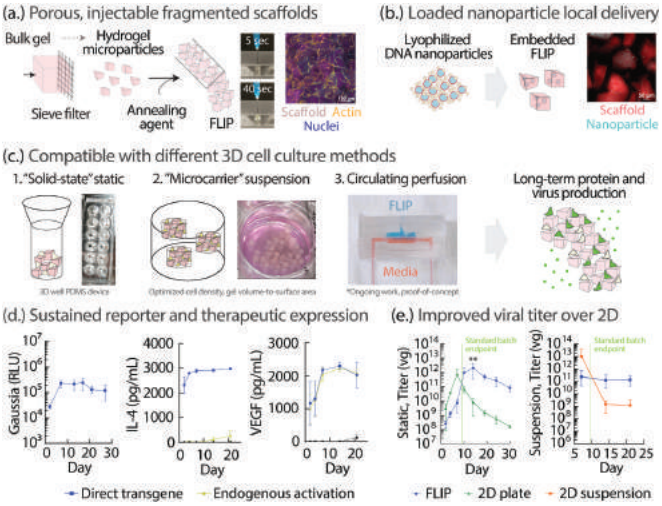
406 Gene Delivery from Flowable Linked Irregular Particle (FLIP) Scaffolds for Advanced Biologics Manufacturing

Evan Kurt, Tatiana Segura

Biomedical Engineering, Duke University, Durham, NC

Purpose: Efficient gene delivery is essential for manufacturing therapeutic biologics, such as proteins and viruses. A key challenge has been high material costs and optimization to meet clinical demand. A possible way to improve production is hydrogel mediated gene transfer, in which nucleic acids are locally delivered via a loaded scaffold, acting as a reservoir for nanoparticles and providing sustained culture and expression. We developed "flowable linked irregular particle" or "FLIP" scaffolds, granular microporous hydrogels that overcome nanoparticle loading challenges and improve cell viability and transfection over time. Here, we demonstrate how FLIP can efficiently produce relevant biologics in a compact 3D environment and be adaptable to current bioreactor technologies. **Methods:** FLIP is prepared by embedding lyophilized polyanion-coated DNA/polyethylenimine nanoparticles within a bulk hydrogel, crosslinked using a degradable linker to allow timed release *[Fig, a-b]*. The gel is converted into fragmented microgels by controlled sieving. Cells are intermixed and secondary chemistry anneals the microgels into the porous FLIP scaffold. We explored several production approaches *[c]*: (1) static HEK293 culture in a FLIP "solid-state bioreactor", (2) suspension culture via FLIP "microcarriers," and (3) perfusion culture in a closed loop circulating system. Aside from reporter (Gaussia luciferase, GFP) and therapeutic (VEGF, IL-4) genes on a single plasmid, we assessed co-delivery of dCas9-VP64/sgRNA plasmids for endogenous protein expression. Last, we assessed triple plasmid delivery of AAV9 components (Helper, Rep/Cap, Transfer) for sustained virus secretion. For each method, we optimized the cell density and scaffold properties for enhanced expression and viability. Controls were either HEK293T plated in 2D tissue culture or HEK239F in suspension. Cells were cultured up to 30 days, with media sampled over time for protein (reporter assays, ELISA) or virus (qPCR, ELISA, MOI). **Results:** FLIP scaffolds previously promoted a sustained rate of reporter transfection, and this remained the case for therapeutic proteins from transgene and endogenous expression *[d]*. Both VEGF and IL-4 benefited from static FLIP culture, with no loss in rate of production compared to controls. For AAV, static FLIP gave sustained production over 2-3 weeks *[e]* before a significant loss in infectivity, while 2D plated cells declined after just one week in titer and quality. In suspension, FLIP production never overcame that of HEK293F, despite sustained titer and higher viability. Suspension

does afford easier scale up and compatibility with current bioreactors; however, the best quality AAV still came from static FLIP, with similar titer, infectivity, and capsid loading efficiency, but in a smaller footprint. Last, as proof-of-concept, we tested a modified solid-state FLIP using a perfusion fluidic device. From the circulating media, we saw improved cell viability and reporter expression compared to static FLIP. Ongoing work on long-term AAV production, scalability, and alternative materials will help to further establish this method. **Conclusions:** FLIP scaffolds offer a novel, more efficient approach to biologics manufacturing, with sustained culture giving better batch yields without loss in product quality, and the platform being easily adapted for specific products or mode of production.



407 Titer Boosting of HEK293-Based AAV Manufacturing Process Using Proprietary Small Molecule Additive and Successful Scale up to 200L

Jackson Leong

MTDC, Tenaya Therapeutics, South San Francisco, CA

Adeno-associated virus (AAV) is quickly becoming a safe and effective therapeutic modality for the delivery of potentially curative treatments for genetic diseases. One of the major challenges associated with AAV GT is to cost effectively produce AAV Drug Product (DP) with adequate levels of critical quality criteria (safety, identity, strength, purity, potency, and quality). Triple transient transfection using HEK293 process is widely used in both clinical and commercial scale manufacturing. The main limitation of HEK293 is scalability and viral productivity. Through the use of high-content screening leveraging deep knowledge of in the areas of cell biology, metabolic, anti-fibrotic, human genetics, tubulin and histone regulation, and extensive chemistry experience, Tenaya has developed a class of proprietary, novel, and selective small molecule boosters (SMB) that can significant increase AAV yield in cell line and cell culture media-independent manner. Additionally, SMB can enhance the scalability of HEK293-process by maintaining consistent yield up to 200L. And finally, SMB has demonstrated to have no impact on purity, quality, safety, and potency of the AAV viral vector and can be readily cleared in standard AAV purification process. This novel and selective class of SMB can potentially be transformational in debottlenecking AAV manufacturing and decrease of cost of AAV gene therapy.

408 Development of a Comprehensive and Risk-Based Viral Safety Assurance Strategy for the Manufacturing of AAV Gene Therapy

Samantha M. Jones

Process Development, Tenaya Therapeutics, South San Francisco, CA

The risk of viral contamination, arising from either the starting materials or the adventitious agents introduced during the manufacturing process, is an inherent feature in all biological products and can have serious consequences during clinical evaluation. Relative to biologics such as monoclonal antibodies or recombinant proteins, assuring the viral safety of gene therapy products is a complex process, as drug products are also viral vector particles. Therefore, having a comprehensive risk-based strategy to ensure viral safety, without impacting the identity, strength, quality, purity, and potency of the viral vector, is important to ensure patient safety. Tenaya Therapeutics, Inc. (Tenaya) has developed a consistent and scalable purification process for the production of adeno-associated virus (AAV) gene therapy made using Sf9/recombinant baculovirus for certain genetic heart diseases. Utilizing its purification process, Tenaya is able to demonstrate robust viral clearance, in terms of Log Reduction Values. This approach includes product- and process-relevant specific and non-specific model viruses and provides adequate assurance that AAV drug product is free of viral adventitious agents with appropriate level of safety margins.

409 Development of Cost-Effective and Scalable Recombinant Baculovirus Production Process for the Manufacturing of AAV

Charles Feathers

Process Development, Tenaya Therapeutics, San Francisco, CA

After the early success of Zolgensma® and Luxturna®, adeno-associated virus (AAV) gene therapy is entering a mature stage and expanding its therapeutic potential to serve broader patient populations suffering from more prevalent genetic diseases. At Tenaya Therapeutics, Inc. (Tenaya), our Gene Therapy platform uses AAVs to deliver genes to specific cells in the heart to correct or compensate for functional defects. Genetic root causes of hypertrophic cardiomyopathy (HCM) and arrhythmogenic right ventricular cardiomyopathy (ARVC) have the potential to be readily corrected *in vivo* using the delivery of AAVs. However, as AAV gene therapy moves into indication with greater prevalence, the feasibility of conventional triple transient HEK293 process as a manufacturing platform to produce sufficient quantities of drug product (DP), is limited by yield and scalability and is subject to high cost of goods (COGS). Tenaya has developed a proprietary manufacturing platform process using Sf9/recombinant baculovirus (rBV), which overcomes the limitations of yield, scalability and mitigates the high COGS. This Sf9/rBV manufacturing process includes a scale-independent recombinant baculovirus production process that consistently produces high quality recombinant baculovirus seedstock while maintaining productivity, quality, purity, safety, and potency of AAV DPs at the 1000L scale.

410 Seamless Scale-Up of Transient Transfection Process for rAAV Production from Shake Flask to Manufacturing-Scale Bioreactor

Eric Karengera[1], Martin Lemaire[1], Ariane Bricteux[1], Anna Doshina[1], Emilie Gateau[1], Nicholas J. DiGioia[2], Carmen Wu[2], Michael Xenelis[2], Matthias Hebben[2], Paul Giroud[3], Julien Depollier[3], Hanna P. Lesch[1]

[1]Exothera, Jumet, Belgium,[2]LogicBio Therapeutics, Lexington, MA,[3]Polyplus-transfection, Illkirch-Graffenstaden, France

Recombinantly produced adeno-associated viruses (AAV) are the predominant viral vectors used for in vivo gene therapies owing to their relatively good safety, long term transgene expression, ability to infect a broad range of cells and ease in achieving high titers at small-scale. One of the main challenges in bringing AAV-based therapies to patients, is the ability to efficiently translate bench-scale processes to commercial GMP manufacturing while meeting the high dosage requirements. In order to overcome this challenge, we have partnered with LogicBio® Therapeutics and Polyplus® for the development of a highly scalable AAV manufacturing platform with a capacity ranging from 1L to 200L and 2000L bioreactor scale. The vector used for the scale-up is a recombinant AAV8 coding for factor IX protein. The suspension process lasting 7 days is performed in batch mode in a stirred-tank bioreactor (STR) and includes a transfection step using the 2 plasmids-system mAAVRx™ technology (LogicBio) and FectoVIR®-AAV transfection reagent (Polyplus). First, some preliminary tests were conducted in shake flasks assessing parameters that are important for process scale-up, such as transfection mix preparation and transfer conditions. Next, the transfection process was translated at 1L scale into BioBLU® 1c Single-Use STR. A titer of $7.89x10^{11}$ vg/ml was obtained at this scale which was comparable to the titer obtained in shake flask using similar transfection conditions (see Figure 1). For the scale-up in STR, the chosen strategy was to maintain constant P/V (power input) and similar superficial gas velocity at all scales. As a first step of the scale-up, the AAV8 production process was successfully performed at 40L scale in an Eppendorf BioBLU® 50c Single-Use Bioreactor yielding a titer of $6.98x10^{11}$ vg/ml (see Figure 1). Following this, a scale-up of the process to 200L in a Pall Allegro 200L STR was performed. Consistent AAV8 titer (see Figure 1), cell growth, cell viability and metabolite profiles were obtained across scales, indicating a successful process scale-up to 200L. The next step is to scale-up the process in Pall Allegro 2000L STR. To sum up, in collaboration with LogicBio® Therapeutics and Polyplus®, Exothera has succeeded to seamlessly scale-up an AAV8 production process from shake flask to 200L scale reaching a titer of above $6x10^{11}$ vg/ml at all scales.

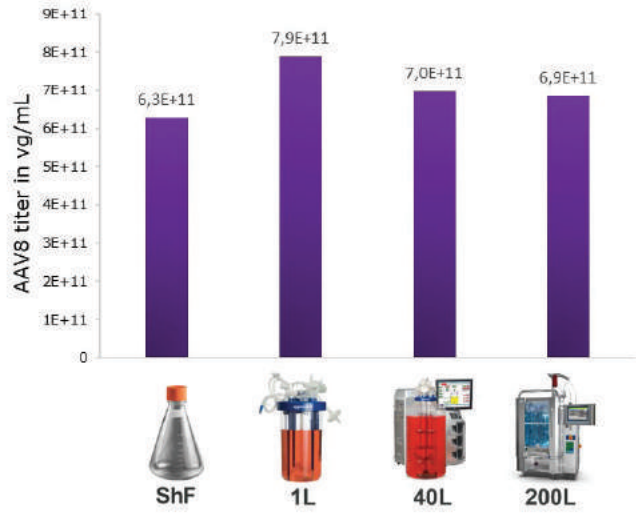


Figure 1: Genomic AAV titer measured by ddPCR on clarified lysate. n=1 at all scales.

411 Scaling-Up AAV- Manufacture GMP Production and Purification Using Innovative Plasmid-Free Technology

Bibek Ghosh[1], Yi-Hsin Fan[1], Ji Hyun Lee[1], YiYu Dong[1], Dominic Masciarelli[1], Alexander Lam[1], Honghu Quan[1], Annie Tran[1], Zhong Deng[1], Joseph Flounlacker[1], Ang-Chen Tsai[1], Bo-Jhih Guan[1], Heather Malicki[2], David Chang[3], Man-shiow Jiang[4]

[1]Process Development, WuXi Advanced Therapies, Philadelphia, PA,[2]Analytical Development, WuXi Advanced Therapies, Philadelphia, PA,[3]WuXi Advanced Therapies, Philadelphia, PA,[4]WuXiApptec, Philadelphia, PA

Adeno-associated viral vectors (AAV vectors) are essential tools for delivering gene therapies to patients, representing around 37% of the advanced therapies market. AAV vector is usually manufactured using plasmid-based transient transfection approaches. However, there are challenges with working with plasmids on a large scale, including cost, consistency and scalability. WuXi Advanced Therapies (WuXi ATU) developed TESSA™ (tetracycline-enabled self-silencing adenovirus) Technology for high physical titer and infectivity to meet the growing demand for AAV manufacture, such as increasing upstream productivities and overall recovery of downstream processes. Thus, it is crucial to develop upstream production and downstream purification strategies that high productivity, maintain yield, cost-effectiveness as well as high purity profiles. TESSA vectors directly encode the genetic material required for AAV production, removing the need for plasmids to perform that function. These vectors take advantage of the dual phases of the adenoviral lifecycle to produce AAV, while limiting adenoviral contamination. Early phase adenoviral gene expression provides help for high titer AAV manufacture, while late phase gene expression, responsible for adenovirus contamination, is switched off. This increases rAAV yield, packaging efficiency and compared with plasmid-based rAAV manufacture. The TESSA system includes co-infection with two adenovirus vectors: one adenovirus encoding a

gene of interest (GoI) and the other encoding AAV's replicative (*rep*) and capsid (*cap*) genes. The resulting physical and infectious AAV titers using TESSA technology were compared with values obtained using triple-plasmid transfection into WuXi ATU single clonal cell line from human embryonic kidney (HEK) 293 parental cells. Upstream production of AAV2 and AAV6 using the TESSA platform has been completed successfully in single use bioreactor. Both AAV6 and AAV2 are consistently produced using TESSA technology in scaling up single use bioreactors. The upstream GC titer of AAV2 is around 20-fold and AAV6 is around 10-fold higher with TESSA compared with triple plasmid transfection. TESSA technology presents a competitive solution for production of AAV, purified using AAVEX™ platforms to evaluate the yield and quality of final product. AAV2 and AAV6 both use a platform process using affinity column, scalable ion-exchange chromatography process. For AAV2, an overall recovery of 36% was achieved with 1.5E+14 total GC per L of upstream production. AUC analysis revealed that the final product obtained 88.2% of full capsids. AAV6 overall recovery of 52% was achieved with >5.0E+14 total GC per L of upstream production. AUC analysis revealed that the final product obtained 88.4% of full capsids. Taken together, WuXi ATU has successfully scaled up AAV vector production using TESSA technology with the product showing significant improvement on vector yield over plasmid-based methods. To ensure stable gene therapy production, the novel TESSA technology is integrated with intricate testing capabilities. This allows for in-house assay development, biosafety, viral clearance, and product release testing, reducing costs and increasing efficiency. Ultimately, this will accelerate the product approval timeline.

412 Global Strategy to Improve the Downstream Manufacturing Process of the Adeno-Associated Viral Vector for Glycogen Storage Disease Type Ia Treatment

Wenjun Di, Hanson Zhou, Dennis P. Chen, Jack Ren, James C. Warren, Chao Huang

Ultragenyx, Woburn, MA

Although recombinant AAV (rAAV) vectors have been a common gene transfer vector in clinical development for greater than a decade, few of these products have been approved/authorized for commercial marketing. Acknowledging the need for a robust, productive manufacturing process, the chemistry, manufacturing, and control (CMC) strategy for a glycogen storage disease type Ia (GSDIa) specific rAAV production has experienced significant development and improvement. Here, we present the downstream process improvement from Process A to Process B for the purification of GSDIa-specific rAAV generated by HEK cell line. By the introduction of the harvest tangential flow filtration (HTFF) step prior to affinity chromatography, multiple aspects of the downstream process were improved, including the step yield of various unit operations and the global harmony of the downstream process, as shown in Table 1. Also, Process B generated a comparable drug substance to that of Process A, as shown in Table 2. Taken together, Process B was expected to enable a robust drug supply for GSDIa patients in Phase 3 clinical trials and beyond.

Table 1. Performance Improvement

Process Step		Process A	Process B	Improvement
HTFF	Product Concentration	N/A	20-fold Increase	HTFF concentrate AAV product concentration by 20-fold
	HCP Reduction	N/A	~50% Reduction	HTFF step gains ~70% HCP reduction prior to Affinity step
Affinity Chromatography	Column Volume (L)	1.0 X	0.2 X	Affinity resin COGS reduction by 5-fold
	GC Step Yield	~60%	~77%	Affinity GC step yield increase by >10% (absolute value)
AEX Chromatography	Column Volume (L)	1.0 X	0.2 X	AEX column COGS reduction by 5-fold
	GC Step Yield	~30%	~60%	AEX GC step yield increase by >30% (absolute value)
FTFF	Filter Size (m2)	1.0 X	0.2 X	FTFF filter COGS reduction by 5-fold
	Concentration Factor	400 X	80 X	FTFF concentration factor reduce by 5-fold

Table 2. Drug Substance Comparability

Quality Attribute	Process A	Process B
Genomic Concentration (GC/mL)	2.7E+13	3.5E+13
Full Capsid %	31%	37%
Residual AAVB Ligand (ng/mL)	<LOQ	<LOQ
Residual Benzonase (ng/mL)	<LOQ	<LOQ
HCP (ng/mL)	<LOQ	<LOQ
Aggregation %	2.3%	1.0%

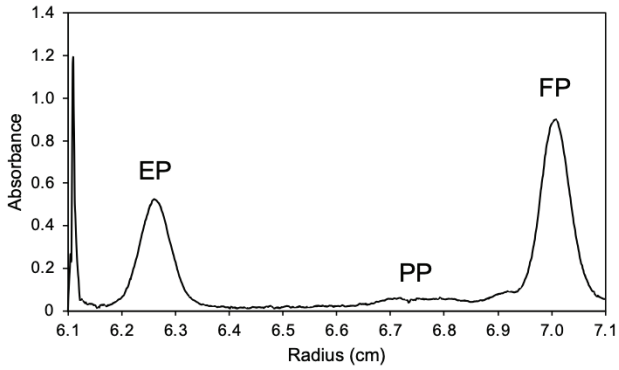
413 Utility and Limitation of Density Gradient Analytical Ultracentrifugation for the Quantitative Characterization of Adeno-Associated Virus Vector

Kiichi Hirohata, Takahiro Maruno, Yuki Yamaguchi, Tetsuo Torisu, Susumu Uchiyama

Graduate School of Engineering, Osaka University, Suita, Japan

Introduction Adeno-associated virus (AAV) vectors are the leading platform for gene delivery of *in vivo* gene therapies. In the upstream process of AAV production, AAV vectors are produced as a mixture of the AAV particles with desired DNA (full particles, FPs), particles with incomplete DNA (partial particles, PPs) or without DNA (empty particles, EPs), and aggregates. Complete removal of impurities other than FPs is generally difficult during the following purification process. Meanwhile the presence of EPs may reduce transduction efficiency and increase the risk of immunogenicity. It is thus essential to assess the purity of AAV drug product more accurately. Sedimentation velocity analytical ultracentrifugation (SV-AUC) and band sedimentation AUC (BS-AUC) have been established that enable accurate quantification of FPs and EPs, as well as other components. However, both SV- and BS-AUC requires to be proficient in measurement and fitting the theoretical model to the experimental data, working several parameters to optimize the match between data and model. Other AUC method, density gradient AUC (DG-AUC), may applicable for AAV vector characterization. In ultracentrifugal field, the solution such as cesium chloride (CsCl) generates the density gradient, and macromolecule form a band where its own buoyant density equal to density of the solution at equilibrium. DG-AUC allows separated bands to be detected by absorbance optics with the multiwavelength (MW) detection. From information on the absorption properties of each band, it is possible to clarify the components contained in the AAV vectors. DG-AUC has also the advantage that one can analyze the obtained data using commercially available software or program, which might be important for the quality control of the virus vectors under cGMP compliant condition.
Results The measurement time was examined that takes for CsCl

density gradient reach at equilibrium in DG-AUC. AAVs with different serotype and different lengths of DNA showed similar time dependence. The characterization ability of DG-AUC was evaluated in comparison with that of SV-AUC. Compared with UV absorption properties of each component determined by MW-SV-AUC, observed peaks in MW-DG-AUC were assigned as shown in the figure. Then we examined the quantification of the ratio of FP and EP (F/E ratio) by DG-AUC. The linear correlation was confirmed for F/E ratio between DG- and SV-AUC and indicated that DG-AUC is a quantitative analytical method equivalent to SV-AUC. Finally, we established the peak assignment flowchart for MW-DG-AUC, then the obtained result was compared that of MW-BS-AUC using AAVs with different DNA lengths. **Conclusion** Using the flowchart, accurate evaluation by DG-AUC tends to difficult compared to SV- or BS-AUC especially for AAVs containing minor components such as PPs or aggregates which leads to undetectable or overlapping peaks. Therefore, one should use SV- or BS-AUC for the more accurate and reliable evaluation of size distribution of AAV vectors for gene therapy. Nevertheless, DG-AUC can also applicable to characterization of any AAV vectors using optimum conditions. In addition, DG-AUC is the only analytical method to evaluate the particle density heterogeneity that cannot be detected by other orthogonal methods. SV- or BS-AUC and DG-AUC are therefore complemental methods to each other for the reliable purity assessment of AAV vectors.



414 Belief BioMed - High Yield rAAV Production Platform with Accurate Analytical Assay

Zengmin Du[1], Wei Jiang[1], Philip C. Sin[2], Jane Zheng[1], Xiao Xiao[1]

[1]Belief BioMed Limited, Shanghai, China,[2]Belief BioMed Limited, Hong Kong, China

Introduction: HEK293 cell and transient transfection method is the most versatile platform for packaging rAAV. However, HEK293 cell platform has been hampered by low yield and high incidence of empty virus particle. Belief BioMed has screened a clonal HEK293 suspension cell line, which has been identified as the optimal rAAV production platform, enabling high-titer rAAV production for multiple serotypes with low empty virus particle (<50%). Here, we present an overview of the current rAAV production platform in Belief BioMed, focusing on performance of the upstream and downstream unit operations in 200L and 500L scale, as well as virus genome integrity, purity and key residual impurity level of rAAV vectors.Conclusion: Process for rAAV manufacture have evolved significantly with the boom of gene therapy field. Product yield has improved to over 1e15vg/L, which will effectively reduce the cost of gene therapy product. From the current data, product A and product B show high yield and consistent quality under the viral vector manufacturing process of Belief BioMed, which demonstrates a linear scalability up to 500L. Additionally, both product A and product B have been applied to clinical trials in China and show high safety and drug efficacy. To further support gene therapy development, future studies are designed to improve the cell density during transfection process and the infectivity of viral vectors.

415 Early Phase Viral Clearance Study Design for AAV Manufacturing Process

Aidan Hawkins[1], Erich Ehlert[2], Sandra Bennun[3], Monica Moreno[4], Vidhi Mishra[3]

[1]Drug Substance Development, UniQure Inc., Lexington, MA,[2]uniQure biopharma B.V, Amseterdam, Netherlands,[3]uniQure Inc, Lexington, MA,[4]UniQure biopharma B.V, Amsterdam, Netherlands

Viral safety is a critical component of the quality evaluation of biotherapeutics to avoid any adverse impact on patients. Viral safety strategy revolves around 3 key pillars: prevention, detection, and removal. This presentation will focus on the final point, removal. Developing a downstream purification process capable of reducing adventitious viruses is critical to ensure patient safety. By performing meticulous, phase-appropriate, viral clearance (VC) studies these removal and inactivation techniques can be tested. It is important that viral safety and process development teams are implementing and continuously improving viral clearance strategies. One of the many challenges that come with designing a viral clearance study is ensuring what is done in controlled labs will be representative of what is happening at production scale. Here, we will be presenting an approach for designing VC studies including scale-down model verification and early phase study design.

416 A New Method for AAV Purification Bypassing Diafiltration, Depth Filtration, and Buffer Exchange

Adnan Dibas[1], Subrata Batabyal[2], Samarendra K. Mohanty[3]

[1]R & D, Nanoscope Instruments, Inc., Bedford, TX,[2]R & D, Nanoscope Therapeutics Inc, Bedford, TX,[3]Nanoscope Therapeutics Inc, Bedford, TX

Purpose: The Typical workflow of AAV purification involves lysis step, concentration (depth filtration/TFF) and column chromatography. The process of depth/diafiltration is laborious, time consuming and expensive. The purpose of this new method is to concentrate lysate and media containing AAV particles without the use of diafiltration and remove unrelated contaminants and cell debris usually eliminated by depth filtration technique. The method also eliminates the need for buffer exchange machine and can make the AAV containing media/lysate ready for FPLC purification. **Methods:** AAV particles were produced in HEK293 suspension cells using the triple transfection plasmid method. Cellular lysates were treated with Benzonase for 1hr at 37°C following by centrifugation for 30 minutes. Total lysate + media were allowed to mix with AAVX beads overnight at 4°C. On the following day, beads were pelleted by centrifugation at RT. Unbound material was removed. Beads were resuspended in lysis buffer for the AAVX and added to small columns. AAV particles were eluted using elution buffer. Samples were dialyzed overnight in 1X PBS containing 0.01% PF-68. Samples were collected and sterile filtered and were subjected to FPLC. The purity of the virus was verified using western blot and as well as Coomassie Blue staining. **Results:** Our platform approach could be applied to different serotypes including AAV2, AAV8, and AAV9. Western blot analysis detected VPs (VP1, 2, and 3) in eluted samples and gel staining shows a significant elimination of non-VPs proteins. The FPLC analysis shows the characteristics peaks for AAV, and the purified samples yielded characteristic protein bands. **Conclusions:** The new purification method using Affinity-bead was successful in eliminating the need for diafiltration and other concentrating methods as well as buffer exchange. This method is cost-effective, scalable, and timesaving for production of different AAV serotypes.

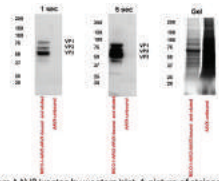

Fig.1. Detection of VPs in eluted samples from AAV2 lysates by western blot. A picture of stained gel is shown on right. VP1, VP2, and VP3 are shown in first lane in eluted fraction. In contrast, unbound fraction showed no VPs. Stained gel confirmed the removal of majority of nonspecific AAV particles (2 lane in left picture).

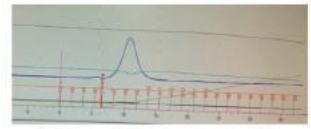

Fig.2. Detection of AAV2 particles and elution from FPLC.

417 Intensified Production Process for Gorilla Adenoviral Vector, GRAd: Yield, Purity, Potency and Stability Results

Stefano Colloca, Adriano Leuzzi, Alessia Noto, Giuseppina Miselli, Eleonora Lilli, Alessandro Moretti, Andrea Canosa, Flavia Cenesi, Michela Gentile, Romina Scala, Stefania Capone, Antonella Folgori, Leonardo Sibilio, Federico Napolitano, Fabiana Grazioli, Virginia Ammendola

ReiThera, Roma, Italy

Introduction: There is a need for viral vectors for vaccine and advanced therapy applications with low seroprevalence in the human population. Simian adenoviruses derived from the chimpanzee, bonobo, and gorilla, are not known to infect or cause pathological illness in humans, and consequently have low/no seroprevalence (0% - 18%) in the human population. Adenoviral vectors derived from simian adenovirus and more specifically from great apes have been studied in thousands of human subjects using vaccine vectors encoding different antigens (relevant to Ebola, malaria, hepatitis C, human immunodeficiency virus [HIV], and respiratory syncytial virus [RSV]). It is well established that this vaccine platform is safe and can generate potent, durable, and high-quality T cell and antibody (Ab) responses. Impact: ReiThera developed a Covid-19 vaccine, based on a novel gorilla adenovirus classified into species C which was isolated from a captive animal and converted into a replication-defective adenoviral vector generating GRAd32 COV2 vector. GRAd32 COV2 vaccine has completed the phase II clinical trial in 2021 showing a well-tolerated safety profile and strong immunogenicity. Methods: In parallel ReiThera has developed a production process based on the proprietary high yield packaging cell line ReiCell 35S based on low passage HEK293 cells. The process was designed to provide high volumetric yield by exploiting perfusion and high cell density at infection in single-use stirred tank bioreactor. The downstream process was based on selective host cell DNA precipitation step followed by membrane chromatography, polishing step and formulation by TFF. Results: The analytical results demonstrated that the process is able to provide a very high yield with the final product meeting all specifications in terms of potency and purity. Importantly, the final product was demonstrated to be stable at +4°C for more than one year. **The process was initially set up in 2L bioreactor and thereafter scaled up to 1000-L and 2000-L single-use STR.** Conclusions: **The technology for viral-vector production is validated. The technology can be used for other vector types, like AAV, especially if a systemic gene therapy requires a large amount of vector production.**

418 Highly Intensified and Low-Cost Manufacturing of Viral Vectors Using HIP-Vax® Technology

Peter Abbink[1], Pamela Russell[1], Todd Sanderson[1], Fue Vang[1], John Dumas[1], Jaison Paliakkara[1], Alfred Luitjens[2], Ahd Hamidi[2], Menzo Havenga[2], Chris Yallop[2], Wilfired Bakker[2]

[1]Batavia Biosciences, Inc., Woburn, MA,[2]Batavia Biosciences, Leiden, Netherlands

The field of virotherapy is rapidly transitioning from early-stage development to clinical efficacy testing and commercial approval. Recent approval of three cell and gene therapy products for beta thalassemia, cerebral adrenoleukodystrophy, and hemophilia B are widely expected to only be the start. Viral vectors are commonly used in virotherapy applications due to their natural ability to infect a broad variety of cells and express genes of interest for extended periods on time or integrate in the host-cell genome and correct or inactivate faulty genes. Although major milestones in clinical outcome of these therapies have been reached, the manufacturing has been met with significant challenges. Therefore, the global roll-out of these novel, life-saving therapies for diseases previously thought uncurable, is held back. Here, we describe the utilization of our HIP-Vax® platform that was developed for manufacturing of viral vaccines with ultralow costs for the production of viral vectors. Through successful process and analytical development, we have been able to produce high titers of viral vectors through several methods in one manufacturing platform, including infection-, transfection-, and induction-based production processes. All methods produced equivalent titers in bioreactor as they did in standard culture flasks, indicating a high compatibility of both traditional as well as next generation manufacturing methods with our HIP-vax® platform. Downstream processing yielded high titer, highly purified drug substance batches for preclinical and clinical evaluation. Finally, our HIP-vax® platform is readily scalable from small scale R&D and early stage clinical trial productions to late stage and commercial scale manufacturing, which will increase efficiency towards licensure. In summary, the HIP-Vax® platform is a valuable addition to the existing manufacturing methods, enabling the delivery of these desired therapies worldwide.

420 AAV8 Capsid Stability Dependence on Mg2+ Ions

Kannan Raghunathan, Daniel Daley, Dwaipayan Sen

Astellas Gene Therapies, San Francisco, CA

As a vector for gene therapy, the adeno associated virus (AAV) family has enjoyed notable success and popularity as of late. These viral capsids undergo tremendous physical stress during production and purification processes, leading to loss of product. Having observed increased on-column stability of adeno associated virus serotype-8 capsids when supplemented with Mg^{2+}, we used monolithic anion exchange chromatography and ddPCR/ELISA based analytical methods to further explore this relationship during column processes. As we demonstrate this effect to be particularly pronounced in empty capsids, we also report its impact on an intentionally empty-only capsid production of AAV8. We finally show that susceptibility to stress increases in the absence of Mg^{2+} ions,

an effect that can be exacerbated by use of a chelating agent, EDTA. The results suggest that the supplementation of chromatography buffers with Mg^{2+} improves yields, as well as the homogeneity of chromatographic species when separated by ion exchange methods. Beyond the reduction in cost of production, this would imply that Mg^{2+} is a necessary component in any effort to enrich full capsids.

421 Step Gradient Development for Full Particle Enrichment of AAV on Anion-Exchange Monoliths is Hindered by Inconsistent Column Lots

Austin T. Raper, Andrew J. Reed, Sydney Hartbarger, Katy Barber, Jingjing Zhang, Younghoon Oh

Early Research Process Development, Downstream, Sarepta Therapeutics, Cambridge, MA

Empty capsids are by-products of adeno-associated virus (AAV) production and are generally accepted as undesirable in drug product preparations due to complications surrounding immunogenicity and dose-related toxicity. Recent proposed draft guidance for Food and Drug Administration (FDA) consideration recommends a maximum release criterion of less than or equal to 30% empty capsids in AAV-based gene therapy products. Efficient control or removal of empty capsids through optimization of vector genome encapsidation during upstream production or through physical separation by downstream unit operations is thus a critical consideration for gene therapy manufacturers. To remove this product-related impurity, downstream purification strategies often aim to exploit the subtle difference in isoelectric point (pI) between full and empty AAV particles through ion-exchange chromatography (IEX). As many AAV serotypes have acidic pI values, anion-exchange (AEX) columns are typically selected as the preferred stationary phase for chromatography as the AAV charge state is maximized in high pH buffer solutions. AEX monoliths (e.g., CIMmultus QA by Sartorius) have emerged as a popular modality for on-column separation of full and empty AAV as they possess several attractive properties, including flow rate independent performance (i.e., binding is not diffusion limited) and large flow-through channels (i.e., well suited for separation of large biomolecules). Indeed, we previously developed a chromatographic method using an anion-exchange monolith to enrich full AAV particles to greater than 90% in drug product preparations. This method employed a shallow linear gradient of salt to elute the loosely bound empty AAV particles first, followed by the more tightly bound full AAV particles at higher ionic strength. While successful at full particle enrichment, this method could be improved for commercial bioprocessing by conversion to a dual step gradient method, wherein a first wash step at a given concentration of salt elutes the empty particles and a second wash step at a higher salt concentration elutes the full particles. Such a method is easier to execute at scale, promising less user interaction, less buffer consumption, and less eluate volume. In this study, we aimed to develop a dual step gradient method on the AEX monolith for full particle enrichment. This work involved screening buffer solutions to identify the ideal salt concentration of the first wash step for maximum elution of empty particles, without elution of full particles, and to identify the minimum salt concentration of the second wash step for maximum elution of full particles. Once these conditions were determined, we then characterized the process robustness, including vector genome recovery and enrichment across runs of various load materials, buffer lots, and columns lots. We found that while the method was at times capable of high vector genome recovery (>90%) and full particle enrichment (>90% full particles), lot-to-lot inconsistencies in the monolith columns often lead to subpar or unpredictable run performance, including significant loss of full particles during the first wash step (e.g., 30% of full particles) due to premature elution. Based on these results and without further improvements to the technology, we do not recommend step gradient development on the monolith columns and instead advise to scale up using a linear gradient method. For sake of comparison, we also successfully developed a dual step gradient method for a resin-based AEX system which showed consistent separation performance regardless of column lot. This research was funded by Sarepta Therapeutics.

422 Next-Generation Rep-Cap Dual Baculoviruses for AAV Production in Insect Cells

Berati Çerikan[1], Teun Slijkerman[1], Zandra Félix Garza[1], Patrick Van Zanen[1], Desiree Hoff-Hooijschuur[1], Viki Kolokotroni[1], Stavros Stamatakis[1], Francisco Ferraz[1], Martin Kangwa[1], Seyda Acar Broekmans[1], Noortje Heidinga[1], Warner Hoornenborg[1], Stijn Waaijer[1], Tycho Hoogland[1], Bas Bosma[2], Finny S. Varghese[1]

[1]Baculovirus Production Unit, Biological Starting Materials, Global Process Development, uniQure Biopharma B.V., Amsterdam, Netherlands,[2]Vector Technology, uniQure Biopharma B.V., Amsterdam, Netherlands

uniQure's AAV-based gene therapy manufacturing platform is based on an insect-cell baculovirus expression system, where infectious baculoviruses deliver the different components needed for AAV production. uniQure's first-generation platform consists of an infection with three separate baculoviruses each containing AAV-Rep, AAV-Cap and the therapeutic cassette. uniQure's next-generation platform is based on a dual baculovirus infection, one containing both AAV-Rep and AAV-Cap (DuoBacs) and the second one containing the transgene. Several Rep designs were evaluated in combination with a representative AAV capsid. These DuoBacs showed improved genetic stability within the baculovirus genome. AAVs produced using these DuoBacs were assessed for several quality parameters in both small and large scale productions. A few of these designs showed improved yield, empty to full capsid ratios, DNA packaging and potency. These designs need to be further investigated in order to assess the in vivo biodistribution and potency.

423 CMC Strategies for AAV Gene Therapies for Highly Prevalent Diseases

Ali Aghajanirefah, Leily Daneshian, Brigit E. Riley

Adverum Biotechnologies, Redwood City, CA

Biological research applications and potential treatments for genetic and prevalent diseases are now being made possible by gene therapy. At present, viruses are the best tools for transferring genes into cells. Recombinant adeno-associated viruses (rAAVs) have become the most popular vectors of choice for many therapeutic and fundamental applications. Approved products and the number of clinical trials

using rAAV are continuously increasing, demonstrating the necessity of standardizing (and improving) the manufacturing, and purification of these vectors to meet the quantitative and qualitative requirements of regulatory agencies. One of the most important factors to move the gene therapy field forward is the Chemistry, Manufacturing, and Controls (CMC), which is responsible for all the activities related to process purity. In this study, we focused on improving our rAAV production system in insect cells (Sf9), which is based on the baculovirus expression vector (BEV) that uses the Bac-to-Bac baculovirus expression system. We modified the selection markers of the donor plasmid (pFastBac) in the Bac-to-Bac system by removing the Gentamicin resistance gene and adding an extra positive selection marker (rpsl) to remove the donor plasmid from recombinant Bacmid preparations. We also evaluated the BEV stability and yield level of rAAV during successive passages of the BEV (P0 vs P2) in insect cells. Our result demonstrated that the modified donor plasmid (pFastBac) leads to enhanced recombinant Bacmid quality and decreased residual encapsulated DNA titer. This represents an important improvement in the rAAV production system which should assist with improved vector preparations for research and clinical applications including prevalent indications with higher overall product demand.Biological research applications and potential treatments for genetic and prevalent diseases are now being made possible by gene therapy. 424 Upstream Optimization Paved a Straightforward Path for High Percentage of Full Capsids in AAV6

James Fasano, Azam Hassaninasab, Daniel Kennedy, Theresa Dao, Jay Cai, Omar Matalka, Christine Beaudry, Miranda Williams, Lorenz Ponce, Arianna Spooner, Emily Sinclair, Bojiao Yin, Maria Mercedes Segura

ElevateBio, Waltham, MA

Adeno-Associated viruses (AAV) are a potent tool in the expanding field of cell and gene therapy as they offer low immunogenicity and can facilitate gene transfer or gene editing for *in vivo* or *in vitro* applications via the efficient delivery of genetic material. However, the AAV potency and safety are highly dependent on the genome packaging efficiency, including full particle percentage among the total particles, the distribution of partial particles, and the amount of empty particles. Because clinical applications for AAV are increasing rapidly, there is a high demand for further increasing yields as well as product quality, particularly for a higher percentage of full capsids in the final product. One of the biggest challenges in current AAV manufacturing is to achieve >70% full particles in the final drug substance/drug product (DS/DP). The percentage of full particles is influenced by several factors including the low percentage of full particles produced from upstream processes, the separation and enrichment processes from downstream purification, etc. Here, we describe a method of upstream optimization to achieve high full particle enrichment (>70% full) in final purified AAV products without further development of the downstream process. A platform process for AAV6 production has been well-established and is based on transient transfection of serum-free cells grown in suspension. In this process, we have evaluated multiple parameters in the upstream production process (for example, cell growth, transfection reagents, DNA concentration, etc) to reach titers > 1e11 vg/mL and >15% full particles based on dynamic light scattering (DLS) using Design of Experiment (DoE) studies in shake flasks. Furthermore, our data demonstrated good scalability from shake flask to a 2L stirred tank reactor (STR) in terms of genome titer and full%. The challenge for the baseline process was that final AAV could only reach ~50% full particles even after IEX enrichment. To avoid changes in the downstream process and accelerate the development timeline for this project, a follow-up DoE was performed to optimize the ratio among 3 transfection plasmids to increase AAV full percentage. Batch purification was used to determine upstream processes with higher percent full particle via DLS, and the top 4 conditions achieved >1.5e11vg/mL and 17-23% full (DLS). Then, the top 2 processes were scaled up into 2L STR and particles were purified through our platform affinity chromatography using AKTA for further verification. The data showed the affinity purified AAVs from both processes were > 1e13 vg/mL and 30-40% full (via Analytical Ultracentrifugation [AUC]). Since the GMP friendly downstream process usually include Ion Exchange (IEX) chromatography after the affinity column to enrich the full particles, these 2 upstream processes have been also applied through IEX separation and our data demonstrated the final AAV titer were at 1e13vg/mL level and most importantly, the full particles were enriched to >70% full. Aiming for offering a scalable and GMP compatible process in a fast timeline manner, the DoE study for upstream optimization provided

a straightforward path to achieve higher genome titer and quality specification (>70% full particles) to meet clinical requirement without making any changes in downstream unit operations.

425 Development and Scale-Up Validation of Small Molecule Enhancers for Increased Viral Vector Yield

Keara Sutherland, Andrea Vervoort, Naveen Haribabu, Ella Korets-Smith, Jondavid De Jong, Jean-Simon Diallo
Virica Biotech, Ottawa, ON, Canada

At-scale manufacturing of gene and cell therapy vectors is a complex process, often resulting in insufficient manufacturing yields to satisfy developmental and commercial demand. While the last decade has seen major advances in the viral platform, bioreactor design, cell line and media formulation optimization, the industry still faces major challenges with production consistency and yield. An often overlooked and underappreciated bottleneck in cell culture-based manufacturing is the presence of cellular innate antiviral immune pathways that remain partially, if not fully, intact in producer cells. These well-conserved pathways are triggered via the detection of foreign nucleic acid and/or molecular bi-products of viral replication/assembly resulting in blunted viral vector yields in both infection and transfection-based manufacturing strategies.Virica's Viral Sensitizers (VSEs™) encompass a proprietary collection of small molecules that enhance the growth of viruses by transiently and efficiently dampening cellular antiviral defenses. Leveraging high-throughput methods, Virica has assembled a library of over 130 small molecules which enhance viral production by transiently antagonizing a broad range of cellular innate antiviral pathways. Owing to different molecular mechanisms, VSEs™ can be combined and formulated for specific uses across various viral and cellular platforms.Here we describe the development of custom small molecule formulations for enhanced production of therapeutically relevant vectors MVA and AAV, using high-throughput methodologies. Furthermore, we present validation data supporting the scalability of these custom formulations in formats representative of large-scale commercial production platforms (iCELLis Nano for MVA; suspension bioreactor for AAV). Ultimately, this data supports the use of small molecule enhancers, such as Virica's VSEs™, for increased production of viral vectors at scale.

426 Optimizing Shelf Life of AAV8 and AAV9: DP Container Closure Selection for Storage and Shipping

Hali Jiang, Conor Lake, Srivanya Tummala, Khan Umaer, Jason Moore, Brian Tomkowicz, Maryam Rahimian, Annie Daniels, Danielle Daniels, Honggeun Park, Tatiana Nanda, Avi Nandi
Center for Breakthrough Medicines, King of Prussia, PA

Rubber stoppered glass vials are a popular primary container closure system for storing and delivering liquid formulations due to their low leachable levels and minimal retention of most drug products. More recently, polymeric vials have gained increasing prevalence due to a more rugged construction and lower cost. With the emergence of adeno-associated viruses (AAVs) as a leading drug platform for gene therapy and the development of new material constructions for container closure systems, the determination of optimal containers with the least impact on product stability is critical for determining storage and shipping conditions as well as maximizing shelf life. Two of the most common serotypes of adeno-associated virus vectors (AAV8 and AAV9) were formulated using a model Tris-HCl buffer and were subjected to storage in four of the most commonly used container closure systems on the market. To evaluate the impact of container closure on product stability, vials were placed under stress conditions meant to mimic real-world handling or conditions used to project long-term stability. The conditions evaluated included extended holds under expected clinical storage temperatures; short-term holds under thermal stress conditions often used to predict shelf life; and other stresses meant to mimic typical shipping and handling, such as shaking, storage on dry ice, and freeze thaw cycling. Product quality was evaluated using a variety of methods to determine changes in concentration, titer, aggregates, empty to full ratio, thermal stability, subvisible particles, infectivity, and turbidity. The findings from this study provide an initial roadmap for gene therapy companies, aiding in the selection of container closure components during drug product development and commercialization.

428 Finding Flexibility in a Templated Vector Manufacturing Process - Understanding Process Efficiencies in the Downstream Purification of a Model AAV Product

Eric Weiss, Joe Orlando
Viral Vector Technology and Innovation, MilliporeSigma - Bedford, Bedford, MA

Templated viral vector manufacturing processes can provide a distinct advantage by reducing overall process development time, hastening delivery of novel therapeutics to the clinic, and ultimately providing improved patient outcomes. However, a templated process must also be flexible enough to accommodate individual vector and transgene combinations that can impact vector production (e.g., variable titers) in the bioreactor and alter harvest composition. These conditions further affect downstream purification causing processing bottlenecks and increasing costs unnecessarily. Here we describe work using model AAV2 in a downstream vector manufacturing process comparing alternative approaches to increase processing efficiencies (including time and cost). Specifically, we focus on improving affinity chromatographic performance by comparing direct loading of clarified lysate to clarified lysate concentrated using tangential flow filtration (TFF) by quantifying changes in the dynamic binding capacity (DBC) of the resin under otherwise identical loading conditions, such as retention time and column volume. Our findings demonstrate areas where we can take advantage of increased loading onto affinity chromatographic resin that accompanies properly TFF-concentrated feed. We identified conditions that resulted in a greater than 4-fold increase in the measured DBC, providing commensurate reduction in both the volume of resin required to process an equal load of clarified lysate as well as the time required to load the material. However, we also model circumstance in which sufficient titer from the bioreactor mitigates the potential benefit of feed concentration and where direct loading of clarified harvest unto the chromatographic resin is more beneficial. Our findings demonstrate the importance of identifying

areas within a viral vector manufacturing template where a deeper understanding of the holistic process can provide flexibility to support diverse products while maintaining development speed necessary to deliver life-changing therapies where they are needed.

429 Optimized AEX Buffer Formulations for AAV Full Capsid Enrichment

Bella Neufeld

Research and Development, Teknova, Hollister, CA

The developed tropism of Adeno-Associated Viruses (AAV) allows them to target human-specific tissues, conferring AAV therapeutics with the ability to become primary vectors for gene delivery. However, obtaining viral titers required to produce the desired therapeutic effect can be challenging due to inherent product related impurities, such as empty capsids. Towards this end, improvement of the Anion Exchange chromatography-based purification (AEX) step has been a major focus in the field. We have employed an extensive design of experiments (DOE) for AAV full capsid enrichment, utilizing multiple process parameters (including pH, numerous elution salts, excipients, surfactants, stabilizers, and osmolytes). In our studies, we have identified a set of serotype-specific buffer formulations that have achieved the required quality attributes of empty capsid removal while maintaining maximum recovery and infectivity of the viruses. A unique feature of these buffer sets is that they provide multiple formulation compositions, allowing selection of the top candidate based on raw material needs, grade, cost, and supply access. These properties afford greater flexibility to scale up manufacturing processes while ensuring high quality therapeutic products.

430 Development and Qualification of a Multiplexed ddPCR Assay to Evaluate DNA Integrity

Isabella Pajevic[1], Bisma Ajaz[1], Peter Webster[2], Brian Collins[2]

[1]Solid Biosciences, Charlestown, MA,[2]Solid Biosciences, Cambridge, MA

Droplet digital PCR (ddPCR) has become a robust and effective method to obtain the titer of gene therapy products. Although ddPCR for the gene of interest (GOI) can effectively quantify the gene product, it does not give information on the integrity of the packaged DNA, which is important for product characterization and process development. A number of genetic approaches are available to assess DNA integrity but often introduce bias or provide partial information. Furthermore, only a few of these methods have been fully qualified. This abstract discusses the advantages of Multiplex ddPCR as a measure of AAV packaged DNA integrity and describes the development and qualification of the method. In principle, Multiplex DNA leverages the use two primer sets, each at opposite ends of the gene of interest. The assay then determines the % of the packaged DNA that has both primer sites intact and thus the full length of the GOI. The presence of only one or the other primer sites is indicative of a truncated or fragmented GOI. Method development was performed and illustrates that AAV capsid could be diluted enough to be separated into the individual droplets to allow for a clear quantification of the individual viral particles. Further development included optimization for sample preparation and dilution which can substantially impact the accuracy of the integrity value. Qualification testing for the Multiplex ddPCR assay included assessment of linearity, accuracy, intermediate precision/repeatability, and specificity. In addition, primer sets across the GOI indicate that strand breaks occur across the gene of interest and not at a specific "hot spot". Through development and Qualification of Multiplex ddPCR, we have shown that the method can quantify the intact gene of interest in a robust, reproducible and precise manner. The qualified method can be used to support process development, product characterization and AAV stability assessments.

431 Prediction of Adeno-Associated Virus Manufacturability by Machine Learning

Jason Wu[1], Eugenia Lyashenko[1], Yu Qiu[2], Sourav R. Choudhury[1]

[1]AAV Technologies Laboratory, Genomic Medicine Unit, Sanofi, Waltham, MA,[2]Digital & Biologics Strategy and Innovation, Sanofi, Cambridge, MA

Gene therapy is transforming human health by addressing rare diseases with single dose-treatments of therapeutic adeno-associated viral (AAV) vectors. However, the exorbitant financial cost of these treatments is a key roadblock for the widespread adoption of gene therapies. Manufacturing cost is a major contributor to Cost of Goods Sold (COGS) for genomic medicines. The lowering cost of high-throughput DNA synthesis, recent advancements in artificial intelligence and increasing computing power have enabled the application of machine learning (ML) to improve manufacturability of AAV capsids. We develop a state-of-the art ML model to predict the manufacturability of AAV capsid mutants based on the amino acid sequence of the capsid monomer, viral capsid protein 1 (VP1). Our model is trained on publicly available data of capsid fitness of AAV2 VP1 single point mutants. First, we use a protein language model (UniRep) to embed mutant protein sequences into biologically meaningful numerical vector representations. Then, we train and evaluate several classical ML regression models to predict the fitness of the mutants. We augmented a Random Forest model trained upon UniRep embeddings with a Ridge regression model trained upon one-hot embeddings that further improved the prediction accuracy of the model. Encouragingly, we achieved a significantly high prediction power (Pearson correlation = 0.82) on the held-out test set using our predictions from the generated UniRep+One-Hot model. Finally, we validate our model on two independent datasets not used for model training. In the first dataset, we show that the model can differentiate between capsid forming and non-forming sequences by their predicted fitness scores (P-value: 0.042). For the second dataset, we achieved high correlation between the model-predicted and the measured fitness score (Pearson correlation =.692). In the future, this model could be used as an *in-silico* screen for AAV capsids to reduce the time necessary for *in-vitro* experiments. With this work, we aim to establish an ML-based platform to increase manufacturability of clinical AAV capsids to make AAV gene therapies economically viable for patients.

432 Development of a Platform for Parallel Functional Evaluation of Cell Type Specific Synthetic Promoters for Gene Therapy

Amanda J. Kedaigle, Aayushi Manchanda, Jonathan Sellon, Kathy So, Pray Xu, Gabriela Pregernig, Tyler M. Gibson, Adam Palermo, Monika S. Kowalczyk

Decibel Therapeutics, Boston, MA

One of the key components adeno-associated viruses (AAVs) is a promoter that drives transgene expression. Optimal promoters are cell type-specific to avoid toxicity, compact to fit into AAV, and drive a precise level of expression. Unfortunately, identifying and functionally testing promoters is laborious and time consuming. To that end, we built a system to screen a library of synthetic promoters and read out specificity and expression levels for each promoter on a single-cell level and in a single experiment. Such a screen allows for rapid selection of cell type-specific promoters from a large number of candidates. Moreover, it can deliver a set of cell type-specific and compact promoters that drive a range of expression levels, allowing for precise control of transgene expression. We created an AAV plasmid with a modified 3' UTR in the transgene cassette that contains a variable DNA barcode sequence compatible with single cell sequencing approaches. This vector served as a backbone to produce an AAV library, where each member contains a different synthetic promoter sequence coupled with a unique barcode. We built and optimized this system via testing AAVs individually and as a library in mouse utricle explants, using immunohistochemistry to evaluate levels of a GFP reporter and to compare against single-cell RNAseq (scRNAseq) detection of the promoter barcode.We used previously internally characterized promoters to build and optimize our technology. Our scRNAseq pipeline detected barcodes for each promoter in our pools and enabled us to read out specificity and expression levels across the cell types and cell states *ex vivo* and *in vivo* in mouse inner ear. We compared the scRNA-seq results to immunohistochemistry data measuring GFP reporter expression and found that the results were consistent in matched single-vector control samples. Following this work, we applied our system to completely novel inner ear promoters and characterized their specificity and expression levels. Our approach allows for fast and efficient synthetic promoter screening to deliver promoters for gene therapy that are compact and drive optimal expression levels of the transgene. This method should allow us to accelerate development and testing of novel gene therapy tools in the inner ear.

433 Mapping Administration Route-Dependent Transduction Profiles of Commonly Used AAV Vectors in Mice by Multiplexed Barcode Sequencing

Sarah Abele, Devona Soetopo, Gregorio Alanis-Lobato, Martin Oti, Werner Rust, Diana Santacruz, Alec Dick, Fidel Ramirez, Kerstin Geillinger-Kästle, Stefan Michelfelder, Benjamin Strobel

Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach an der Riß, Germany

AAVs are important gene therapy vectors and attractive research tools to modulate gene expression in various tissues of interest. Both preclinically and clinically, the biodistribution and thus transduction profiles of AAV variants heavily depend on the administration route. Yet, despite the plethora of available capsids and the continuous selection of novel improved capsid-engineered variants, a systematic evaluation of the administration route dependency of AAV tropism has been lacking so far. Here, we established the transduction profiles of a unique collection of 34 well-known AAV capsid variants (wild types and published engineered capsids) for three administration routes, namely intravenous (i.v.), intraperitoneal (i.p.) and intratracheal (i.t.) injection, in C57BL/6 mice by state-of-the-art multiplexed biodistribution analyses based on AAV genome-barcoding. To that end, the AAV library ($1.36x10^{12}$ vector genomes per animal) was injected into eight animals per administration route, and DNA and RNA were isolated from all major organs 14 days later. Vector genomes (DNA) and transcripts (RNA) were then quantified by next-generation amplicon-sequencing. As expected, the analysis confirmed a pronounced liver transduction by most AAV variants after i.v. administration, as well as known transduction patterns for benchmark capsids, for example AAV-PHP.eB (brain) and AAV2-ESGHGYF (lung). In contrast, i.p. administration decreased the liver tropism of many vectors and led to capsid-specific changes in overall biodistribution. While some variants showed prominent transduction of the diaphragm, for other AAVs, broader distribution was observed, as evident from enhanced expression in abdominal and thoracic tissues. To further validate these results, the biodistribution profiles of selected AAV library variants were individually assessed in follow-up studies via qPCR and histology. For local delivery to the lung by i.t. administration, bulk amplicon-sequencing identified AAV6.2 and other AAV6 variants as well as AAV-DJ as the most efficient vectors for pulmonary gene expression in mice. Given the cellular heterogeneity of the lung, including several epithelial subtypes, mesenchymal cells and residential immune cells, for which AAV targeting efficiency has been largely unknown so far, we finally aimed to further develop the barcode sequencing approach towards single-cell resolution. Therefore, the barcoded AAV pool was applied i.t. into four C57BL/6 mice ($1.08x10^{12}$ vector genomes per animal), and a protocol for lung dissociation and high-viability single cell recovery was established. Following additional optimization of the Chromium 10x single-cell RNA-sequencing workflow by implementation of an additional cDNA library-based barcode amplification step, we were able to map the distribution of all AAV library variants to defined lung cell clusters and to identify the most efficient variants for each cell type. In summary, we established AAV transduction profiles for 34 AAV variants following i.v., i.p. and local lung delivery and further demonstrated feasibility of AAV biodistribution analysis at single cell resolution in the murine lung. Our data inform preclinical study design by enabling the selection of optimal vectors and administration routes for improved targeting of murine tissues and cell types of interest.

434 DNA-PKcs Inhibition Boosts rAAV Transduction in Polarized Human Airway Epithelia

Kang Ning[1], Siyuan Hao[1], Cagla Aksu Kuz[1], Shane McFarlin[1], Zehua Feng[2], Ziying Yan[2], Jianming Qiu[1]

[1]The University of Kansas Medical Center, Kansas City, KS,[2]University of Iowa, Iowa City, IA

Recombinant Adeno-associated virus (rAAV) vectors have been widely used for therapeutic gene transfer in the studies of human gene therapy. rAAV vector drives persistent transgene expression in targeted tissues. AAV capsid directed evolution or rational design has evolved clinically desirable AAV capsids that exhibit higher transduction efficiency in tissues of cells, for example, AAV2.5T capsid was selected from the directed evolution of an AAV capsid library in human airway epithelia. In this study, we found rAAV2.5T transduction of well differentiated/polarized primary human airway epithelium (HAE) cultured at an air-liquid interface (HAE-ALI) induced a DNA damage response (DDR). The induced DDR was featured with phosphorylation of replication protein A32 (RPA32), histone variant H2AX (H2A histone family member X), and all three phosphatidylinositol 3-kinase-related kinases (PIKKs): ATM, ATR, and DNA-PKcs. While treatment of ATR pharmacological inhibitors or *ATR* gene knockdown inhibited rAAV2.5T transduction, DNA-PKcs inhibition or targeted gene knockdown increased rAAV2.5T transgene expression significantly in HAE-ALI. Notably, DNA-PKcs specific inhibitor NU7441 worked as a "booster" to further increase rAAV2.5T transgene expression after treatment of doxorubicin, whereas the epithelial barrier functions remained. Thus, our study provides evidence that DDR is associated with rAAV transduction in well differentiated HAE. Also, the study suggests that DNA-PKcs inhibition has the potential to boost rAAV transduction and that pharmacological compounds that block the DDR may be used as an augmenter to enhance rAAV transduction efficiency.

435 Primate-Conserved Carbonic Anhydrase IV and Murine-Restricted Ly6c1 Are New Targets for Crossing the Blood-Brain Barrier

Timothy F. Shay, Erin E. Sullivan, Xiaozhe Ding, Xinhong Chen, Sripriya Ravindra Kumar, David Goertsen, David Brown, Jost Vielmetter, Máté Borsos, Annie W. Lam, Viviana Gradinaru

California Institute of Technology, Pasadena, CA

The blood-brain barrier (BBB) presents a major challenge to delivering large molecules to study and treat the central nervous system (CNS). This is due in part to the scarcity of effective targets for BBB crossing, the identification of which is the crucial first step of drug development. Here, we leveraged a panel of adeno-associated viruses (AAVs) previously identified through directed evolution for improved BBB transport to reverse engineer protein targets for enhanced BBB crossing. We identify both murine-restricted Ly6c1 and primate-conserved carbonic anhydrase IV (Car4; CA4) as novel receptors for crossing the BBB. We demonstrate how these receptors can unlock new experimental and computational target-focused engineering strategies by creating the enhanced Ly6c1-binding vector AAV-PHP.eC and by applying AlphaFold2-enabled in silico methods to rank capsids against identified receptors and generate capsid-receptor binding models. Here, with Car4, we add a completely new receptor to the very short list currently available for crossing the BBB in humans and, with Ly6c1, we validate a pipeline for receptor-targeted engineering. The identification of Car4/CA4 and structural insights from computational modeling provide new paths toward human brain-penetrant chemicals (drugs) and biologicals (including gene delivery).

436 The Potential Mechanism and Universality of the AAP Degron Model in the Process of AAV Capsid Assembly

Anusha Sairavi, Swapna Kollu, Colton Stensrud, Hiroyuki Nakai

Department of Molecular and Medical Genetics, Oregon Health & Science University School of Medicine, Portland, OR

The formation of adeno-associated virus (AAV) capsid is a multi-step assembly process in which the AAV assembly activating protein (AAP) plays a crucial role at various steps including stabilization of AAV VP capsid monomers and subsequent transport of the VP capsid protein from the cytoplasm to the place in the nucleus where the virion formation takes place. Since persisted interaction between VP and AAP at the VP-VP interface would affect multimerization of VP proteins and hence hinder capsid formation, AAP must be removed effectively from VP proteins by a certain mechanism in the process of capsid assembly. In this regard, we have proposed the "AAP degron model" in which AAP's ability to promote self-disintegration once the VP-VP multimerization process is initiated, is critical for the assembly of VP proteins into capsids. To support this model, our lab has previously shown that the hydrophobic region (HR) in the N terminus of AAPs derived from AAV1, 2, 3, 5, 6, 7, 8, 9, 10 and 12 (i.e., AAP1, 2, 3, 5, 6, 7, 8, 9, 10 and 12) has a degron. However, it has remained puzzling that the HR in AAP4 and 11 does not show a degron activity, which does not align well with the AAP degron model. Here, we show that, despite the heterogeneity of the degron function in the AAP HR region among the different serotypes, the AAP degron model is still valid for AAV4 and 11; therefore, it is the universal model that explains effective removal of AAP in the capsid assembly process. This conclusion is supported by our new discovery that the conserved core (CC) region of AAP4 and 11 contains a degron. In addition, we could identify a single amino acid critical for the HR degron function. In the study, we compared amino acid sequences in the HR regions between degradation-prone HRs (AAP1, 2, 3, 5, 6, 7, 8, 9, 10 and 12) and degradation-resistant HRs (AAP 4 and 11) by sequence alignment and found that leucine (L) at position 25 (note: the amino acid position number is based on AAP9) is conserved across all degradation-prone AAP HRs except for AAP12 and the degradation-resistant HRs harbor threonine at the corresponding position. Using an AAP9HRL25T mutant fused to FLAG-GFP, we compared the GFP expression against the wild-type AAP9HR-FLAG-GFP. Unlike the wild type, the AAP9L25T mutant showed a retention of GFP expression albeit at a level lower than the FLAG-GFP control. Reciprocally, we found that GFP expression of AAP4HRT25L mutant showed a decrease in GFP expression compared to the wild-type AAP4HR-FLAG-GFP control. These observations demonstrate that the amino acid at position 25, which is either leucine or threonine, plays a critical role in the AAP's HR degron activity. Next, we investigated potential impacts of AAP retention on capsid assembly using the degradation-prone wild-type

AAP9 and the degradation-resistant AAP9L25T mutant. Consistent with the AAP degron model, the production of AAV9 VP3 particles was completely abrogated with the AAP9L25T mutant, indicating that persistent presence of AAP is detrimental to capsid assembly. Having obtained a plethora of evidence supporting the AAP degron model, our efforts were then directed towards identifying a degron in other AAP functional domains besides HR within AAP4 and 11 whose HR is devoid of a degron to reconcile our observations. Consequently, we confirmed that AAP4 and 11 indeed carry a degron, not in the HR, but in the CC region. We are currently working on identifying amino acid residues within the CC region of AAP4 and 11 responsible for degradation. These results significantly further our understanding of the function and mechanism of AAP in the process of capsid assembly.

437 A Viral Toolbox to Target and Manipulate Distinct Cortical Interneuron Subtypes

Yating Wang, Deepanjali Dwivedi, Min Dai, Elisabetta Furlanis, Josselyn Vergara, Brenda Leyva, Sarah Du, Rohan Badiani, Aniqa Tarafdar, Justin McMahon, Bram Gorissen, Jordane Dimidschstein, Gordon Fishell

Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, MA

Recombinant AAV (rAAV) can drive long-term gene expression *in vivo* and hence has become a popular gene delivery vector for research and gene therapy. However, to better leverage rAAV as a research and therapeutic tool, the expression of transgene needs to be regulated in a tissue/cell-type specific or context dependent manner. To address this, significant efforts have been made to modify the AAV capsid. However, the extend of specificity capsid choice can offer is relatively limited. Enhancers are non-coding elements that can regulate gene expression and can control the activity or spatial-temporal pattern of gene expression. In recent years, we and others have identified a number of enhancers that, when incorporated into rAAV vectors, can restrict the transgene expression to particular neuronal populations. Yet, viral tools to access and manipulate fine neuronal subtypes are still limited. Here, we performed systematic analysis of single cell ATAC-seq and RNA-seq data to identify enhancer candidates for each of the cortical interneuron subtypes. We then screened these candidates and successfully identified enhancers that are highly selective for distinct cortical interneuron populations in mouse and non-human primate. These enhancers, when used in the context of different effectors, can target (fluorescent proteins), observe activity (gCaMP), manipulate (opto- or chemo-genetics) and trace the connectivity (used in conjunction with mono-synaptic rabies) of specific neuronal subtypes. We also validated our viral tools across species. Thus, we present the development of a powerful set of tools for the study of cortical interneurons and the neural circuits to which they contribute. Moreover, our enhancer identification and validation strategies have the potential for use in tissue/cell-type specific or context dependent tools for therapeutic use.

438 Prenatal Administration of AAV9-GFP in Fetal Lambs Results in Widespread Biodistribution and Transduction of Female, but Not Male, Germ Cells

Beltran Borges[1], Antonia Varthaliti[1], Marisa E. Schwab[1], Maria Clarke[1], Akos Herzeg[1], Christopher Pivetti[2], Nalin Gupta[1], Cathryn Cadwell[1], Ghiabe Henri Guibinga[3], Shirley Phillips[3], Tony Del Rio[3], Fatih Ozsolak[3], Denise Imai-Leonard[2], Diana J. Laird[1], Lingling Kong[4], Charlotte Sumner[4], Tippi C. MacKenzie[1]

[1]University of California San Francisco, San Francisco, CA,[2]University of California Davis, Davis, CA,[3]Novartis Pharma AG, San Diego, CA,[4]Johns Hopkins University, Baltimore, MD

Introduction: Prenatal somatic cell gene therapy could lead to treatment of early onset genetic disorders such as spinal muscular atrophy (SMA). Given the success of AAV9-SMN vector for the treatment of children with SMA, we tested the safety and biodistribution of AAV9-GFP in fetal lambs using a similar viral dose. **Methods:** Fetal lambs were injected with $1x10^{14}$ vector genomes/kg (equivalent to neonatal dose of AAV9-SMN) of scAAV9-GFP through the umbilical vein (UV, n=13) on e75 and harvested after 3 weeks or 2 months. 4 animals were injected intracranially (IC) through the cisterna magna. Vector biodistribution was evaluated using ddPCR for vector genomes (vg) and immunofluorescence. Toxicity analyses included maternal and fetal biochemistries and measurement of anti-AAV9 and anti-GFP antibodies. **Results:** Survival to harvest was >88% for both injected and uninjected; 3 fetuses (2 injected, 1 uninjected) in 2 litters suffered in-utero demise, likely secondary to chorioamnionitis. We detected widespread biodistribution of vg in all tissues examined (brain, spinal cord, liver, skeletal muscle, blood, placenta and gonads) with decreased levels at 2 months compared to 3 weeks ($p<0.05$ in heart, liver, diaphragm, lung, and lumbar spinal cord). Detection of vg in maternal ewes was low except in pregnancies with fetal demise. Widespread GFP expression in lamb tissues was observed at both time points including in multiple regions of the brain and spinal cord, diaphragm, and quadriceps muscles. We did not detect any histopathological toxicity in dorsal root ganglia. There was evidence of systemic toxicity including growth restriction, transient elevation of total bilirubin (in ewes and lambs), and histopathologic abnormalities in the liver, kidney, and cerebellum. We also detected anti-AAV9 (but not anti-GFP) antibodies in both ewes and lambs. Staining for the germ cell marker DDX4 demonstrated co-localization of GFP in ovarian germ cells (which also stained positive for the meiosis marker SYCP3); in contrast, GFP+ cells in testes did not stain with DDX4 or SYCP3. Integration analysis of gonads (3 female, 3 male) demonstrated integration of AAV in all samples, representing 40 different integration sites with very low (less than 7%) vector rearrangement rate. Integration events were not observed in genes previously associated with adverse events in gene therapy trials; however one of the samples showed integration in gene TMP3. **Discussion:** We confirmed widespread distribution of AAV9-GFP after systemic injection at a gestational age, comparable to the second trimester in humans. Robust GFP expression in spinal cord and muscle suggest potential benefits for patients with SMA or muscular dystrophy. However, prenatal administration of a dose that is equivalent to weight-adjusted clinical dose of AAV9-SMN resulted

in toxicity. Detection of vector in female, but not male germ cells could be secondary to the timing of double-strand DNA breaks associated with meiosis in fetal oocyte development, which could facilitate vector transduction and, possibly, integration. Lack of anti-GFP antibodies is encouraging for conditions in which antibodies against transgene-encoded proteins can limit efficacy. These results support the use of the sheep model for prenatal gene therapy experiments, including testing different vector doses and other strategies to limit toxicity; however, they also underscore the need to prevent germline integration.

439 Characterization of the AAV ITR Host Protein Interactome

Tyler Brittain, Máté Borsos, Viviana Gradinaru
California Institute of Technology, Pasadena, CA

Recombinant Adeno-Associated Viruses (AAVs) are the leading choice for gene therapy delivery, with hundreds of clinical trials currently ongoing. However, hurdles remain before we can use this technology safely, with two main concerns being specificity and cellular toxicity. Cellular toxicity, mediated either by the immune response or by innate cellular defenses, is an ongoing struggle for the field. While these issues are complex, they stem partly from a common source: that the AAV interactome across different cell types is largely uncharacterized. In embryonic stem cells (ESCs) and neural progenitor cells (NPCs), AAV infection has been shown to activate DNA damage pathways, leading to apoptosis. Interestingly, in both cases, the induced apoptosis is dependent on the inverted terminal repeats (ITRs) of the transgene, which inspired efforts to engineer the ITR to prevent its interaction with host cellular factors. Here we set out to identify host factors that recognize the ITR, potentially enabling future engineering to prevent downstream cell signaling and improve transduction. We found that, when exposed to AAV, human NPCs have a distinct apoptotic phenotype while differentiated GABAergic neurons lose their apoptotic phenotype. To identify hNPC-unique ITR binders, we performed immunoprecipitation coupled with mass spectrometry (IP-MS) in lysates of hNPCs and hGABAergic neurons, stringently filtering the MS data to remove non-specific binding. We identified proteins involved in the DNA damage response and endosomal transport as well as components of the proteosome and spliceosome. Interestingly, many of these proteins were not selected in previous CRISPR screens for increased AAV transduction. By continuing to elucidate which host factors recognize the ITR and induce apoptosis in hNPCs, and extending our analysis to multiple cell types, we hope to establish the groundwork for an ITR interactome. This knowledge may facilitate the design of better transgenes to improve cell specificity, reduce cell toxicity, and make gene delivery safer and more efficient.

440 Generation of DNA Aptamers Against Pancreatic Surface Receptors Towards AAV Cell-Specific Targeting

Stephen L. Trisno, Francesco Puzzo, Mark A. Kay
Stanford University, Stanford, CA

Adeno-associated virus (AAV) is a small DNA virus that has been closely studied for its potential for human gene therapy. There are multiple serotypes of AAV and recombinant AAV that have differential transduction efficiency and specificity towards different tissues, yet no cell type-specific AAV vectors have been created to date. In order to understand and improve cell/tissue transduction efficiency and specificity, our lab has been investigating the use of unnatural amino acid substitutions in combination with click-chemistry to conjugate AAV capsids with DNA and RNA aptamers that recognize specific cell surface receptors. Here, we utilized a version of Cell-SELEX (Systematic Evolution of Ligands by Exponential enrichment) in an attempt to generate aptamers that bind cell surface receptors. Specifically, we selected receptors reported to be present on pancreatic endocrine (GLP1R) versus exocrine (SCTR) cells. These receptors were exogenously expressed in a cell line to generate positive (+receptor) versus negative (native cell line) selection targets for Cell-SELEX. A random single-stranded DNA library underwent 10 rounds of selection, and at the conclusion of every selection cycle, a fraction of the library was taken for NGS analysis. Our preliminary analysis revealed progressively diminishing library complexity from ~$2x10^7$ to ~$9x10^5$ unique sequences from the initial to the final selection cycle, respectively. Upon filtering out rarer species represented below a 10^{-4} frequency, 803 unique sequences remained. Of these 803 sequences, many were similarly enriched when comparing between one receptor's selection versus the other receptor's selection, which likely represent sequences with non-specific binding to the cell line. For the remaining highly enriched sequences, additional steps are required to identify which sequences are the most promising candidates. Future steps include characterizing the affinity and specificity of these enriched sequences to the surface receptors of interest, and eventually using the selected aptamers for conjugation with AAV.

441 Targeting AAV Vectors to the CNS via De Novo Engineered Capsid-Receptor Interactions

Qin Huang[1], Albert Chen[2], Ken Y. Chan[1], Hikari Sorensen[1], Andrew J. Barry[1], Bahar Azari[3], Thomas Beddow[1], Qingxia Zheng[1], Binhui Zhao[1], Isabelle G. Tobey[1], Fatma Elzahraa Eid[1], Alina Chan[1], Benjamin E. Deverman[1]
[1]Broad Institute of MIT and Harvard, Cambridge, MA,[2]Harvard University, Cambridge, MA,[3]Electrical & Computer Engineering Department, Northeastern University, Boston, MA

Viruses have evolved the ability to bind and enter cells through interactions with a wide variety of host cell macromolecules. We engineered peptide-modified adeno-associated virus (AAV) capsids that transduce the brain through the introduction of de novo interactions with two proteins expressed on the mouse blood-brain barrier (BBB), LY6A or LY6C1. The in vivo tropisms of these capsids are predictable as they are dependent on the cell- and strain-specific expression of their target protein. This approach generated hundreds of capsids with dramatically enhanced central nervous system (CNS) tropisms within a single round of screening in vitro and secondary validation in vivo thereby reducing the use of animals in comparison to conventional multi-round in vivo selections. The reproducible and quantitative data derived via this method enabled both saturation mutagenesis and machine learning-guided exploration of the capsid sequence space. Notably, during our validation process, we determined that nearly all published AAV capsids that were selected for their

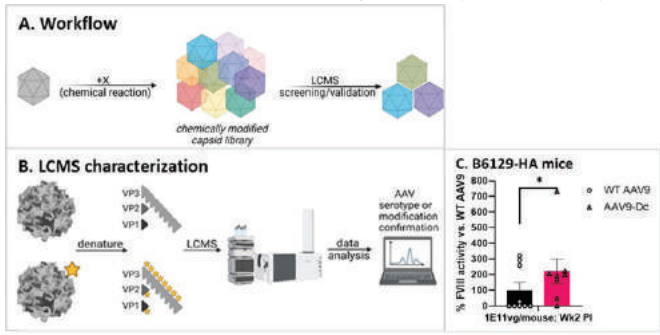
ability to cross the BBB in mice leverage either the LY6A or LY6C1 protein, which are not present in primates. This work demonstrates that AAV capsids can be directly targeted to specific proteins to generate potent gene delivery vectors with known mechanisms of action and predictable tropisms.

442 High Throughput LCMS Characterization to Promote Chemically Engineered AAV Capsids Development

Anh K. Lam, Kentaro Yamada, Junping Zhang, Dylan Frabutt, Patrick Mulcrone, Roland W. Herzog, Weidong Xiao

Indiana University School of Medicine, Indianapolis, IN

Adeno-associated virus (AAV) has emerged as a leading platform for gene therapy. With the skyrocketing rate of AAV research and the prevalence of many new engineered capsids being investigated in preclinical and clinical trials, capsid characterization plays a vital role in serotype confirmation and quality control. Further, peptide mapping the capsid proteins might inevitably be a future requirement by regulatory agencies since it is a critical step in good manufacturing practice (GMP) for biotherapeutic characterization. To overcome many challenges that traditional methods like SDS-PAGE and Western blots carry, liquid chromatography & mass spectrometry (LCMS) allows high resolution & sensitivity with great accuracy in characterizing the AAV capsid proteins. Our optimized LCMS method provides quick sample preparation, fast and high-throughput 4-min run, and high sensitivity, which allows for very efficient characterization of wild-type and engineered capsids. As a proof of concept, one top chemically engineered variant, AAV9-Dc carrying Factor-VIII, is shown to produce significantly higher gene expression in mice, compared to the unmodified AAV9 capsid. This study also reports the usage of LCMS/MS peptide mapping of AAV capsid proteins to determine the most accessible Lysine residues targeted by chemical modifications. Our protocols are anticipated to promote the development and discovery of novel AAV capsid variants with high accuracy and efficiency.



443 Strong Universal Micro-Promoters for Transgene Expression in Recombinant Adeno-Associated Viral Vectors

Sunghee Chai[1], Leslie Wakefield[2], Mason Norgard[3], Bin Li[1], David Enicks[1], Daniel L. Marks[3], Markus Grompe[1]

[1]Papé Family Pediatric Research Institute, Oregon Stem Cell Center, Oregon Health & Science University, Portland, OR,[2]Papé Family Pediatric Research Institute, Oregon Stem Cell Center, Oregon Health & Science University, Portland, OR,[3]Department of Pediatrics, Oregon Health & Science University, Portland, OR

Recombinant adeno-associated virus (rAAV) is a versatile and effective gene delivery tool for clinical gene therapy. However, the constrained packaging capacity of rAAV for cargo DNA up to 4.7 kb limits the diseases it can target. Here we report two unusually small promoters that enable the expression of larger cDNAs than standard promoters. These micro-promoters are only 84 bp (MP-84) and 135 bp (MP-135) in size but have strong activity in most cells and tissues. The sequence of the micro-promoters originates from the human insulin (MP-84) and glucagon promoter (MP-135). While the micro-promoters do not have an enhancer, AAV2 ITR is required for their promoter activity. We show here universal activity of MP-84 and MP-135 expressed from rAAVs in cultured cell lines, human pancreatic islets, and primary hepatocytes in culture, as well as in mouse brain and skeletal muscle *in vivo*. We further tested the capability of the micro-promoters to express DNA and RNA editing CRISPR-Cas systems in rAAV. The DNA editing rAAV expresses the spCas9 gene from MP-84 and the RNA editing rAAV the RfxCas13d gene from MP-135. These rAAVs also contain and package an expression unit for a guide RNA, since their final viral genome is smaller than 5 kb due to the small size of the micro-promoters. A proof-of-principle study targeting stably expressing EGFP showed efficient INDEL formations by the DNA editing rAAV. Hence, MP-84 and MP-135 will enable the therapeutic expression of genes and genetic engineering units that are currently too large for rAAV vectors.

444 Engineered Cardiac-Specific AAV Capsids from a Novel Next-Generation Platform (next-CAP) with Cross-Species Selection for Cardiac-Targeted Gene Therapy

Gregor Habeck[1], Joerg Schweiggert[1], Kristin Cimen[1], Xenia Kramp[1], Hugo A. Katus[1], Marc Lerchenmueller[1], Matthias Mietsch[2], Rabea Hinkel[2], Patrick Most[1], Martin Busch[1]

[1]AaviGen GmbH, Heidelberg, Germany,[2]Deutsches Primatenzentrum, Goettingen, Germany

Background: Heart failure (HF) remains a leading cause of death and morbidity worldwide given the shortage of curative cardiac and cardiopulmonary transplantation. With HF incidence on the rise globally, targeting the underlying genetic and molecular foundation of the various HF types by viral-based gene delivery bears the potential to transform future clinical care of a relevant health care segment. In this regard, adeno-associated viruses (AAV) with engineered tropism for the heart are viewed as a key factor to generate solutions for safe and efficient delivery of therapeutic gene replacement,

silencing or editing systems to the diseased heart with minimized off-target organ transduction after a simple systemic administration **Technology & Results:** Here, we report the development of next-generation cardiac-specific AAV capsids using our experimental-bioinformatic AAV capsid eingineering platform (next-CAP) allowing for the serial high-throughput tracking and capturing of individual capsids across various tissues in different mammalian species (mouse, farm pig, non-human primate). A highly diverse capsid library with more than 100 million variants was generated from eight natural human AAV isolates integrating DNA shuffling and peptide display approaches. The library underwent a two-step *in vivo* evolution within the three animal models where in a first round cardiac-enriched capsid sequences were amplified from heart tissues serving as template to generate the AAV library for the second in vivo screening. By implementing a unique molecular identifier strategy for each capsid variant, we combined long- and short-term sequencing to achieve a comprehensive biodistribution resolution of all variants of interest. This allowed to capture novel AAV capsid variants displaying highest enrichment in hearts over all other organs, including the liver. In addition, we were also able to identify dual-organ AAV capsids showing preferred enrichment in a skeletal muscle/heart or brain/heart combinations. Subgroups of top heart-AAV capsid portfolio displayed an overall sequence homology of up to 99.5% identity further highlighting the presence of novel conserved heart-homing motifs. As producibility was another inherent selection criteria of our competitive in vivo screen, our cardiac-specific AAV capsid portfolio further provides scalable manufacturing characteristics. **Conclusion:** Our proprietary portfolio of novel heart-specific AAV capsids now enables the systematic development of optimal therapeutic capsid-promoter-transgene ensembles for further dose-expression, -efficacy and -toxicity assessment to the meet demands of the various hereditary and acquired HF indications in suitable model systems. Moreover, syndromes with secondary heart involvement (e.g., muscular dystrophy or neurological diseases) are amenable to our dual-organ capsids. In summary, we developed an efficient and versatile platform for the generation of next-generation AAV capsids for heart-specific gene therapy of yet uncurable rare and common cardiac diseases.

445 High-Throughput Generation and Identification of Novel AAV Capsids with Enhanced Properties for Gene Transfer Applications in the Central Nervous System

Irvin T. Garza[1], Vijayashree Ramesh[1], Hye Ri Kang[1], Erik A. Lykken[1], Mehmet Takar[1], Widler Casy[1], Cynthia B. Trygg[2], Stephen E. Braun[2], Steven J. Gray[1]

[1]UT Southwestern Medical Center, Dallas, TX,[2]Tulane National Primate Research Center, Covington, LA

Adeno-associated viral (AAV) vectors are effective vehicles in the delivery of genetic payloads for research and the treatment of diseases. There have been hundreds of naturally derived AAV capsids from tissues of humans, non-human primates (NHPs), and several other animals. AAV9 has emerged as the dominant vector in the development and translation of treatments targeting the central nervous system (CNS), but it has significant limitations including skewed biodistribution toward peripheral organs and the liver (as opposed to the CNS), and sub saturating CNS biodistribution even at the highest feasible doses. While many clinical trials continue to show success utilizing naturally occurring AAV capsids, the therapeutic window continues to be quite narrow with the limited tissue tropism they potentiate. Recombinant AAVs are exhaustively expensive and difficult to manufacture, and thus the manufacturing costs associated with high-dose human trials is one of the main prohibitive factors to initiate those studies. Aside from limitations in manufacturability, high doses of viral particles or unfavorable biodistribution can result in liver and dorsal root ganglion toxicity. These issues can be addressed with more efficient and better targeted capsid technology, which we aimed to address by generating novel AAV libraries combined with directed evolution. We show that coupling of directed evolution and single-molecule real time (SMRT) sequencing within mice and NHP establishes a pipeline to generate and identify novel capsids with superior characteristics compared to WT AAV9. We conducted a parallel screen in mice and NHPs utilizing mixed libraries of shuffled whole capsid chimeric AAVs, and AAV9-based libraries generated from targeted mutagenesis. Of note, the libraries involved modifications across the length of the capsid rather than localized peptide insertions, which was enabled by SMRT sequencing to gather high-content sequence data of the libraries and selected capsids. We utilized wild-type C57BL6, cell-type specific reporter mice, and NHPs with either intravenous or intrathecal lumbar puncture injection. Sequences of thousands of novel variants were recovered from both species across several CNS regions, cell types, and peripheral tissues. Hits were selected in an unbiased manner and top choices assessed for features such a manufacturability, in vivo tropism, and in vivo gene transfer efficiency. Our analysis thus far suggests a degree of species specificity among certain AAV variants, an observation that has plagued the discovery and translation of new viral vectors. However, we've also identified a number of capsid variants that appear to be positively selected for across both mice and NHPs. Our results suggest that libraries generated through whole capsid modification, coupled to advancements in sequencing technologies, may facilitate the generation and identification of novel AAV vectors in a high-throughput manner.

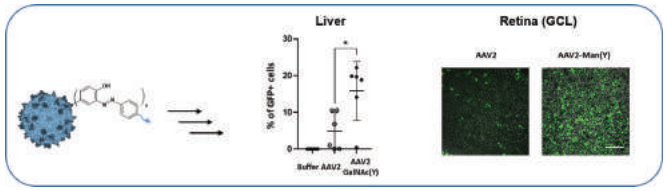
446 Novel Chemical Tyrosine Functionalization of Recombinant Adeno-Associated Viral Vectors to Improve Liver and Retina Gene Transfer Efficiency

Mathieu Mevel

Université de Nantes, Nantes, France

AAV gene therapy represents decades of biological and clinical research and still challenges need to be overcome to exploit all the potential of these vectors. Here, we focused on a chemical bioconjugation strategy to modify tyrosine (Y) residues on recombinant AAV capsids with carbohydrate ligands. The covalent coupling reaction was done by aromatic electrophilic substitution of the phenol of tyrosine residues with diazonium salt derivatives. *N*-acetylgalactosamine (GalNAc) sugar was used as an asialoglycoprotein receptor targeting unit for specific liver delivery, and the mannose sugar (Man) for targeting of specific retinal cells. After validation of the chemical coupling using a panel of analytical assays, we evaluated *in vivo*, in mice, the efficiency of rAAV2-GalNAc(Y) for liver and rAAV2-Man(Y) for retina in

comparison with rAAV2 (all vectors carrying an eGFP reporter gene expression cassette under the control of an ubiquitous promoter). In the liver, at one-month post intravenous injection, we observed significantly higher levels of GFP positive hepatocytes with a broader distribution with rAAV2-GalNAc(Y) than with rAAV2 (mean=16% and 5% of GFP positive cells, respectively). These data suggest a clear benefit of the tyrosine modified-rAAV2 capsid. In the retina, at one-month post subretinal-injection, the quantification of GFP fluorescence demonstrated a significantly higher number of fluorescent cells and overall density of the fluorescence after transduction with rAAV2-Man(Y) than with rAAV2. The ganglion cell layer (GCL) also showed increased fluorescence. This suggests either an improved uptake of the rAAV2-Man(Y) vector by ganglion cells, or a better diffusion of this vector through the tissue layers. Taken together, our findings reveal that the chemical remodeling of tyrosine on therapeutic vectors may become a valuable alternative to genetic engineering methods to improve organ tropism and protein expression in some specific cells. These results open up the use of the tyrosine modified vectors for gene therapy strategies targeting liver diseases, glaucoma and optic neuropathies.



447 Optimization of AAV-DARPin Fusions to Redirect Capsid Tropism

[1]REGENXBIO Inc., Rockville, MD,[2]Athebio AG, Schlieren, Switzerland,[3]Rutgers, The State University of New Jersey, Piscataway, NJ

Adeno-associated virus (AAV)-mediated gene therapy is a rapidly growing field with immense potential to deliver curative treatments to patients with unmet needs. For many indications, the utility of AAVs as delivery vectors is limited by their broad tissue tropism and lack of cell- and tissue-type specificity. This necessitates high doses to confer therapeutic benefit in the tissue of interest, thus increasing the risk of off-target effects and toxicity. In this study we developed chimeric AAV vectors that incorporate designed ankyrin repeat proteins (DARPins) engineered to target cell membrane receptors of interest. Athebody® DARPins are small "plug & play" binding proteins composed of ankyrin repeat units: an N- and C-terminal cap along with one to three internal repeats. Unlike full-length antibodies or antibody fragments, their small size (10-16 kDa), robust fold, high stability and lack of disulfide bonds make DARPins well-suited for incorporation into viral vector capsids. We optimized multiple parameters of the DARPin-AAV fusion construct and production including the VP insertion site, linker length, linker composition, VR mutations, and transfection conditions. DARPins of different repeat numbers, binding affinities, and receptor targets were also tested. We evaluated a set of receptors that can be harnessed to target the brain by ferrying molecules across the blood-brain barrier and other tissues. We chose one of these receptors as the target and selected high-affinity Athebody® DARPins by means of ribosome display, obtaining binders with a range of binding affinities down to picomolar affinity, and cross-reactivity with mouse, cynomolgus macaque, and human orthologs. Using our optimized AAV-DARPin construct, vector production titer and VP ratios could be maintained to near those of the unmodified vector. We found that DARPin insertions in VR-IV of VP1 could mediate >25-fold increased transduction of HEK293 cells over-expressing the target receptor compared to the unmodified vector. Insertions in VR-VIII of VP1 or at the N-terminus of VP2 increased transduction but to a lesser extent while the linker composition (glycine-serine linker vs proline-threonine linker) had minimal impact on transduction activity.

448 The Capsid Race: Multiplexed Analysis and Comparison of Rationally Engineered AAV CNS Capsids *In Vivo*

Elena Pimentel[1], Sebastian Kieper[2], Fiona Moreno[2], Tom van der Zon[1], Bas Bosma[1], Noun Bashir[1], Stijn Waaijer[1], Pedro Espinosa[1], Tycho Hoogland[1], Mercedes Valls[1], Milja Pesic[1], Angga Kusuma[3]

Developing novel adeno-associated virus (AAV) capsids that can transduce cells in the central nervous system (CNS) via systemic administration is one of the most intriguing challenges in the field of AAV-based gene therapy. The inefficiency of blood-brain barrier (BBB) crossing and high-level sequestration and transduction of peripheral organs limit the CNS application of first generation AAV-based vectors due to the narrow therapeutic window. Therefore, several next generation AAV capsids have been engineered in recent years resulting in CNS capsid variants with a different mode of action. In this study, 26 wild-type serotypes as well as rationally designed CNS capsids were compared in a parallel and multiplexed 'race' *in vivo* to determine which capsid would transduce the brain most efficiently when administered systemically. The capsids were individually produced with each having a barcoded reporter transgene, pooled, and the resulting cocktail was intravenously (IV) administered to 7-week-old C57BL6 and BALBc mice. Two weeks after injection, both brain (frontal, caudal, cerebellum) and liver, as peripheral organ representative, were sampled. The barcoded reporter transgene was amplified by PCR and the resulting amplicons analyzed by next-generation sequencing (NGS) to assess the level of enrichment of each CNS capsid in each tissue. In addition, single-cell RNAseq (10X Genomics) was performed to determine the cell tropism of each capsid in each respective tissue of the CNS. Six of the engineered CNS capsids showed significantly enhanced transgene expression compared to wild-type AAV9 in both mice strains. In particular, CapX-38, a modified AAV9 capsid, showed between ~218 and ~33-fold higher brain transduction, depending on the mouse strain and brain region. Intriguingly, CapX-25, containing an additional modification in the VR-IV loop, presented itself with up to ~46-fold higher brain transduction, while showing ~37-fold decreased transgene expression

in liver of both mice strains. Single-cell sequencing results confirmed that transgene expression was mainly neuron-specific for both CapX-38 and CapX-25, showing their potential use for CNS gene therapy via systemic delivery. Utilizing this multiplexed 'race' analytical strategy can quickly identify the most promising capsid candidates for certain applications. Finally, the results of this study also highlight the importance of VR-IV loop in AAV capsid engineering to harness new capsids with interesting phenotypic features.

449 Biodistributional Study of Novel AAV-F Capsid vs AAV9 after Neonatal Intravenous Delivery

Anna Keegan[1], Wing Sum Chu[1], Ellie Chilcott[1], Juan Diaz Antinao[1], Ng Joanne[1], Simon Waddington[2], Rajvinder Karda[2]

[1]Institute for Women's Health, University College London, London, United Kingdom,[2]University College London, London, United Kingdom

AAV9 gene therapy has shown great pre-clinical & clinical efficacy, including Zolgensma for Spinal Muscular Atrophy. The use of systemic delivery of AAV9 gene therapy for neurological disorders requires the use of high vector titres to achieve a therapeutic effect. However, this can lead to off-target effects. Thus, the use of a different AAV capsid may be necessary to reduce off-target toxicity and ensure therapeutic efficacy in the central nervous system (CNS) and other systemic organs, with lower AAV volumes and concentrations. A novel synthetic AAV capsid, AAV-F has previously reported extensive CNS targeting after a single intravenous delivery to adult mice than its titre-matched paternal AAV9 capsid. However, this has not been replicated in neonatal mice. Our study aimed to investigate AAV-F capsid (containing a CAG promoter driving green fluorescent protein reporter (GFP)) after a single intravenous delivery to new-born mice, to establish biodistribution of vector for severe early-onset neurological disorders. Wild-type C57BL/6J mice were injected intravenously via superficial temporal vein within the first 24 hours of life with titre-matched AAV-F and AAV9 (1e12 vector genomes per ml). 5-weeks post-injection, treated mice and untreated controls were sacrificed and tissue were collected. Transduction efficacy was assessed by performing immunofluorescence. Using automated image analysis, the percentage of GFP-positive neurons and astrocytes were quantified. Our results showed AAV-F had a significantly higher expression profile of neuronal and astrocytic targeting throughout the brain when compared to titre-matched AAV9. In addition, there was greater targeting of visceral organs with AAV-F in comparison to AAV9. Overall, we have shown AAV-F to have a greater transduction efficiency within the CNS and systemic organs. Therefore, identifying AAV-F as an ideal capsid to treat early onset severe neurological disorders.

450 Efficient Transduction in Kidney Tubules with Minimum Off-Target Effects by Renal Vein Injection of Select AAV Capsids

Taisuke Furusho, Kei Adachi, Mia Galbraith-Liss, Anusha Sairavi, Ranjan Das, Hiroyuki Nakai

Department of Molecular and Medical Genetics, Oregon Health & Science University School of Medicine, Portland, OR

The advent of the next-generation sequencing (NGS)-based clinical diagnostics revealed unexpectedly high prevalence of monogenic kidney diseases not only in pediatric but also adult chronic kidney disease (CKD) cases, which has made CKD an attractive target for AAV vector-mediated in vivo gene therapy. However, gene delivery to the kidney has been challenging due to its low efficiency and inability to effectively target clinically relevant cell types such as renal tubular epithelial cells. Although recent progress in capsid engineering has led to generation of numerous AAV capsids with novel phenotypes, they have not yet been characterized in depth in the context of renal gene transfer. Especially, route of administration (ROA)-dependent differences in renal transduction profiles among different AAV capsids have yet to be investigated. Here we present a comprehensive profile of renal transduction of multiple AAV capsids delivered by two different ROAs, that is, intravenous injection (IV) and renal vein injection with the local blockage of the arterial, venous and urinary flow (RV), and show that effective transduction of renal tubules with minimizing off-target effects, which has not been possible by IV, could be attained by a combination of select AAV capsids and RV. In the study, we produced a DNA/RNA-barcoded AAV library containing a total of 47 AAV capsids, injected C57BL/6J mice with the library via IV or RV, and harvested the kidneys 6 weeks post-injection for the AAV Barcode-Seq analysis. This analysis revealed that AAV9 most efficiently transduces the kidney by IV among the 47 AAV capsids but AAV9 is outperformed by five AAV capsids including AAV-KP1 when administered by RV. Subsequently, we produced AAV9 and AAV-KP1 vectors expressing tdTomato under the control of the CAG promoter and injected them into mice via IV or RV to validate the Barcode-Seq observations and further characterize these capsids in renal gene transfer. The result showed that, although the renal transduction efficiency and cell type tropism of AAV9 remain the same regardless of ROAs, showing mesangial cell and interstitial cell transduction, AAV-KP1 can significantly enhance renal transduction by RV, showing >30 times better transduction than AAV9 only when RV is used. AAV-KP1 efficiently transduced cortical renal tubule epithelial cells, mostly proximal tubules by RV, while only mesangial cells were transduced by IV, emphasizing the importance of the choice of ROA and AAV capsid for effective transduction in renal tubules. In addition, by quantifying AAV vector genomes in the kidney and blood in mice shortly after AAV RV injection, we found that more vector genomes remained within the AAV-KP1-injected kidney than the AAV9-injected kidney, and accordingly, blood vector concentrations of AAV-KP1 vector were two orders of magnitude lower than those of AAV9, leading to much less vector spillover to non-target organs including the liver by RV injection of AAV-KP1. On the other hand, off-target transduction of AAV9 was not different between IV and RV. These results demonstrate that effective renal tubular transduction, which was not possible before, has now become attainable by careful selection of AAV capsid and ROA.

451 Our Proprietary Manufacturing Process, mAAVRx, Enables Improved AAV Manufacturing in Different Suspension HEK293 Systems

Nannan Jia, June Deng, Shiliang Hu, Yinxing Chen, Noel Walsh, William Lee, Carmen Wu, Lauren Drouin, Nicholas DiGioia, Jing Liao, Matthias Hebben

Alexion, AstraZeneca Rare Disease, Lexington, MA

Transient transfection (TT) of suspension HEK293 is one of the most robust AAV manufacturing platforms in the genetic medicines field due to its proven scalability and applicability to different therapeutic genes. The combination of novel plasmid design with optimized production process (within TT system) can further reduce manufacturing cost, which is one of the major challenges in the genetic medicines field. Previously, we reported that our proprietary manufacturing process, mAAVRx, achieves increased product yield, increased quality and more potent AAV vectors in scalable suspension HEK293 cells. For further improvement, we compared our novel plasmids to conventional three-plasmid system in two production systems: a) Expi293F cell line + transfection reagent FectoVIR; b) AAV-Max system with its own cell line, culture media, transfection reagent, enhancer and lysis buffer. Using the conventional three-plasmid system, FectoVIR in Expi293F cells outperformed the AAV-Max system. In contrast, using our proprietary manufacturing process, mAAVRx, the AAV-Max kit generated higher titers than Expi293F+FectoVIR. This trend was consistent across a series of different AAV capsids. In addition to the improvement in yield, further analysis of the quality of the purified vectors was also performed and compared. Using AAV-Max, mAAVRx led to a significant reduction in packaged plasmid DNA compared to the traditional three-plasmid system. The potency of the vectors was also assessed. These results help to further understand the quality of the vectors produced using mAAVRx. In summary, our proprietary manufacturing process, mAAVRx can be successfully applied to different production systems. The increase of the vector titers and vector purity could reduce the cost of goods and improve product quality, respectively.

452 Identification of AAV Variants Enriched in Skeletal Muscle and Muscle Stem Cells via Peptide-Display Library Screening

Michael R. Emami[1], Courtney Young[2], Xinjun Zhang[1], Giorgia Del Vecchio[1], Cloelia Decioccio[1], Ana Orlowsky[3], April D. Pyle[1], Melissa J. Spencer[1]

[1]UCLA, Los Angeles, CA,[2]MyoGene Bio, San Diego, CA,[3]David Geffen School of Medicine, Los Angeles, CA

Duchenne muscular dystrophy (DMD) is a monogenic disease caused by out-of-frame mutations in the *DMD* gene, which results in lack of dystrophin production. We have previously demonstrated efficient systemic delivery of CRISPR/Cas9 using adeno associated virus serotype 9 (AAV9) to achieve gene correction and dystrophin restoration in muscle tissues. However, the natural myonuclear turnover of skeletal muscle (SkMu) and inability of AAV vectors to efficiently target muscle stem cells (MuSCs), reduces the number of CRISPR-corrected myonuclei and dystrophin expression over time. We hypothesize that a lifelong therapy will require genomic correction of both SkMu and MuSCs, particularly when targeting the DMD pediatric population. Here, we develop and screen an AAV peptide-display library by modifying AAV serotype 9, by integrating a unique heptameric peptide on the capsid surface that corresponds to the packaged vector genome, in order to select for novel AAV capsid variants with enhanced tropism to SkMu and MuSCs. After two consecutive rounds of selection *in vivo*, using the *mdx* mouse model of DMD, we identified 42 MuSC-enriched and 37 SkMu-enriched capsid candidates with high fold enrichment scores after the first and second steps in the screening process. The 42 MuSC-enriched capsid variants contain a heptameric peptide consensus sequence overrepresented by glycine amino acids while the 37 SkMu-enriched heptameric candidates are dominated by glycine and serine amino acids. In addition, we determined 8 of the 42 MuSC-enriched and 5 of the 37 SkMu-enriched capsid candidates contained low fold enrichment in off-target organs, such as the liver, which may suggest a capacity for liver de-targeting. Lastly, our analysis confirmed 9 shared capsid variants that are highly enriched in SkMu and MuSCs, which are being prioritized in ongoing validation studies to determine which AAV capsid variants have superior transduction efficiency to SkMu and MuSCs compared to the parental AAV9 as well as novel AAV variants, such as AAVMYO, recently identified to be SkMu-tropic. Identifying skeletal muscle and muscle stem cell-tropic AAVs offers the potential to provide a long-lasting supply of CRISPR-corrected muscle stem cells and a life-long sustainable therapy for DMD and other neuromuscular disorders.

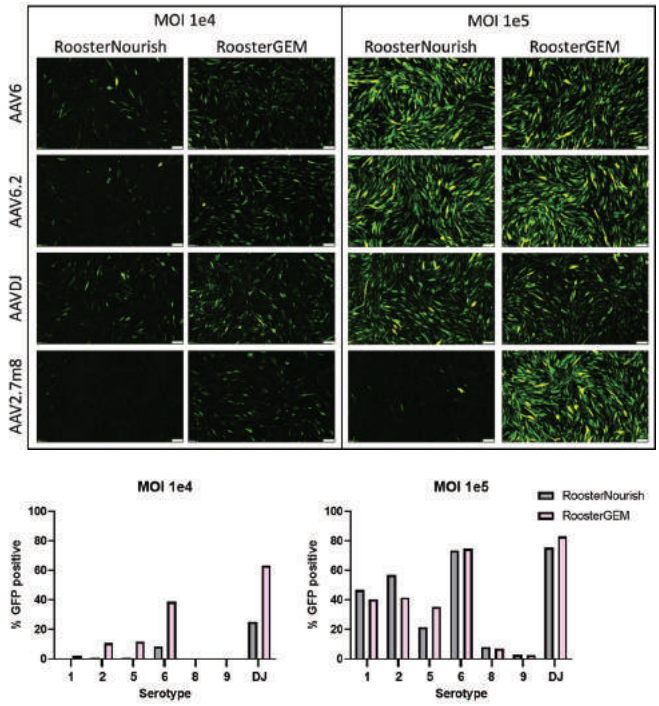
453 AAV Transduction of MSCs is Enhanced by Genetic Engineering Medium

Mary Doolin, Therese Willstaedt, Michael Boychyn, Jon Rowley

RoosterBio, Frederick, MD

Introduction Adeno-associated virus (AAV) is currently being used in clinical trials for a variety of indications due to its safety and efficacy. AAV gene transfer to Mesenchymal stromal Cells (MSCs) has been shown to enhance a wide range of MSC functions *in vivo*. For example, *in vivo* administration of AAV-modified MSCs has been shown to increase neuroprotective effects, promote bone regeneration, and decrease immune rejection. Despite the prevalence and promise of AAV, existing literature shows variability in AAV transduction efficiency and optimal serotype for MSCs. We have previously demonstrated that a genetic engineering medium increases the transduction/transfection efficiency of MSCs with lentivirus/mRNA. Our goal herein was to determine which AAV serotype(s) transduce(s) MSCs and to explore if a genetic engineering medium can enhance AAV transduction of MSCs. **Methods** Bone marrow-derived MSCs (BM-MSCs) were plated such that they were 80% confluent the following day. AAV from one of two vendors was diluted in RoosterNourish growth medium or RoosterGEM genetic engineering medium to the appropriate MOI, then added to cells. After an overnight incubation, medium was exchanged to fresh growth medium. Transduction efficiency was evaluated using widefield microscopy and flow cytometry. **Results & Discussion** In an initial screening, AAV serotypes 1, 2, 3, 4, 5, 6, 6.2, 7, 8, 9, rh10, DJ, DJ/8, PHP.eB, PHP.S, 2-retro, QuadYF, and 2.7m8 were evaluated at MOI 1e4 and 1e5. At MOI 1e4, AAV6, AAV6.2, and AAVDJ were observed to transduce MSCs in growth medium, but genetic

engineering medium enhanced transduction efficiency (Figure 1). Additionally, genetic engineering medium enabled the transduction of serotype AAV2.7m8. At MOI 1e5, AAV6, AAV6.2, AAVDJ, AAVPHP.S, and AAVquadYF were observed to transduce MSCs in growth medium and genetic engineering medium (Figure 1). genetic engineering medium also enabled the transduction of MSCs with serotypes AAV2, AAV3, and AAV2.7m8. We then transduced MSCs using AAV sourced from a different vendor to ensure consistency between AAV preparations. In this case, AAV serotypes 1, 2, 5, 6, 8, 9, and DJ were evaluated at MOI 1e4 and 1e5. At the lower MOI of 1e4, AAV2, AAV5, AAV6 and AAVDJ transduction were enhanced by genetic engineering medium, compared to growth medium (Figure 2). At the higher MOI of 1e5, all serotypes transduced MSCs with roughly the same efficiency in genetic engineering medium as in growth medium. AAV8 and AAV9 only sparsely transduced MSCs. In summary, AAV6 and AAVDJ are the optimal serotypes for the BM-MSCs herein. Additionally, genetic engineering medium enhances AAV transduction at low MOIs, but does not provide added benefit once the MOI reaches a certain high level. Future work aims to transduce MSCs with a functional gene to modulate MSC phenotype.



454 Development of Genome-Modified Generation Z (GenZ) Single-Stranded AAV Vectors with Improved Transgene Expression in Human Cells *In Vitro* and in Mouse Liver *In Vivo*

Keyun Qing[1], Jakob Shoti[1], Aneesha Nath[2], Geoffrey D. Keeler[3], Arun Srivastava[2]

[1]University of Florida, Gainesville, FL,[2]University of Florida College of Medicine, Gainesville, FL,[3]University of Florida, Gainesvile, FL

The wild-type (WT) AAV contains a single-stranded DNA genome, and expresses its genes poorly, because there is no host cell RNA polymerase that can transcribe a single-stranded DNA. Similarly, transgene expression from recombinant ssAAV vectors is also largely sub-optimal since the viral second-strand DNA synthesis is strongly inhibited by phosphorylated forms cell host chaperone protein, FKBP52, binding to the D-sequence at the 3'-end (*Proc. Natl. Acad. Sci., USA*, 94: 10879-10884, 1997). It has not been possible to delete the D-sequence at the 3'-ITR as it serves as the "packaging signal" for the AAV genome (*J. Virol.*, 70: 1668-1677, 1996). Previously, we also reported that the distal 10-nucleotides (nts) in the D-sequence are dispensable (*J. Virol.*, 71: 3077-3082, 1997). In the current studies, we generated an N10-sequence library in which the proximal 10-nts in the D-sequence were replaced with random 10-nts to test the hypothesis that one or more of these N10-sequences will not only allow successful packaging of the AAV genome, but also evade FKBP52-mediated inhibition of the viral second-strand DNA synthesis, thereby allowing robust transgene expression from ssAAV vectors. One such sequence, 5'-ATGTGCTTGA-3', was identified that allowed successful rescue, replication, and packaging of the AAV genome. This sequence was inserted in a recombinant AAV2 genome replacing the proximal 10-nts in D-sequence at both ITRs flanking an expression cassette containing a firefly luciferase-enhanced yellow fluorescent protein (FLuc-EYFP) under the control of the chicken β-actin (CBA) promoter, designated as generation Z ("GenZ") ssAAV vector. Transduction efficiencies of wild-type (WT) and GenZ ssAAV2-CBAp-FLuc-EYFP vectors were evaluated in human HeLa cells *in vitro*, the results of which are shown in **Figure 1A**. The extent of the transgene expression from the GenZ AAVrh74 vectors was ~20-fold higher than that from the WT AAVrh74 vectors. Transduction efficiencies of WT and GenZ ssAAV2-CBAp-FLuc-EYFP vectors were also evaluated in C57BL6/J mice following intravenous delivery *in vivo*. As can be seen in **Figure 1B**, the GenZ ssAAVrh74 vectors averaged ~5-fold increase in transgene expression in the liver, compared with that from the WT ssAAVrh74 vectors. The observed increase in transgene expression was not as pronounced *in vivo* since AAVrh74 vectors are closely related to AAV8, and ssAAV8 vectors transduce mouse liver very efficiently. Taken together, these studies document that (i) A GenZ ssAAV DNA genome has been created that overcomes the problem of viral second-strand DNA synthesis; and (ii) The GenZ ssAAV vectors behave more like scAAV vectors, but without the size-limitation. The GenZ ssAAV DNA genome can be packaged into any AAV serotype capsid vector; and packaging of the GenZ ssAAV DNA genomes in capsid-modified NextGen AAV serotype vectors should further enhance the performance of Opt^{Z} vectors, the availability of which has significant implications for their potential use in achieving high-efficiency transgene expression of larger genes.

This research was supported, in part, by a sponsored research grant from Sarepta Therapeutics, and from the Kitzman Foundation.

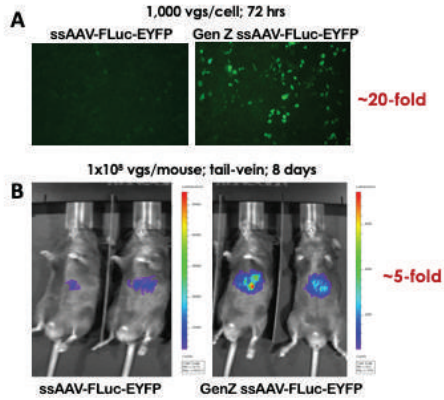


Figure 1: Transduction efficiency of WT and GenZ ssAAVrh74 vectors in human HeLa cells *in vitro* **(A)**, and in C57BL/6 mice *in vivo* **(B)**. HeLa Cells were transduced with each vector at 1,000 vgs/cell and transgene expression was visualized under a fluorescence microscope 72 hrs post-transduction. Approximately $1x10^8$ vgs of each vector were injected via the tail vein and whole-body bioluminescence images were obtained 8-days post-vector administration.

455 *In Vivo* Selection in Non-Human Primates Identifies AAV Capsids Having Enhanced Transgene Expression and Biodistribution in Spinal Cord after Intrathecal Administration

Casey A. Maguire[1], Killian S. Hanlon[1], Karen Kozarsky[2], Sean Clark[3], Yi Gong[4], Ming Cheng[5], Demitri de la Cruz[6], Nikita Patel[1], Miguel Santoscoy[5], Diane M. Nguyen[1], Josette Nammour[1]

[1]The Massachusetts General Hospital, Charlestown, MA,[2]SwanBio Therapeutics Ltd., Bala Cynwyd, PA,[3]SwanBio Therapeutics Ltd., Princeton, NJ,[4]Massachusetts General Hospital, Boston, MA,[5]Massachusetts General Hospital, Charlestown, MA,[6]Neurology, The Massachusetts General Hospital, Charlestown, MA

Systemic administration of adeno-associated virus (AAV) vectors for spinal cord gene therapy has challenges including toxicity at high doses and pre-existing immunity that reduces efficacy. Intrathecal delivery of AAV vectors into the spinal cord can avoid many of the issues of systemic delivery, although achieving broad distribution of the vector and transgene expression throughout the spinal cord is challenging and leakage to the periphery may occur. Here we performed two rounds of *in vivo* biopanning in non-human primates with an AAV9 peptide display library injected intrathecally and performed insert sequencing on DNA isolated from either whole tissue (conventional selection), isolated nuclei, or nuclei from transgene-expressing cells. A subsequent barcoded pool of 13 candidates and AAV9 was compared at the DNA (biodistribution) and RNA (expression) level in spinal cord and liver. Most of the candidates displayed enhanced biodistribution compared to AAV9 at all levels of spinal cord ranging from 2 to 265-fold. Nuclear isolation or expression-based selection yielded 4 of 7 candidate capsids with enhanced transgene expression in spinal cord (up to 2.4-fold), while no capsid obtained by conventional selection achieved that level (0 out of 6). Furthermore, several capsids displayed lower leakage to the liver of up to 1,250-fold, compared to AAV9, providing a remarkable on target/off target biodistribution ratio. Currently, we are evaluating these capsids' transduction performance (transduction efficiency, cellular tropism) after intrathecal injection in mice. The selection method described here should be useful in clinically relevant large animal models.

456 Successful Production of Monoclonal Antibodies Against Fully Assembled AAV Anc80 Capsid by a Simple DNA Vaccination Method

Mia Galbraith-Liss, Helen Rappe Baggett, Kei Adachi, Hiroyuki Nakai

Department of Molecular and Medical Genetics, Oregon Health & Science University School of Medicine, Portland, OR

With the advent of technologies that can effectively create genetically engineered AAV capsids with novel biological phenotypes, the repertoire of novel AAV capsids has significantly expanded. Monoclonal antibodies (mAbs) against these novel AAV capsids would provide useful reagents to study them; however, conventional methods for the production of mouse mAbs are often expensive and complex. Accordingly, the resource of mAbs for newly emerged genetically engineered capsids still remains very limited. Here, we report a novel, simple and inexpensive method for effectively producing mouse mAbs against fully assembled AAV capsids by intravenous injection of plasmid DNA into mice and demonstrate proof of concept of the method by successfully generating anti-AAV Anc80 mouse mAbs that react specifically with fully assembled AAV Anc80 capsid, which do not currently exist. In this method, DNA vaccination is accomplished by producing fully assembled AAV capsids in hepatocytes in mouse liver by hydrodynamically delivering the following two plasmid DNAs via the tail vein: one expressing AAV VP3 protein and the other expressing AAP under the control of the CMV promoter. In the study, to immunize mice with AAVAnc80 viral capsids, 10 eight-week-old BALB/c female mice were injected with 50 microgram each of pCMV-AAVAnc80VP3 and pCMV-AAP2 plasmids in 100 mL/kg saline via the tail vein using a hydrodynamic injection technique at days 0, 14, 21, 28, and 35. At the 3-week time point, serum samples were collected and anti-AAVAnc80 antibody titers were assessed by an AAVAnc80 capsid antibody ELISA and an HEK293-based neutralizing antibody (NAb) assay using an AAVAnc80-CMV-luc vector. The result demonstrated that the animals developed antibodies against AAVAnc80 capsids and all of them showed neutralizing activities. At the 6-week time point, 2 mice that showed high titers of NAbs against AAVAnc80 were selected for the generation of monoclonal antibody-producing hybridoma cell lines. The spleens were harvested from these two mice and splenocytes were then isolated and fused with a mouse myeloma cell line. By screening approximately 700 hybridoma clones by ELISA, we obtained a total of 20 candidate clones producing mAbs. Among them, 9 mAbs were fully characterized for their ability to bind fully assembled capsid (f+ or f-), their ability to bind monomer (m+/m-), their ability to neutralize (n+/n-), cross-reactivity against AAV2, 5 and 9 (c+/c-) and isotypes. Please note that f+ and f- indicate the presence and absence of the ability to bind fully assembled capsid, respectively, and the other designations (m, n and c) follow the same. As a result, we could obtain mAbs that can be categorized into the following four distinct groups: (1) f+m-n+c-, (2) f+m-n+c+, (3) f+m+n-c-, and (4) f+m+n-c+. Using the 1B11 and 2A7 mAbs (Category 1 mAbs) that

can specifically recognize fully assembled AAVAnc80 capsids and do not cross-react with other AAV serotypes, we have successfully established fully assembled capsid-specific AAV Anc80 ELISA that does not cross-react with other serotypes. This method can be readily applicable to production of mAbs against any AAV serotypes and emerging genetically engineered AAV capsids for which mAb reagents are not currently available.

457 Protein Expression/Secretion Boost by a Novel Unique 21-mer c*is*-Regulatory Motif (Exin21) via mRNA Stabilization

Wenhui Hu, Yuanjun Zhu, Sami Saribas, Brittany Bodnar, Ruotong Zhao

CMDR, Temple University Lewis Katz School of Medicine, Philadelphia, PA

Boosting protein production is invaluable in both industrial and academic applications. We discovered a novel expression-increasing 21-mer *cis*-regulatory motif (Exin21) that inserts between SARS-CoV-2 envelope (E) protein-encoding sequence and luciferase reporter gene. This unique Exin21 (CAACCGCGGTTCGCGGCCGCT), encoding a heptapeptide (QPRFAAA, designated as Qα), significantly (34-fold on average) boosted E production. Both synonymous and nonsynonymous mutations within Exin21 diminished its boosting capability, indicating the exclusive composition and order of 21 nucleotides. Further investigations demonstrated that Exin21/Qα addition could boost the production of multiple SARS-CoV-2 structural proteins (S, M, and N) and accessory proteins (NSP2, NSP16, and ORF3), and host cellular gene products such as IL-2, IFNγ, ACE2, and NIBP. Exin21/Qα enhanced the packaging yield of S-containing pseudoviruses and standard lentivirus. Exin21/Qα addition on the heavy and light chains of human anti-SARS-CoV monoclonal antibody robustly increased antibody production. The extent of such boosting varied with protein types, cellular density/function, transfection efficiency, reporter dosage, secretion signaling and 2A-mediated auto-cleaving efficiency. Mechanistically, Exin21/Qα increased mRNA synthesis/stability, and facilitated protein expression and secretion. These findings indicate that Exin21/Qα has the potential to be used as a universal booster for protein production, which is of importance for biomedicine research and development of bioproducts, drugs and vaccines.

458 Characterization of Adeno-Associated Virus Composed of N-terminal Clipped VP3

Takayuki Onishi[1], Michika Nonaka[1], Kentaro Ishii[1], Takahiro Maruno[1], Mitsuko Fukuhara[1], Tetsuo Torisu[1], Maeda Masaharu[2], Noriko Yamano-Adachi[1], Takeshi Omasa[1], Susumu Uchiyama[1]

[1]Department of Biotechnology, Graduate School of Engineering, Osaka University, Suita, Japan,[2]Osaka Consolidated Laboratory, Manufacturing Technology Association of Biologics, Suita, Japan

rAAV capsid is composed of three viral proteins (VPs): VP1, VP2, and VP3. The VP composition of rAAV capsid is estimated to be a molar ratio of 1:1:10. To ensure the safety and efficacy of rAAV drugs for human gene therapy, the stoichiometry of VPs of rAAV vector should be carefully monitored and controlled. Recently, highly sensitive analytical techniques have identified that Clipped VP3, which is 8 amino acid residues shorter than VP3, is present in low amounts in addition to the conventional VPs in many serotypes. Clipped VP3 is suggested to be generated by leaky scanning, in which the ribosome misses the VP3 start codon, however the effect of Clipped VP3 generation on the VP assembly remains unclear.In this study, we investigated the strategy to promote, or suppress Clipped VP3 generation in rAAV vector. Characterization of the AAV variants was performed, including stoichiometry of VPs were determined by capillary gel electrophoresis (CGE), amino acid analysis of VPs was measured by LC-MS, transduction efficacy assay using HelaRC32 and HEK293 cells.

459 An Integrated Adeno-Associated Vector Development Platform for Inner Ear Disorders

Charlene Vaux, Rafik Boudra, Sandra Pierredon, Guillaume Olivier, Christophe Tran Van Ba, Lise Barrot, Rambeau Pierre, Julie Duron Dos Reis, Anais Riviere, Pauline Liaudet, Audrey Broussy, Anne-Gabrielle Harrus, Selma Dadak, Arnaud Giese, Patrice Vidal, Laurent Desire

Sensorion, Montpellier, France

Background: The inner ear is a diverse mosaic of highly specialized cells including sensory hair cells, supporting cells and spiral ganglion neurons, all of which play an important role in the process of hearing. More than half of the congenital non-syndromic deafness cases have a genetic cause that affect specific cell populations in the cochlea. Gene therapy is a promising avenue for those patients, but requires precise spatiotemporal transgene expression. AAV-based gene transfer shows great potential for the treatment of hearing loss, as they provide stable gene expression over long period of time in post-mitotic cells and are relatively safe to use. Furthermore, AAV cell-specific tropism and transgene expression patterns can be fine-tuned through AAV capsid engineering and the addition of regulatory sequences in the expression cassette. Development of new AAV gene therapy programs for hearing loss is dependent on the efficient screening of new capsids and vectors of interest targeting specific cell populations within the cochlea, and on the subsequent production of the candidates to be evaluated. **Method:** We developed an in-house research grade AAV production and capsid purification protocol in small scale cultures, eliminating the need for specialized equipment such as bioreactors and ultracentrifuge, and greatly speeding up productions while cutting down on costs. This protocol yields high viral titers comparable with commercial AAV productions (range: 5E+12 to 5E+13 VG/mL, depending on the AAV serotype), show very minimal endotoxin contamination, high AAV purity, and is therefore compatible with *in vivo* use. We observed high transduction efficiency and low toxicity *in vitro* on HEK293T cells and ex vivo on murine organ of Corti explants. Injections of these AAV in the inner ear through the round window membrane of p15 mice is well tolerated and leads to widespread transduction of multiple cell types within the organ of Corti, stria vascularis and the vestibule. As expected, the transduction profile is dependent on the AAV serotype. In order to expand our molecular toolbox to precisely target cells of interest in the cochlea, we generated a library of new synthetic capsids through domain shuffling and used those vectors to encapsulate an eGFP expression cassette under the control of a cytomegalovirus (CMV) ubiquitous promoter to track cell transduction. Using our integrated AAV screening platform, we are

able to rapidly produce the new AAV "in house", inject them in the cochlea of p15 mice and assess the transduction profile 2 weeks later. Promising AAV candidate showing transduction of cell types of interest are further modified to improve specificity. Tropism and transduction efficacy studies are completed by local tolerability studies, audiometry (including auditory brainstem responses (ABRs), distortion product otoacoustic emissions (DPOAEs) recordings). Behavioral startle response tes[LD1] ts are also performed to ensure that sound signal integration is not disrupted by the surgery and/or the viruses. **Conclusion:** In summary, we have developed an integrated AAV discovery platform that allow us to design new AAV vectors tailored for addressing a variety of inner ear pathologies and to test for their specificity and efficacy *in vivo*

460 Diversity Analyses in AAV Libraries Containing Peptide Insertion Using Short- and Long-Read Next-Generation Sequencing Approaches

Marco Zahn[1,2], Sinclair Cooper[3], Ross M. Fraser[3], Thekla Bung[1,2], Carlos Martin de Hijas[1,2], R. Jude Samulski[1,4], Sherif Gabriel[1], Kathleen Boerner[1,2]

[1]R&D, Asklepios BioPharmaceutical, Inc. (AskBio), Research Triangle Park, NC,[2]AskBio GmbH, Heidelberg, Germany,[3]R&D, Asklepios BioPharmaceutical, Inc. (AskBio), Edinburgh, United Kingdom,[4]UNC Gene Therapy Vector Core, University of North Carolina at Chapel Hill, Chapel Hill, NC

Specificity and efficiency are key factors in the design of viral vectors in gene therapy. In the field of adeno-associated viruses (AAV) vectors, several approaches have been investigated to create variants that target different tissues with high specificity and efficiency. Insertion of peptide ligands into variable regions (VR) of the AAV capsid, enabled vector de-targeting from off-target tissues as well as improvement of on-target cell transduction. Early development of these modified vectors includes the initial design and production of an AAV library containing up to millions of variants with differently recombined peptide insertions in the VRs. Quality control is essential to confirm the intended diversity of the library and to also rule out any biases for certain variants before going to in-vivo experiments. Here we investigate a short-read (Illumina) and a long-read (Oxford Nanopore) 2nd and 3rd generation sequencing approach for diversity estimation. We used our previously designed plasmid library containing 6000 different peptides inserted in both VR-IV and VR-VIII leading to a theoretical diversity of 3.6E+07 variants. We generated amplicons covering both peptide insertions from both the plasmid and AAV libraries. After library preparation, both Illumina and Nanopore sequencing will be performed, followed by subsequent bioinformatic analysis. Here, the generated reads of both approaches will be aligned to the reference containing all possible variant sequences. This approach allows us to estimate the diversity of the library in both the plasmid and the virus configuration. Potential biases towards over-representation of single variants will be detected before application to in-vivo experiments. The same approaches will be performed after injection of an AAV library into animals to monitor the specificity of the variants by analyzing different tissue samples. In summary, we show a comparison of short- and long-read NGS approaches to estimate AAV library diversity and an approach for tracking potential biases of peptide insertion variants that may lead to improved specificity and efficiency of AAV vectors.

461 *In Vivo* Gene Delivery Using Exosomes Engineered to Contain AAV Improves Transduction Efficiency and Resists Neutralizing Antibodies

Russell McConnell, Sevda Lule, Tong Zi, Su Chul Jang, Aaron Noyes, Sriram Sathy

Codiak BioSciences, Cambridge, MA

Background: Adeno-associated virus (AAV) is a commonly used gene therapy vector due to its excellent safety profile, stability, and duration of transgene expression. One major limitation of current AAV vectors are neutralizing antibodies (nAb), which are present in many potential patients (preventing treatment) and develop in patients following an initial dose (preventing re-administration). Packaging within exosomes (exoAAV) is a potential strategy to protect AAV from antibody-mediated neutralization, allowing efficient transduction even in the presence of high nAb titers. We have developed a method for engineering exosomes to package AAV (engEx-AAV), resulting in a potent vector that resists antibody-mediated neutralization and shows strong transduction capacity when administered in vivo. **Methods:** A camelid nanobody (VHH) phage display library was constructed from PBMCs isolated from an alpaca immunized with AAV9. The library was panned for pH-sensitive binders and twelve sequences were identified. VHH sequences were produced as recombinant proteins and confirmed to bind AAV9 using an ELISA assay. Stable cell lines were generated expressing a VHH sequence fused to an EV-localizing peptide derived from BASP1. Cells were transiently transfected with plasmids for AAV production and cultured for three days before engEx-AAV purification by differential and density gradient ultracentrifugation. AAV loading into exosomes was evaluated by qPCR, Western Blot, and ELISA. In vitro transduction assays were performed using HeLa cells to assess transgene expression. To determine the relative activity of different preparations in vivo, AAV9 or engEx-AAV9 were administered intravitreally into the eyes of rodents and transgene expression assessed using immunohistochemistry. **Results:** Exosomes purified from cells stably expressing BASP1-VHH fusions demonstrated roughly equivalent protein levels of all VHH constructs, as assessed by Western blot. However, despite containing similar levels of VHH protein, considerable differences were observed in the amount of AAV present in purified exosomes, ranging from equivalent to un-engineered exoAAV up to ~100-fold higher, as assessed by qPCR. Western blot analysis showed that the level of AAV capsid protein correlates with the amount of AAV transgene DNA across samples. In vitro transduction assays showed variable responses, with many of the VHH sequences failing to efficiently transduce cells while others exhibited robust transgene expression at levels significantly above that observed with either AAV or non-engineered exoAAV. Upon Intravitreal administration, engEx-AAV demonstrated improved transduction across all layers of the retina compared to dose-matched AAV. **Conclusions:** Engineering exosomes to carry an AAV-binding ligand can dramatically increase the amount of loaded AAV. We identified three VHH sequences that were able to load AAV into exosomes and allow efficient transduction of recipient cells. Our results

show that production of functional, nAb-resistant exoAAV can be greatly increased by optimized engineered exosomes. In vivo studies demonstrated improved and uniform transduction across all layers in the retina when AAV was packaged inside exosomes.

462 Application of Cas-9 Guided Adapter Ligation (nCATS) and Long Read Sequencing to Assess Quality of Gene Therapy Products

Dustin Hittel[1], Leo Dimnik[1], Aneal Khan[2]

[1]Discovery DNA, Calgary, AB, Canada,[2]Discovery DNA and M.A.G.I.C. Clinic Ltd, Calgary, AB, Canada

Gene therapy products use polynucleotide constructs, containing the transgene, which is packaged into a protein-based nanoparticle to deliver the transgene to cells. Polynucleotide transgenes used for gene therapy can be constructed using flanked inverted terminal repeats (ITRs) around the transgene of interest. The ITRs help form concatamers that can persist as episomes in transduced cells. A gene therapy product; however, may contain undesirable constructs that have fragmentation, changes in cassette orientation, damaged or truncated elements, translocations or other abnormalities. These changes may result from the transfection process or the actual transgene construct. These impurities may render the transgene ineffective, contribute to genotoxicity, the need for higher doses and production of larger production quantities because the effective dose with an intact transgene is reduced. We found polynucleotide transgenes containing ITRs can provide regions of duplexed DNA which can serve as adapters. We then applied targeted Cas-9 guided ligation adapters (nCATS) from which we performed long read Nanopore sequencing. Using a model 4.8 kilobase (kb) AAV vector, we identified batches were the actual polynucleotide constructs varied in size from less than 500 bases up to 4.42 kb. We quantified the number of fragments along this distribution to show how much of the intended transgene is actually in the product. Our method simultaneously assessed single nucleotide variants (SNVs), structural variants and CpG methylation in a single reaction using only 3 ug or less of genomic DNA. Sequencing results showed orientation of the transgene elements, nucleotide and structural variants to show what the actual product contains. We feel this method can be used to assess the purity, provide quality assurance and quality control for gene therapy agents used in human gene therapy trials and quality control between different batches and transgene experiments.

463 Engineering Novel AAV Capsids for Cardiac Gene Delivery

Ze Cheng, Emilee Easter, Charles Feathers, Jackson Leong, Beatriz Lim, Samantha Jones, Joe Woods, Alekhya Parvathaneni, Christopher A. Reid, Emily R. Nettesheim, Karl Doerner, JianMin Lin, Frank Jing, Whittemore Tingley, Timothy Hoey, Kathryn N. Ivey, Laura M. Lombardi

Tenaya Therapeutics, South San Francisco, CA

Gene therapy is an emerging treatment option for both acquired and inherited cardiac disorders. While certain known adeno-associated virus (AAV) serotypes can achieve moderate transduction of the heart, the requirement of high doses and the substantial viral load to the liver or off-target cell types raise the critical need for novel AAV capsids with improved properties. We have established in-house AAV capsid engineering capabilities and successfully screened more than 30 diverse, proprietary AAV libraries representing more than one billion unique capsids in multiple *in vitro*, *in vivo*, and *in silico* models to discover novel AAV capsids that can target the different cardiac cell types through different routes of administration. Targeting cardiomyocytes following systemic delivery is critical to enable gene therapy treatments for many cardiac conditions and AAV9 is currently the workhorse capsid for this type of gene therapy. To identify novel capsids that outperform AAV9, we performed two rounds of directed evolution studies in NHPs with AAV libraries built on multiple parental capsids focusing on selecting novel capsids that efficiently transduce the heart while being de-targeted from the liver. We further compared 102 candidates using pooled, RNA/DNA-barcode-based methodology in NHPs, mice, pigs, and human induced pluripotent stem cell-derived cardiomyocytes (hiPSC-CMs) and identified multiple novel AAV capsids with superior properties including improved heart-to-liver ratio, improved cardiomyocyte transduction, and consistency between different species. Finally, we scaled up the production of our top novel capsid candidates with a clinically relevant manufacturing platform and validated their improved heart-to-liver tropism in NHPs at a clinically relevant dose. Together, these novel AAV capsids may enable more efficacious and safer next generation gene therapies for cardiac disorders.

464 Stepwise Evolution of the AAV5-Derived Capsid VCAP-100 Identifies Novel Variants with Improved CNS Transduction and Liver Detargeting Following Systemic Injection

Damien Maura, Jennifer C. Yu, Matthew Child, Roop Kaur, Zachary Thorpe, Xiaoqin Ren, Netsanet Gebremedhin, Jiangyu Li, Jiachen Liu, Timothy Fiore, Dillon Kavanagh, Alexander Kubiak, Kyle Grant, Ambreen Sayed-Zahid, Tyler Moyer, Kristin P. Graham, Alexander Kutchin, Johnny Yao, Todd A. Carter, Mathieu E. Nonnenmacher

Voyager Therapeutics, Cambridge, MA

Adeno-Associated Virus (AAV)-gene therapy shows great promise to treat a wide array of human genetic diseases. However, current therapies are limited by target tissue transduction and liver-associated toxicity, especially when administered systemically. Recent efforts aiming at engineered AAV capsids for improved transduction of the central nervous system (CNS) have been largely focused on AAV9, partly because of the propensity of this serotype to cross the blood-brain barrier more easily than other AAVs. Alternative AAV serotypes, however, could offer unique features in terms of tropism, tissue specificity, manufacturability or immunogenicity. We focused our engineering efforts on AAV5, a highly divergent AAV serotype with a low prevalence of preexisting neutralizing antibodies in the general population. We previously reported the discovery of VCAP-100, an AAV5 derived capsid with improved CNS transduction from the intravenous (IV) route in both non-human primate (NHP) & rodent species. In this study, we aimed at 1) further improving VCAP-100's CNS transduction, and 2) reducing liver transduction to improve AAV safety profile. Leveraging our proprietary RNA-driven TRACER

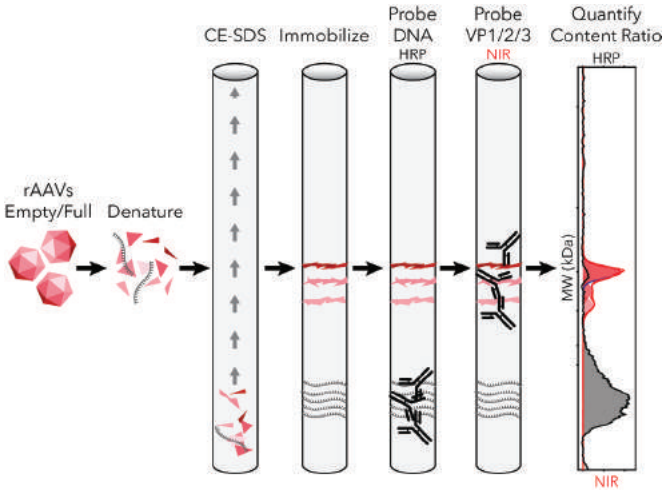
evolution platform, we further evolved various surface regions of VCAP-100 and AAV5 capsids that may play a role in brain and liver tropism. To increase the probability of maintaining the cross-species tropism properties of VCAP-100, biopanning was performed in parallel in NHPs and rodents. We identified several families of capsids based on sequence homology, improved brain tropism, and liver detargeting. In our pooled capsid library assays, one particular family of VCAP-100 derivatives displayed up to 300-fold liver detargeting and 6-fold improved brain transduction in NHP over the parental sequence. Another family of AAV5 derivatives included variants with up to 1700-fold improved brain transduction in NHP and 45-fold in rodent over the AAV5 serotype. These novel capsids will be further validated individually to determine cellular tropism. Interestingly, most variants only exhibited a limited number of amino acid substitutions, supporting the idea that significant tropism improvement can be achieved with minor changes in capsid surface residues. Overall, this study identified new VCAP-100 liver detargeted variants and CNS tropic AAV5 derivatives that further validate our proprietary TRACER platform, and could display an improved safety profile.

465 Rapid Quantification of Capsid Content of Adeno-Associated Viruses (AAVs) by Capillary Electrophoresis-Based Western Analysis

Francisco Ramirez, Rachel Talis, Jiaqi Wu, Charles Haitjema, Chris Heger

Applications Science, Bio-Techne, San Jose, CA

Gene therapy utilizing Adeno-associated viruses (AAVs) is on the rise, with two AAV-based treatments already approved by the FDA and many more in clinical development. AAVs are a potent gene delivery tool, but their complexity lies in their two key components: the proteinaceous capsid (composed of VP1, VP2, and VP3) and the contained DNA cargo. During AAV manufacturing, monitoring the number of fully loaded particles versus empty or partially filled ones is crucial as it affects their efficacy. Currently, determining the empty/full status of an AAV sample is a challenge, and most methods require significant amounts of purified sample. To address this, we introduce a new approach for measuring both the DNA and capsid protein content of AAV particles using a capillary-based western blotting platform (Simple Western). This method separates VP1/VP2/VP3, and the capsid DNA based on size and quantifies them using immunodetection. Our results demonstrate strong correlation with the % full obtained by orthogonal techniques. With good sensitivity, linearity, and the ability to analyze 24 samples in just 5.5 hours using only 3uL of sample per well, this method provides a rapid and efficient way to assess the % full status of AAV samples.



466 A Platform for Interrogating Transgene Silencing and Epigenetic Signatures of AAV Genomes

Robert M. Fusco[1], Eric Walton[2], Aravind Asokan[2]

[1]Biomedical Engineering, Duke University, Durham, NC,[2]Duke University, Durham, NC

Loss of transgene expression following administration of AAV-based gene therapies is a well-established clinical challenge. For instance, clinical studies investigating AAV gene therapies for hemophilia have demonstrated an anti-capsid T-cell response, elevation of liver enzymes, and subsequent loss of therapeutic transgene expression. Separately, non-human primate studies have confirmed the number of vector genomes in the liver is far in excess of the number of transduced hepatocytes, potentially attributable to host factors exerting transcriptional silencing. However, mechanisms underlying the loss/silencing of expression remain elusive. Here, we report the use of CRISPR/Cas9-based activators and repressors to demonstrate the upregulation and downregulation of different promoter driven transgenes *in vitro*, respectively. We observe a significant decrease in gene expression and a modest increase in gene expression when targeting the inverted terminal repeats of the AAV genome using Cas9-KRAB and Cas9-VP64 fusions with their corresponding guide RNAs, respectively. In addition, data pertaining to interrogation of different host proteins and their potential roles in altering epigenetic signatures on AAV genomes will be presented. The overarching goal of these studies is to develop a roadmap for understanding the molecular mechanisms dictating silencing of AAV vector genomes and implications for clinical gene therapy thereof.

467 A Robust Machine Learning Algorithm for Improving AAV Capsid Performance

David Brookes, Jeffrey Chan, Farhan Damani, Jeff Gerold, Rishi Jajoo, Stephen Malina, Alex Mijalis, Joyce Samson, Sam Sinai, Flaviu Vadan, Cameron Webster

Dyno Therapeutics, Watertown, MA

Machine learning (ML) methods have shown promise in designing AAV capsids. Current methods typically fall under one of two

paradigms. The first relies on searching directly in the protein sequence space to find high-performing capsids using a regression model which maps sequences to target properties. These methods benefit from explicitly maximizing the desired property but are susceptible to pitfalls such as finding many false positives. The second paradigm sidesteps optimization by drawing protein samples directly from a generative model that learns a representation of functional AAVs and tries to generate similar capsids (e.g., Variational Autoencoders (VAE)). These methods generate capsids with an above-baseline functionality but don't typically produce high-performing samples, as that was not their original objective. Here we propose and experimentally validate VAEprop, a method combining the benefits of both approaches, which improves transduction more effectively than generative modeling or by searching in protein sequence space alone. To do this, we augment a traditional VAE's low-dimensional continuous representation by jointly training it with a regression model that maps the learned representation to the target property. The joint training procedure learns a meaningful and rich representation in which protein sequences with similar property measurements and sequence-level characteristics map to nearby points, but proteins with different measured properties map far from each other, even if the sequences contain shared motifs. By doing so, VAEprop transforms input sequences, which are tricky to optimize directly, into a continuous space better suited for optimization. After training the model on experimental data, we use it to find new points in the continuous learned representation space with a high predicted property value under the regression model. These points are then remapped to generate novel capsid sequences using the VAE. Critically, to improve on previous methods, we develop a novel stopping criterion that prevents our optimization from trailing off into regions far from the training data using the knowledge of the VAE. Our results show that our method is less likely to generate non-functional capsid sequences. We apply VAEprop to optimize transduction by designing thousands of variants of wild-type AAV9 comprising mutations in variable loop regions of VP3. Our validation assay targets the transduction of HEK293T cells in culture, as the shorter time between sequence design and capsid characterization enabled us to assess algorithmic performance quickly. In this setting, we compare VAEprop to two baseline methods by designing sequences using each method. The first samples sequences from a VAE, and the second optimizes sequences using a genetic algorithm (direct optimization). We show that VAEprop improves upon both methods. VAEprop successfully designs capsids at edit distances to wild-type of up to 16, of which almost half package. In comparison, only around a quarter of variants designed by the genetic algorithm successfully package. Furthermore, VAEprop's best-performing capsids transduce cells 16-fold better than AAV9 and between 2-4 fold better than the competing baselines. Most notably, the advantages offered by this method over baselines are equally applicable to in-vivo settings for capsid design, enabling effective optimization of capsid properties with high therapeutic relevance.

468 A Modular, Antibody-Based AAV Retargeting Platform for Efficient and Specific *In Vivo* Gene Delivery

Leah Sabin, Michael Stec, Kyle Plasterer, John Dugan, Pascaline Aime-Wilson, Poulami Samai, Valerie LeRouzic, Naveen Khan, David Golann, Nicole Keating, Caryn Galligan, Tazeen Ishmam, Rachel Sattler, Clarisse Lou Jose, Samvitha Cherravuru, Ammar Tareen, Chris Schoenherr, Min Gao, Matthew Anderson, Lynn Macdonald, Mark Sleeman, Sven H. Moller-Tank, Christos Kyratsous

Regeneron Pharmaceuticals, Tarrytown, NY

Adeno-associated virus (AAV) is a leading viral vector used in gene therapy to treat human diseases. Although AAV has many advantages as a gene therapy vector, one of the drawbacks to its use in systemic gene delivery, particularly for disorders that manifest in multiple organ systems, is the tendency to preferentially transduce the liver and require exceptionally high vector doses to effectively transduce peripheral tissues. Several safety concerns associated with high dose systemic AAV therapies have emerged in recent years, highlighting the need for more efficient AAV vectors that can achieve efficacy at lower doses. Although capsid library-based selection approaches are a powerful method to identify novel capsids with desired properties, the translatability of such capsids between species remains a challenge. Thus, we sought to develop a species-agnostic, modular AAV retargeting platform that utilizes rational capsid engineering and monoclonal antibodies to redirect viral particles to target cells. To accomplish this, we are using a protein tagging system to covalently couple antibodies to surface-exposed variable loops on the viral capsid. The tropism of the conjugated capsid can be further modified or abolished through the introduction of point mutations in the amino acid residues that serve as primary determinants of vector tropism. We have successfully used this approach to retarget multiple AAV serotypes to specific cell types *in vitro* and *in vivo,* using the cellular target of the retargeting antibodies to drive the specificity of infection. To establish the antibody retargeting platform and optimize it for *in vivo* applications, we focused on two target tissues with a clear need for better systemic delivery: skeletal muscle and central nervous system (CNS) targeting via efficient blood brain barrier (BBB) crossing. For muscle targeting, we identified a protein, CACNG1, that is specifically expressed in skeletal muscle. For BBB crossing, we chose Transferrin receptor (TfR), which is known to play a role in transcytosis of cargo across the BBB. Using panels of monoclonal antibodies raised against these target proteins, we demonstrate that AAV particles can be retargeted to skeletal muscle and can efficiently cross the BBB in an antibody-dependent manner *in vivo*. Retargeting can be achieved using bivalent antibodies, fabs, and scFvs, and using multiple AAV serotypes. Retargeted capsids display enhanced on-target delivery and marked liver detargeting compared to AAV9, a standard wildtype capsid used for muscle delivery and BBB crossing in human clinical trials. To demonstrate the cross-species translatability of our platform, we show that our antibody-targeted muscle-specific capsids outperform AAV9 when compared head-to-head in non-human primates using a barcoded library approach. Importantly, our retargeted capsids demonstrate enhanced delivery of therapeutic transgenes and improved functional rescue in mouse models of disease compared to standard

wildtype serotypes. Taken together, our modular antibody-based AAV retargeting system represents a novel platform for translatable, targeted gene delivery that holds promise for accelerating the development of effective gene therapies for a variety of human diseases.

469 Long-Read Sequencing of Diverse AAV *cap* Libraries through Barcode-Labeled Short Reads (BLaSR)

Ana Carneiro[1], Danqing Zhu[2], David V. Schaffer[3]

[1]Chemical and Biomolecular Engineering, University of California, Berkeley, Berkeley, CA,[2]University of California, Berkeley, Berkeley, CA,[3]University of California Berkeley, Berkeley, CA

Directed evolution is a high-throughput approach for creating and identifying novel AAV variants with enhanced properties, such as infectivity, targeted delivery, tissue spread, or immune evasion. The ability to deeply sequence these libraries offers insight into the evolutionary process, as well enable earlier identification of effective variants; however, accurate characterization of these diversified AAV libraries is not possible due to limitations in current sequencing technologies. Short read next-generation sequencing has a relatively low error rate and can capture variant mutations in which mutations are restricted to a specific region or within the read length, yet libraries diversified via methods such as error-prone PCR or random shuffling, in which diversity is spread through the full *cap* ORF, are unable to be correctly sequenced as individual clones. Long read sequencing offers this potential, but at substantially lower read depth and high error rates (1-15%). Here, we have made progress in addressing the limitations of both long- and short-read sequencing methodologies to profile a diverse AAV *cap* (~2.2kb) library. We demonstrate a new synthetic long-read sequencing methodology we term Barcode-Labeled Short Reads (BLaSR) that can sequence a diverse AAV *cap* library using a randomly-barcoded Tn5 transposon system. We harness the random and unbiased mechanism of the Tn5 transposon to insert random barcodes into the AAV *cap* library such that each *cap* variant contains insertions with a unique, identifiable barcode. This allows for the generation of barcode-linked next-generation sequencing short reads in which reads with the same barcode can be traced to the same AAV variant and thus be assembled into the longer *cap* variant sequence. We have engineered a robust pipeline to ensure highly efficient barcoded-Tn5 insertion into the AAV genome and have assembled thousands of AAV *cap* variants with an average 20-40x read depth, with a path towards considerably larger numbers of sequenced *cap* variants per run through further optimizations. Moreover, the use of BLaSR is not limited to AAV *cap* libraries; rather, this long-read sequencing methodology can be applied to other diverse DNA libraries that cannot otherwise be accommodated by next-generation sequencing.

470 High-Throughput AAV Screening Platform on Retinal Organoids to Target Cell Types

Jannick Imbach, Timo Kleindienst, Stefan Spirig, Zoltan Raics, Valeria Arteaga, Yanyan Hou, Susana Posada Céspedes, Cameron Cowan, Magdalena Renner, Josephine Juettner

Institute of Molecular and Clinical Ophthalmology Basel, Basel, Switzerland

Targeted gene delivery to only disease-critical cell types greatly enhances the therapeutic potential of adeno-associated virus (AAV)-mediated gene therapy and reduces undesirable side effects. This can be achieved by placing a specific on-off switch for gene expression - a promoter - in the viral genome. Since the precise mechanisms of cell type specific expression are not yet understood, many promoter variants need to be tested to find the ideal expression profile to treat a particular disease. Currently, human retina explants from post-mortem donations are used for individual testing of AAV promoter variants, but limited availability and significant labor constrain the number of variants that can be compared. Human retinal organoids closely resemble most cell types of the human retina and can be generated in large amounts. The semi-automated platform we developed uses the more available model system of retinal organoids to pre-screen promoter variants in AAVs with higher throughput. Our pipeline starts with cloning of AAV plasmids harboring promoter variants driving GFP expression in a 96-well plate format, followed by high throughput production of AAVs on a small scale sufficient to infect retinal organoids. High-resolution 3D live imaging of infected organoids is applied to evaluate the AAV promoter variants for expression in the therapeutically most relevant cell types. After quantitative image analysis, screened promoter variants are ranked for further testing on human retina explants. Besides speeding up the discovery of new cell-type targeting promoter sequences for gene therapy, this will result in new tools for understanding retinal diseases using organoids as a model.

471 A Robust and Flexible Baculovirus-Insect Cell System for AAV Vector Production with Improved Yield, Capsid Ratios and Potency

Alex M. Ward, Yoko Marwidi, Hoang-Oanh Nguyen, David Romero-Santos, Sumita Bhardwaj, Gabriel Ernie, Garrett Lew, Michael Trias, Jada Padilla, Hung Tran, Kathleen Meyer, Richard Surosky

Sangamo Therapeutics, Inc., Richmond, CA

Manufacturing of recombinant adeno-associated viruses (rAAV) for gene and cell therapy applications has increased significantly and spurred development of improved mammalian and insect cell-based production systems. We developed a baculovirus-based insect cell production system- the Sangamo (SGMO) Helper- with a novel gene architecture and greater flexibility to modulate the expression level and content of individual Rep and Cap proteins. In addition, we incorporated modifications to the rAAV6 capsid sequence that improves yield, capsid integrity and potency. Production of rAAV6 using the SGMO Helper had improved yields compared to the Bac-RepCap helper from the Kotin lab. SGMO Helper-derived rAAV6 is resistant to a previously described proteolytic cleavage unique to baculovirus-insect cell production systems and has improved capsid ratios and potency, *in vitro* and *in vivo*, compared to rAAV6 produced

using Bac-RepCap. NGS sequence analysis demonstrated that the SGMO Helper is stable over six serial passages and rAAV6 capsids contain comparable amounts of non-transgene DNA as rAAV6 produced using Bac-RepCap. AAV production using the SGMO Helper is scalable using bioreactors, with similar improvements in yield, capsid ratio and *in vitro* potency. Our studies demonstrate that the SGMO Helper is an improved platform for rAAV manufacturing to enable delivery of cutting-edge gene and cell therapies.

472 Rational Engineering of the AAV P5 Promoter Improves Recombinant Vector Purity

Stephen M. Winston[1], Mark A. Brimble[2], Isaiah Reeves[3], Yunyu Spence[1], Pei-Hsin Cheng[1], Christopher L. Morton[1], Andrew M. Davidoff[4]

[1]Department of Surgery, St. Jude Childrens Research Hospital, Memphis, TN,[2]Department of Immunology, St Jude Children's Research Hospital, Memphis, TN,[3]Department of Surgery, St. Jude Children's Research Hospital, Memphis, TN,[4]St. Jude Children's Research Hospital, Memphis, TN

Previous work has demonstrated that both P5- and ITR-associated nucleic acid contaminants from plasmids used to produce recombinant adeno-associated virus (rAAV) vectors can be expressed *in vivo*, highlighting a need to further characterize their implications and develop strategies to increase vector purity. These sequences are encapsidated within fully functional virions, resulting in transcription and translation of undesired plasmid-derived sequences. We hypothesized the packaging of contaminant plasmid sequences is related to the P5 promoter structure and Rep gene expression during production, and that by manipulating critical elements of the P5 promoter and modulating Rep expression, we can reduce the encapsidation of these contaminant sequences. To prevent this encapsidation, we explored the use of homologues from alternative serotypes as replacements for the commonly used P5 promoter in rAAV production. Our data indicate that the use of homologous or rationally designed Rep protein Binding Elements (RBE) and Terminal Resolution Sequence (TRS) loop modifications to the P5 promoter can reduce encapsidation of nearby DNA by roughly ten-fold. Additionally, we found that replacing the canonical AAV2 P5 promoter with alternative homologues can reduce the frequency of encapsidation of contaminants from distant hotspots by over 20%. A subset of these surrogate promoters also improves viral titer by 30-40% during small scale rAAV production in a transgene agnostic manner. Meanwhile, replacing the P5 promoter with a non-related viral promoter, results in aberrant Rep expression, low titers, and high contamination. Rep westerns and fluorescent reporter assays highlight changes in promoter activity correlated with changes to vector titer and purity. These assays were used to identify the implications of promoter modifications on promoter function. Modifications which improved purity and had the most detrimental effect on viral titer, had the strongest impact on promoter activity. Specifically, we observed decreased large Rep expression and increased small Rep expression. We then found that additional modifications to compensate for altered promoter activity rescued viral titer, suggesting these assays may be relevant in establishing and optimizing conditions for rAAV production. These modified promoters may prove to be viable alternatives to the canonical AAV2 P5 routinely used in rAAV production. Large scale production, vector characterization and *in vivo* assays with these new AAV promoters are currently underway. In conclusion, rAAV contamination can be reduced by rationally engineering the P5 promoter. Our findings have implications for making safer, purer products for rAAV gene therapy.

473 Human Bocavirus 1 Muscle Transduction Efficiency Following Local and Systemic Injections in a Murine DMD Model

Bryan Hu[1], Yongping Yue[1], Xiufang Pan[1], Dongsheng Duan[1,2,3]

[1]Department of Molecular Microbiology and Immunology, School of Medicine, University of Missouri, Columbia, MO,[2]Department of Biomedical Sciences, College of Veterinary Medicine, University of Missouri, Columbia, MO,[3]Department of Chemical and Biomedical Engineering, College of Engineering, University of Missouri, Columbia, MO

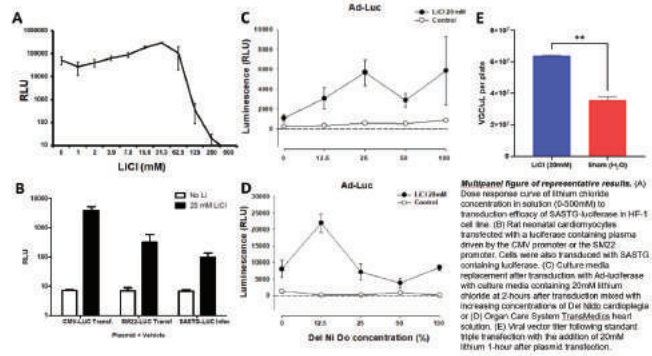
Adeno-associated virus (AAV)-mediated gene therapy is the leading approach to treating various human diseases. However, certain gene editing and replacement strategies are unviable due to the limited ~4.7kb packaging capacity of AAV. Human Bocavirus (HBoV)-mediated gene therapy is a relatively new alternative with an advantageous ~5.5kb packaging capacity. Here, we evaluated the local and systemic muscle transduction efficiency of the HBoV1 vector in mdx mice, a murine Duchenne muscular dystrophy model. The HBoV1 reporter vector expressed green fluorescent protein (GFP) under the transcriptional regulation of the cytomegalovirus promoter. The same vector genome was packaged in AAV8/9 for comparison. Local delivery was studied by intramuscular injection to the tibialis anterior (TA) muscle (n=4 mice). The HBoV1-GFP vector was injected into the left TA muscle at the dose of 3.80E10 vg/muscle. The right TA muscle received the AAV8/9-GFP vector at the dose of 0.24E10 vg/muscle, 0.95E10 vg/muscle, 3.80E10 vg/muscle, or 7.60E10 vg/muscle. Systemic delivery was studied by tail vein injection at the dose of 3.80E11 vg/mouse (n=2 mice). Tissues were harvested at four weeks post-injection. For the local injection study, we detected robust GFP expression in muscles that received 0.95E10 vg/muscle, 3.80E10 vg/muscle, and 7.60E10 vg/muscle of the AAV vector. GFP expression was not detected in the muscle that received 0.24E10 vg/muscle of the AAV vector. Weak GFP expression was observed in one HBoV1 vector-injected muscle. No GFP expression was detected in the remaining three HBoV1 vector-injected muscles. Vector genome copies were quantified with quantitative real-time PCR. We found a correlation between GFP expression and vector genome copy number in both AAV and HBoV1-injected muscle. Overall, for the same dose, the vector genome copy number was substantially lower in the muscles that received the HBoV1 vector. We are currently processing and evaluating the various tissues from the intravenously injected mice. We will report our findings at the 26th annual meeting.

474 The Effect of Lithium on Viral Vector Production and Gene Delivery

Michelle Mendiola Pla[1], Jun-Neng Roan[2], Franklin H. Lee[1], Dawn E. Bowles[1]

[1]Surgery, Duke University Medical Center, Durham, NC,[2]Surgery, National Cheng Kung University Hospital, Tainan, Taiwan

Background. Viral vector yield and potency of viral vectors remain significant issues that limit the manufacturing of gene therapies and maintain the costs of production exceedingly high. A number of chemicals have been reported to improve viral vector production and gene delivery. Here we investigate the effects of lithium (Li), a widely used drug for treating mood disorders, whose major effect is through inhibition of glycogen synthase kinase-3. We characterize the addition of Li at various steps of viral vector production and transduction: plasmid production, triple transfection for viral vector production, gene delivery by vector transduction or plasmid transfection. ***Methods.*** Plasmids used for AAV production were isolated from *E. coli* using the PureYield Plasmid Maxiprep System (Promega, WI). Li was added into the bacterial culture 3-hours prior to plasmid isolation and DNA concentration was measured using a NanoDrop spectrophotometer (Thermo Fisher, MA). Recombinant Adeno-associated viral vectors (rAAV) were generated by standard triple transfection. rAAV titers were measured using quantitative PCR (BioRad, CA). The Adenoviral (Ad) vector was obtained from the Pittsburgh Human Gene Therapy Center (Pittsburgh, PA) and expanded in our lab. Various cell types were plated on 96-well plates at 10,000 cells per well and were transduced at 24-hours after plating with either 1,000 Ad viral particles per cell or 10,000 rAAV particles per cell. 293 cells were transfected with plasmids driven by either the cytomegalovirus (CMV) or smooth muscle 22 (SM22) promoter using either polyethylenimine or Fugene 6 (Roche, Switzerland). Two-hours following either vector transduction or plasmid transfection, Li was added, and luciferase activity was assessed via luminometry 48 hours later. For some of the viral vector transduction experiments, a mixture of culture media with cardioplegia solution (Del Nido solution, Baxter Inc, IL; Organ Care System heart solution, TransMedics, MA) was used during the transduction period. Luciferase reagent (ONE-Glo, Promega, WI) was added to the cells and luminometry was performed with a Veritas luminometer (Turner Biosystems, CA). ***Results.*** Luciferase activity increased 3-5-fold when 20mM of LiCl was added at 2-hours post-transduction of HeLa cells, HF-1 cells, and rat neonatal cardiomyocytes with AAV 1, 2, 5, 6, and SASTG viral vectors. Luciferase activity also enhanced 532- and 44.7-fold for CMV-luciferase and SM22-luciferase plasmids compared to experiments in the absence of lithium., respectively. Addition of lithium did not enhance plasmid yield from bacteria. Addition of 20mM Li led to a significant 1.8-fold enhancement in the number of rAAV particles produced. Transgene expression using Ad vectors were improved by LiCl in human aortic tissue and 20mM LiCl addition 2-hour post transduction improved transgene expression of the Ad vectors that was originally suppressed by cardiac perfusion solutions. ***Conclusion.*** We describe that Li has enhancing effects in different steps of viral vector production and gene delivery. Given its low cost and already FDA approved status for clinical use, it is an attractive molecule for implementing in widespread viral vector production and gene therapy delivery. We describe consistent upregulation of gene expression in eukaryotic cells provided plasmid, AAV, or Ad regardless of type of cell or promoter used. unknown.



475 Advanced Dual AAV Vector-Intein Mediated Systems: Improving Dual Vector Doses

Mariana Valentim Ferreira, Sofia Fernandes, Ricardo Silva, Cristina Peixoto, Ana S. Coroadinha

Animal Cell Technology, IBET, Oeiras, Portugal

Background and novelty: Adeno-Associated Viral (AAV) vectors are one of the most well-established vectors used in the clinic for *in vivo* gene therapies. Despite significant improvements since their development, AAV vectors still present several limitations. One major bottleneck is the small packaging size restricting its use to treat diseases requiring the delivery of large genes. To overcome this, dual AAV vector delivery systems relying on protein trans-splicing can be applied to reconstitute large proteins, being the split-intein DnaE sequence from *Nostoc Punctiforme* (Npu DnaE) currently the most used. However, it presents low reconstitution efficiencies, demanding higher vector dose administration to attain efficient therapeutic effects. Low-quality vector preparations can also contribute to limited gene reconstitutions by promoting vector competition and inhibiting transduction. This work seeks to overcome inefficient protein reconstitution rates and decrease vector doses of current dual AAV vector-intein-mediated systems by applying split-inteins with unmatched trans-splicing rates combined with higher-quality AAV vectors. **Experimental approach:** Studies were conducted to evaluate the performance of engineered-consensus (Cfa) and cyanophage-like Gp41-1 split-inteins when compared to the Npu DnaE split-intein. AAV expression cassettes were developed to encode frGFP terminal halves fused to split-inteins. Full-length frGFP controls containing intein a.a. remaining (Scar-frGFP) after split-intein reaction were developed. Protein reconstitution was assessed by transient transfection and dual-AAV co-transduction. Impact of AAV vector quality (percentage of empty and full particles) on dual-AAV co-transductions was assessed. An upstream-to-downstream process was performed with and without a full particle enrichment step (using anion exchange chromatography). Dual-AAV co-transductions using low AAV vector doses are under evaluation. **Results and discussion**: Transfection studies showed a 2-fold decrease in fluorescence intensities with Scar-frGFP control constructs when compared to non-scared frGFP, revealing that intein residues impact frGFP protein function. Cfa and Gp41-1 presented over

2-fold higher reconstitution rates than NPU DnaE and almost 100% frGFP reconstitution. Dual-AAV2 co-transductions were performed to determine optimal transduction conditions by testing different vector doses ($1x10^4$-$5x10^4$ V.G./cell). Results demonstrated 40% decrease in fluorescence intensity compared to single transductions, suggesting vector competition. Initial Cfa and GP41-1 split-inteins dual-AAV co-transductions resulted in 10% more frGFP reconstituted positive cells than Npu DnaE. The established AAV vector full particle enrichment step increased over 3-fold the quality of the viral preparations. On average, 60-75% of full AAV particles were obtained in all AAV2 split-intein productions. Dual-AAV2 co-transduction studies with different vector doses are currently undergoing, to determine the impact of viral vector quality with optimized split-inteins. This work showed improved protein reconstitution efficiencies, revealing Cfa and Gp41-1 as promising split-inteins for dual AAV delivery. Further developments combining these split-inteins with enhanced vector qualities will enable the reduction of AAV dose in therapeutic administrations, paving the way for the delivery of large therapeutic transgenes.

476 Novel mRNA Delivery System Based on Positive-Sense Single-Stranded RNA Viruses

Jiabao Han, Hanyu Bai, Wei Li, Qi Zhou
Institute of Zoology, Beijing, China

Background: The CRISPR (clustered regularly interspaced short palindromic repeats) gene editing technique has been extensively exploited in numerous hereditary illnesses. However, limitations in cargo size, off-target effects, and insertional mutagenesis prevent it from being used *in vivo*. Transferring mRNA could solve these issues, as mRNA delivery systems are one of the most promising approaches to transfer genes of interest.Methods: We created a non-replicating mRNA viral vector based on the Semliki Forest virus (SFV). Several cell lines, including those generated from human, mouse, and hamster, were used to confirm the effectiveness. We used Ai9 mice to show the new vector's biodistribution. Neutralizing antibodies, blood chemistry, and histology of various administration routes were also tested to investigate the immunological responses to high-dose injection.Results: We developed a non-replicating viral mRNA delivery method based on the SFV. This new displayed remarkable transduction efficiency in various cell lines. The viral particles distributed in livers, spleens, skeletal muscles and brains via intravenous injection and efficiently delivered into the central nervous system via intracerebroventricular injection. Little inflammation was seen in response to high-dose treatment in both the histology and blood chemistry. Similar to other viral vectors, neutralizing antibodies were discovered one week after injection and decreased over time. Conclusions: We created an mRNA delivery method with excellent transduction efficiency and little immunogenicity. We confirmed the efficacy in multiple cell lines and the biodistribution in Ai9 mice and exhibited the immunological responses of several administration routes. This innovative mRNA vector offered a promising option for RNA therapy.

477 A Comprehensive Characterization of Full, Partial, and Empty Lentiviral Vectors

Vijetha Bhat, Peng Wang, Chien-Ting Li, Victor Paredes, Bingnan Gu
Lonza Houston Inc., Houston, TX

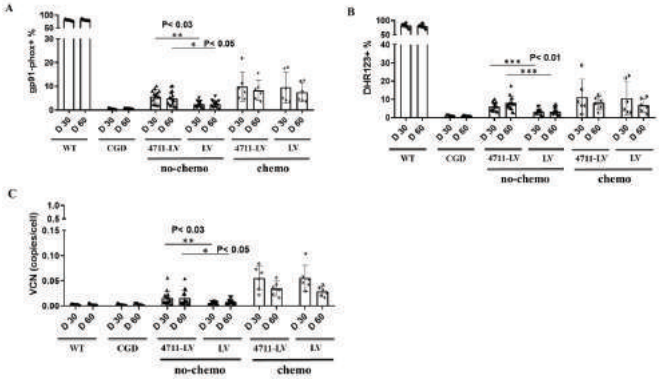
Lentiviral vectors are biological vehicles used to deliver therapeutic genes ("payload") into cells. The characterization of lentiviral vectors is challenging due to their complex physical structure. To be considered functional, lentiviral vectors require at least three critical components: 1) An outer envelope, comprised of VSV-G protein 2) A capsid housing the genetic material, comprised of p24 protein and 3) The payload itself constituted by the therapeutic gene. Since there is no assay currently on the market that measures all three attributes, scientists must piece together data from several different assays to understand the composition of the vector, which is often laborious and unreliable. Currently, a microarray chip-based assay on the market can offer a partial characterization of lentiviruses. However, this assay does not provide any information on the presence or absence of the payload. This is an integral piece of information which would determine the functionality of the lentiviral vector. In this study, we developed a new characterization method that selectively targets VSV-G, p24 and the RNA payload by using a permeant fluorescent nucleic acid stain [a]. Using this method, we can quickly visualize and quantitate the lentiviral vector at three separate levels for a comprehensive understanding of lentiviral vector products. Importantly, this method can enable new vector design and process optimization to enrich full lentiviral vectors.
[a] Patent pending.

478 Improved *In Vivo* Lentiviral Gene Therapy of Chronic Granulomatous Disease

Haokuan Yuan[1], Xiaomei Wu[1], Hongwei Liu[1], Yuchen Liu[2], Lung-Ji Chang[2]
[1]Medicine, University of Electronic Science and Technology of China, Chengdu, China,[2]Geno-Immune Medical Institute, Shenzhen, China

Background: Chronic granulomatous disease (CGD) is a congenital immunodeficiency characterized by severe life-threatening infections. CGD patients lack reactive oxygen species (ROS) in phagocytic leukocytes and often develop widespread tissue granulomas. Gene therapy based on autologous hematopoietic stem cell transplantation (HSCT) is a promising treatment for CGD, but the poor tolerance of CGD patients to transplantation-related chemotherapy presents a major limitation to this strategy. "*In vivo*" gene therapy is based on direct delivery of transgenic vehicles into patients, which could overcome the difficulties in HSCT. The standard VSVG-pseudotyped lentiviral vector (LVs) have been shown ineffective for direct *in vivo* injection, since VSVG is rapidly inactivated by human complement and innate immunity. We have previously demonstrated LV-*CYBB* (cytochrome B-245 beta chain, or p91-phox) expression by universal or myeloid-specific promoter through *ex vivo* HSCT gene therapy could correct CGD phenotype in X-CGD mice (DOI: 10.1089/hum.2022.140). Here we report an improved direct *in vivo* LV gene delivery strategy based on minimal immune suppressive conditioning and an innovative major histocompatibility complex (MHC) knock down LV system to increase intravenous (iv) LV gene therapy

efficacy. **Methods:** To increase iv LV gene delivery efficiency, X-CGD mice (X-CGD; B6.129S-Cybb^{tm1Din}/J) were pre-treated with chemo-conditioning (busulfan 5 mg/kg), cyclophosphamide 100 mg/kg and dexamethasone 5 mg/kg). In addition, the 293T-based LV packaging cells were modified with cytomegalovirus-based MHC-knock down genes (US11 and ICP47) and innate immune escape protein CD47 (4711-LV). The CGD mice were iv injection of 2x10^9 transduction units (TU) 4711-LVs carrying a myeloid-specific miR223 promoter driving the expression of *CYBB*. The transgene expression, vector copy number (VCN), and CGD phenotype correction were investigated. **Results:** We compared *in vivo* LV gene therapy in CGD mice with or without chemo-conditioning, using regular LV-*CYBB* or 4711-LV-*CYBB.* The expression and function of the LV-*CYBB* were analyzed by intracellular gp91-phox staining and DHR123 assay 4 and 8 weeks after iv gene delivery. Based on flow cytometry, we detected gp91-phox positive cells in the blood after 4 and 8 weeks as the following, no-chemo-4711-LVs: 1.98-10.22% and 1.34-10.24%, no-chemo-LVs: 0.6-5.14% and 0.26-5.87%, chemo-4711-LVs: 4.76-21.8% and 3.61-15.6%, chemo-LVs: 3.56-17.95% and 3.65-12.59%, as compared with WT mice: 76.5-84.2% and 78.98-86.12% (Fig. A). Functional analyses of ROS showed the following, no-chemo-4711-LVs: 3.1-10.09% and 2.65-17.53%, no-chemo-LVs: 0.25-6.21% and 0.81-6.99%, chemo-4711-LVs: 1.74-28.73% and 2.61-12.6%, chemo-LVs: 2.78-22.95% and 1.98-11.59%, as compared with WT: 70.19-91.86% (Fig. B). The LV VCN in the peripheral blood was detected by qPCR as the following, no-chemo-4711-LVs: 0.58-5.61% and 0.26-5.4%, no-chemo-LVs: 0.12-0.93% and 0.18-1.75%, chemo-4711-LVs: 2.22-8.4% and 1.62-5.6%, chemo-LVs: 2.96-10.39% and 1.66-4.27% after 4 and 8 weeks, respectively (Fig. C). The results supported that the use of 4711-LVsincreased *iv* LV gene delivery efficiency even without chemo-conditioning.**Conclusion:** We have developed a novel 4711-LV system to improve direct iv LV gene delivery without chemo-conditioning. This new strategy could potentially improve *in vivo* LV gene therapy applications.



479 A Nonclinical Method for Identifying an Anti-Drug Antibody Response Against an Oncolytic Virus Therapeutic

Kaitlynn Graca, Ashlee Bell-Cohn, Joyce Swenson, Joseph Seco, Richard Dambra, Alexandra Gurka, Alison J. Johnson, Kathryn Phoenix, Christine Grimaldi, Michael Franti, Adam Vigil, Joseph Ashour
Boehringer Ingelheim, Ridgefield, CT

Introduction: Oncolytic vectors (OVs) as a novel therapeutic modality create unique challenges for anti-drug antibody (ADA) assay development; there is limited guidance for assessing immunogenicity, the drug is complex and contains multiple viral proteins that are immunogenic, and assay development may pose high material demand requirements. Here, we present a nonclinical assay to detect and characterize the presence of ADA against a therapeutic OV. **Methods**: To identify the presence of ADA, a plate-based screening and confirmatory assay was developed. Whole virus was used as the coating material to capture ADA. The positive control was a polyclonal antibody generated from rabbits immunized with OV. Commercially sourced naïve mouse serum was used to determine the cut points of the assay and identify positive individuals. Samples consisted of serum collected from Balb/C mice dosed once with therapeutic OV and serum collected from Balb/C and C57Bl/6 mice dosed three times with therapeutic OV. Alternative antibodies against viral proteins were interrogated as positive controls and although not selected, they provided insight into the condition of the virus bound to the plate. The immune response against viral proteins is confirmed through Western blot using immunized mouse serum as the probing material and recombinant proteins and immunogen as loading materials. **Results**: An ADA assay was successfully developed to determine the presence of ADA against OV using naïve and OV-dosed mouse serum samples. Using the developed ADA assay, it was determined Balb/c mice generated ADA against OV after a single dose. In a separate Balb/C and and C57 mouse study, upon repeat dosing (a total of three doses), ADA was also detected at relatively similar levels as the single dose study. Western blot data confirmed an ADA response against the viral proteins N, M, and GP. Finally, we demonstrate, using monoclonal antibodies to the viral nucleoprotein and matrix protein, that positive signal is obtained using whole virus, suggesting that these antigens may be present on the exterior of the viral membrane as well. **Conclusions**: Our assay demonstrated an approach to identify treatment emergent ADA response against a novel OV therapeutic. Although it is not feasible to identify pre-existing ADA in laboratory mice that would not have prior exposure to OV, it is anticipated that pre-existing ADA in humans would be detectable with the clinical version of this assay due to the sensitivity of the assay. This assay would allow for the ability to determine presence/absence of pre-existing ADA prior to enrollment of a patient to a clinical trial and to provide insight into drug efficacy after repeat dosing.

480 Discovery Platform for Identification of Novel Cell Type Specific Synthetic Promoters for Gene Therapy Vectors

Michal Bilski[1], Oleksandr Dudchenko[1], Heloisa Gabriel[1], Jack Williams[1], Elhana Forsberg[1], Sarah Dowding[1], Bronwyn Broadhurst[1], Yves Du Toit[1], Purnima Kompella[1], Richard Parker-Manuel[1], Ryan Cawood[2], David W. Brighty[1]

[1]Discovery and Internal Research, OXGENE (Oxford Genetics), Oxford, United Kingdom,[2]OXGENE (Oxford Genetics), Oxford, United Kingdom

The goal of gene therapy is to be able to achieve strong and very specific expression of a therapeutic gene. Most fundamental control of gene expression takes place at the promoter region which controls the transcription of a gene. For gene therapy vectors, viral promoters can be ubiquitously and constitutively active, which may lead to abnormally high cellular levels of a therapeutic transgene. Conversely, host cell promoters, though tissue-specific, may only provide low level gene expression and are typically of considerable size, not optimal for use in viral vectors. Lack of promoter optimisation may lead to transgene toxicity, unwanted immune activation and/or therapeutic failure. Promoter engineering provides unique opportunities to improve clinical performance of the viral vector and thereby improve the safety of gene therapies. Here, we have developed a strategy for synthetic promoter design, based on in-house-generated transcriptomic data, epigenetic datasets and bioinformatic sequence analyses. Using either known or de novo identified native cis-regulatory elements functional in target tissues, combinatorial synthetic promoter libraries were designed to allow massively parallel activity screens. We sought to use RNAseq-based screening of barcoded transcription units to identify novel synthetic promoters and determine the relative frequency and transcriptional activity of these promoters in specific target cell populations. Champion promoters demonstrated robust cell- or tissue-specific patterns of expression (~10-100 times stronger in target cells) and transcriptional activity varied dramatically between promoters (<10-fold difference). Our data indicate that rational promoter design coupled with suitable screening campaigns can be valuable tools for improving the performance of viral vectors and the on-target safety of gene therapies.

481 Single-Cell Lentiviral Vector Integration Sites and Clonal Tracking Assay for Cell and Gene Therapy

Yilong Yang, Khushali Patel, Chieh-Yuan Li, Shu Wang, Benjamin Schroeder, Saurabh Parikh

Mission Bio, South San Francisco, CA

Lentiviral vector (LV) has been widely adopted as an efficient vehicle to deliver transgenes into cells due to its long-term efficacy. However, the semi-random integration of LV has raised safety concerns due to its potential to trigger tumorigenesis during CAR-T therapy. To mitigate this issue, characterization of vector integration on clonal expansion after gene therapy has become a crucial practice to monitor the activity of retroviral vectors on in vivo selection of patient clones. Here, we developed a single-cell resolution, lentiviral vector integration site assay to survey the co-occurrence of specific integration sites with somatic genomic variants. Based on a set of LV transduced cell lines with known integration sites validated by orthogonal data, a targeted panel was designed to cover 5' and 3' ends of each integration site with predefined integration orientations. Samples include negative control and LV transduced cell lines with known vector copy numbers ranging from one to four copies. Using a titration experiment design, we demonstrate the capability to quantitatively detect individual cells harboring specific vector integration sites and longitudinal tracking of cell clones with different vector copy numbers. Furthermore, another set of 99-plex human genome amplicons are included to characterize somatic variants in the cell population of a sample. Taken together, a high throughput single-cell multi-omics platform enabled us to simultaneously identify somatic variants along with vector integration events in individual cells, providing both potential functional mutation identification and clonal tracking capabilities. The development of single-cell lentiviral vector integration sites and clonal tracking assay provides a unique opportunity to better study longitudinally CAR-T cell clonal expansion and lead to a more effective therapeutic agent.

482 *APOE*-Targeted Epigenome Therapy for Late Onset Alzheimer's Disease

Ornit Chiba Falek[1], Boris Kantor[2]

[1]Neurology, Duke University, Durham, NC,[2]Neurobiology, Duke University, Durham, NC

Background: There is an urgent need to shift the paradigm of Alzheimer's disease (AD) drug discovery to the development of new targets. *APOE* is the strongest and most reproducible genetic risk factor for late-onset AD (LOAD). Moreover, 50% reduction in *APOE* levels showed beneficial effects in AD cellular and mouse models. Thus, *APOE* gene holds promise as a potential therapeutics target for LOAD. Here, we developed an epigenome therapy platform to reduce *APOE*e4 expression by targeted modification of the epigenome landscape across *APOE* locus. **Methods:** We developed epigenome therapy based on CRISPR/deactivated(d)Cas9 editing technology fused with a repressor molecule and delivered by viral vehicle. We designed a set of gRNAs to target regulatory elements in *APOE* region and within exon 4 overlapping the SNP that defines the *APOE*e4 allele. We validated our epigenome therapy platform *in vitro* using human induced pluripotent stem cell (hiPSC)-derived models and *in vivo* using mice. **Results:** The viral dCas9-repressor vector showed a robust decrease, ~50%, in *APOE*-mRNA levels in hiPSCs and the derived cholinergic neurons, microglia, and organoids models. The system specifically targeted the *APOE*e4 allele exhibiting the reduction effect in all hiPSC-derived cellular and organoids models with the e4-allele while there was no effect in the *isogeneic* hiPSC-derived models homozygous for the e3-allele. Further examination of the transduced e4/4 organoids demonstrated that the specific reduction in *APOE*e4 expression led to lower Aβ42/40 levels. Moving onto *in vivo* studies, we stereotactically injected the viral dCas9-repressor vector into the mice hippocampus. The results showed a significant decrease amounting to ~70% in mouse endogenous *Apoe* expression, demonstrating a strong and specific repression effect *in vivo*. **Conclusions:** Collectively, our results provided *in vitro* and *in vivo proof-of-concept* for the utility, efficacy, and specificity of the *APOE*-targeted epigenome therapy. Our epigenome therapy strategy for targeted fine-tuning of *APOE*e4 expression based on dCas9 technology is *translational* toward the development of a therapeutics approach to prevent and/or delay LOAD

onset. Furthermore, the technology offers the opportunity to refine the platform for the development of gene-specific and even allele- and cell-type- specific therapies, and by that enables the advancement of strategies for precision medicine in LOAD.

483 Automating the Analysis of Genomic Damage: Instability and Genotoxicity Using AI and Machine Learning

Christopher J. Tompkins

Research and Product Development, KromaTiD, Longmont, CO

Structural variants, such as inversions and translocations, are common by-products of cellular engineering processes such as CRISPR editing and insertion of transgenes. These variants are formed by misrepair of DNA and result in a heterogenous mixture of low-prevalence variants that involve edit-site, off-target and random DNA breakpoints. **d**irectional **G**enomic **H**ybridization™ (dGH™) is a unique cytogenetic technique for mapping the structure and structural variation of many individual genomes in single cells. Based on images of millions of DNA probes designed against a reference genome and hybridized to metaphase chromosomes, dGH assays provide true de novo, unbiased detection of structural variants as small as 2Kb anywhere in the genome. dGH is ideal for measuring these editing by-products as well as potentially genotoxic outcomes such as sub-clonal outgrowth, insertional mutagenesis and chromothripsis. While as few as 20 single-cell genomic maps can be sufficient to detect high prevalence structural variants, achieving sufficient detection power for the low prevalence (<1%), potentially genotoxic variants requires mapping of hundreds to thousands of single-cell genomes. Due to cost and turnaround time, reliance on manual counting limits dGH assay analysis to hundreds of cells per sample. In this study we demonstrate the automation of the entire dGH workflow using AI and machine learning techniques, removing this limitation and thereby making detection of ultra-low prevalence, potentially genotoxic variants practical and efficient.

484 *In Vivo* CRISPR Base Editing of Angptl3 via Lipid Nanoparticle Delivery

Jennifer Khirallah[1], Hanan Bloomer[2], Gregory Newby[3], Hyunjoon Rhee[1], Maximilian Eimbinder[1], Changfeng Huang[1], Yamin Li[4], Zheng-Yi Chen[5], David Liu[6], Qiaobing Xu[2]

[1]Biomedical Engineering, Tufts University, Medford, MA,[2]Tufts University, Medford, MA,[3]Biomedical Engineering, Broad Institute, Cambridge, MA,[4]Biomedical Engineering, SUNY, Syracuse, NY,[5]Department of Otolaryngology, Harvard Medical School, Boston, MA,[6]Chemistry, Harvard, Boston, MA

Human dyslipidemia diseases, such as coronary artery disease (CAD) and Non-alcoholic fatty liver disease (NAFLD), are classified by an abnormally high-level of cholesterol and/or fats in the blood. *Angptl3* has been identified as a potential target of interest for treating dyslipidemia diseases as it encodes for angiopoietin-like 3 (ANGPTL3), an enzyme that regulates plasma lipoprotein levels. Loss of function (LOF) variants of *Angptl3* are naturally occurring with no known associated complications. Individuals with these mutations have shown reduced levels of plasma low-density lipoprotein cholesterol (LDL-C) and triglycerides (TG) and protection against CAD. Therefore, we rationalized that inducing a LOF in *Angptl3* may protect against these diseases. Utilizing a base editing approach, we package BE mRNA and a *Angptl3*-targeting sgRNA within a liver targeting lipid nanoparticle (LNP) to KO *Angptl3.* First, we formulated LNPs containing one of three lipids (306-012B, Lipid88 and Lipid10) by loading them with ABE8e and one of two different single guide RNAs (sgRNAs), sgRNA_SA or sgRNA_SD. We then injected them *in vivo* and collected the liver 7 days later. From extracted liver DNA and NGS we found that Lipid88 achieved the highest editing efficiency with both candidate sgRNAs. Next, to test the long-term efficacy, we injected mice and analyzed editing. After 7 days, we found that mice treated with LNPs achieved high editing efficiency in the liver (>60%) and limited editing in seven other organs (<2%) (Figure 1).

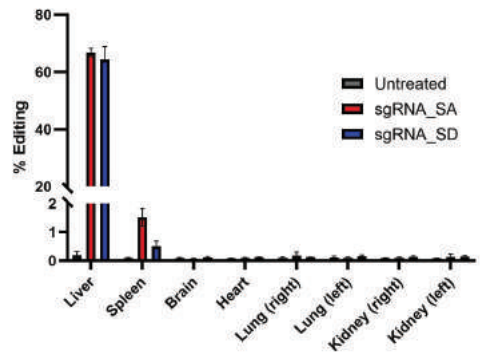


Figure 1. LNP biodistribution.

We also tested the therapeutic effect by performing analyzing serum levels of ANGPTL3, LDL-C, and TG. We observed a significant reduction in serum levels at day 7 and 30 using one or both of our sgRNAs compared to untreated mice (Figure 2).

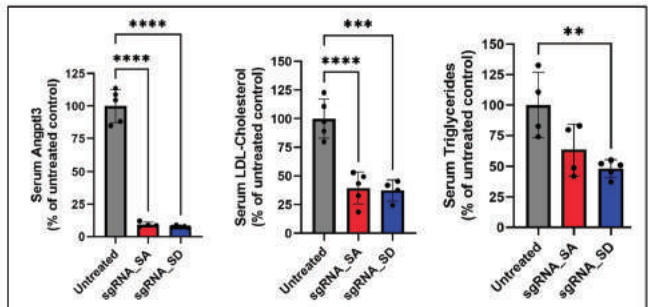

Figure 2. ANGPTL3, LDL-C, and TG levels after 30 days. Significance measured by one-way ANOVA.

Additionally, to assess the toxicity of these treatments, we used a higher dose (2 doses), proposing that a higher dose of our treatment would be more toxic than a lower dose (1 dose) and after 48 hours we collected blood and tested the levels of alanine transaminase (ALT), aspartate transaminase (AST), and interleukin-6 (IL-6). High levels of ALT and AST are associated with liver damage and high levels of IL-6 are associated with an increased immune response. We determined that there was no significant increase in toxicity associated with these treatments. In conclusion, the knockout of *Angptl3* has shown to lower levels of LDL-C and TG and protect against diseases such as CAD and NAFLD. It is of particular interest to see if this KO can additionally be used as either a treatment or prevention for NAFLD. This will be

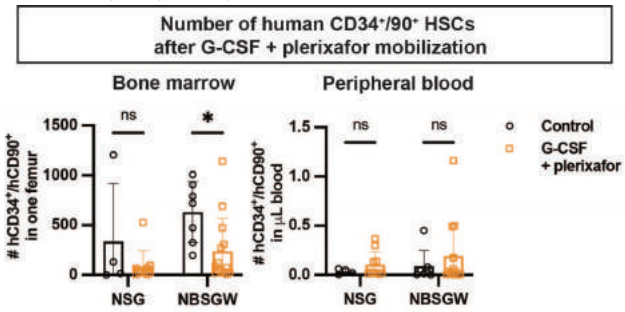
done by analyzing the effect of our LNPs using both an obese mouse line known to develop NAFLD and a wild type mouse line on a high fat and cholesterol diet.

485 Evaluation of Humanized Mouse Models for *In Vivo* HSC Gene Therapy

Seunga Choo, Carl B. Wolf, Heather M. Mack, Mitchell J. Egan, Hans-Peter Kiem, Stefan Radtke

Translational Science and Therapeutics Division, Fred Hutch Cancer Center, Seattle, WA

In vivo hematopoietic stem cell (HSC) gene therapy is a promising strategy that eliminates the need for burdensome leukapheresis, myeloablation, and transplantation. To preclinically test novel therapeutic reagents for in vivo gene therapy, humanized mouse models are invaluable tools. Three conditions must be satisfied to demonstrate effective in vivo gene therapy in humanized mouse models. First, the model should support high human HSC engraftment in the bone marrow (BM) so there are enough CD34$^+$ CD90$^+$ long-term HSCs (LT-HSCs) to target. Second, human HSCs in the murine BM need to become accessible to the therapeutic reagents introduced in vivo. HSCs in the BM are largely inaccessible to the reagents introduced in circulation and mobilization is considered the best way to make HSCs accessible. Lastly, human HSCs in mice should be permissive for the therapeutic agents such as viral vectors. Here, we comprehensively compared humanized NOD.Cg-*Prkdc*^{scid} *Il2rg*^{tm1Wjl}/SzJ (NSG) and NOD.Cg-*Kit*$^{W-41J}$ *Tyr* $^+$ *Prkdc*^{scid} *Il2rg*^{tm1Wjl}/ThomJ (NBSGW) strains for CD34$^+$ CD90$^+$ HSC engraftment, mobilization, and vector transduction in vivo. For this, we humanized irradiated NSG and non-irradiated NBSGW neonates with human umbilical cord blood-derived CD34$^+$ cells. First, we observed that the NBSGW strain supports significantly higher human CD34$^+$ CD90$^+$ engraftment in the murine BM compared to the NSG strain. Surprisingly, we found hundreds of CD34$^+$ CD90$^+$ HSCs in the peripheral blood (PB) of both strains, indicating that there is a low-level circulation of human HSCs in these humanized mouse models. Next, we treated humanized mice with granulocyte-colony stimulating factor (G-CSF) and AMD3100 (plerixafor) to assess HSC mobilization. Despite successful mobilization of human HSCs from the BM of NBSGW mice, there was no corresponding increase in the number of HSCs in the PB. Since mobilization was not successful in making human HSCs available in circulation, VSV-G pseudotyped lentivirus encoding GFP was directly injected into the BM. Although GFP-positive cells were found in the BM, none of the GFP-positive cells were CD34$^+$ CD90$^+$, indicating that the lentivirus could not efficiently target LT-HSCs. To investigate the reason for the inefficient in vivo viral transduction of human HSCs, we analyzed the expression of low-density lipoprotein receptor (LDL-R), a major entry port of VSV-G pseudotyped lentiviral vectors, on steady-state human CD34$^+$ CD90$^+$ HSCs from the mouse BM as well as from leukapheresis samples from G-CSF-treated human donors. In both cases, we found a very low-level expression of LDL-R indicating that steady-state as well as freshly isolated G-CSF-mobilized human HSCs have limited accessibility to VSV-G based viral vectors. From our findings, we concluded that NBSGW mice provide a better platform to test in vivo human HSC targeting strategies due to high LT-HSC engraftment. Our work also warrants for a development of VSV-G-independent gene therapy strategies such as adenovirus or measles virus to target HSCs in vivo. Another alternative is surface-engineered viral vectors for HSC-specific targeting. Considering the wide usage of humanized mouse models and HSC mobilization in the field, our work highlights the importance of identifying a proper model and method to study in vivo HSC targeting strategies.



486 Population-Wide Gene Disruption in the Murine Lung Epithelium via AAV-Mediated Delivery of CRISPR-Cas9 Components

Honglin Chen

Molecular Biology, Genentech, Inc - South San Francisco, South San Francisco, CA

With the aim of expediting drug target discovery and validation for respiratory diseases, we developed an optimized method for in situ somatic gene disruption in murine lung epithelial cells via AAV-mediated CRISPR-Cas9 delivery. Achieving high editing efficiency on a populational-level in alveolar cell type II (AECII) and airway epithelium, e.g. club and ciliated cells, is of particular value given the roles these cell types play in cystic fibrosis, chronic obstructive pulmonary disease, and idiopathic pulmonary fibrosis. We optimized parameters including AAV capsid serotype, route of administration, Cas9 variant, and AAV vector configuration driving Cas9 expression. We demonstrated feasibility and efficiency of sequential AAV intratracheal dosing with combinatorial guide RNA expression cassettes. Application of these optimized methodologies in a reporter mouse model (Rosa26-LSL-tdTomato) showed gene editing rates up to ~85% in AECII and distal airway cells. The most robust editing efficiency could be demonstrated in a SpCas9 transgenic mouse model, where we observed i. >90% depletion of a target gene product (USP30) at the protein level and ii. population-wide cell transdifferentiation post *Notch2* gene perturbation in distinct epithelial cell types. Notably, after repeat dosing, minimal to no associated inflammation was observed in treated animals. In addition, we observed and characterized AAV vector integration events that occurred at the on-target cleavage site with a frequency of ~12% in lung cells, highlighting a complicating factor with AAV-mediated delivery of DNA nucleases. Taken together, we demonstrate a uniquely effective approach for somatic engineering of the murine lung, which will greatly facilitate the modeling of disease and therapeutic intervention.

487 Optimal Ratio for Nuclease and Donor AAV Vectors in a Genome Editing Approach for Ornithine Transcarbamylase Deficiency

Jenny A. Greig, Ilayaraja Muthuramu, Claude C. Warzecha, John White, Zhenning He, Hong Zhang, Yanqing Zhu, Jason Lamontagne, Peter L. Bell, Lili Wang, James M. Wilson

University of Pennsylvania, Philadelphia, PA

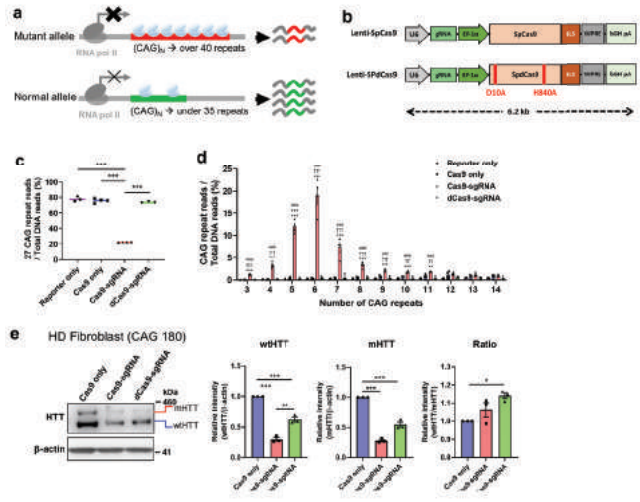
Our group previously described a genome editing approach for the treatment of ornithine transcarbamylase deficiency (OTCD) in rhesus macaques. OTCD causes lethal episodes of hyperammonemia, and we have proposed a treatment approach in which newborns that survive initial hyperammonemic episodes are treated with gene insertion of a functional copy of the OTC gene. Our genome editing approach consists of dual administration of an adeno-associated virus (AAV) vector expressing an ARCUS meganuclease to create a double-stranded break in a safe harbor site within the *PCSK9* locus and a second AAV vector to deliver a human OTC minigene for knock-in at this site. Following highly successful studies in newborn rhesus macaques in which up to 20% of the liver was expressing human OTC, we evaluated the impact of vector ratio for the meganuclease and donor vectors. We performed studies in a mouse OTCD model that was rendered susceptible to the M2PCSK9 meganuclease through germ-line modification of exon 7 of the endogenous *Pcsk9* gene. After injecting the two vectors into newborn mice at a ratio of 1:1 or 1:3 for the meganuclease to mouse OTC donor vectors, we challenged the mice with a high-protein diet to induce lethal hyperammonemia and evaluated the mice for survival, body weight changes, and transgene expression. By day 7 of the high-protein diet challenge, all untreated OTCD mice had to be euthanized due to a body weight loss of >20% (n=5). In comparison, all mice injected with a low vector dose at a ratio of either 1:1 (both vectors administered at a dose of 10^{13} genome copies [GC]/kg) or 1:3 (10^{13} GC/kg of meganuclease vector and 3×10^{13} GC/kg of donor vector) survived the duration of the high-protein diet challenge (10 days, n=8-10). Both treatment groups exhibited reduced weight loss at day 6 of the high-protein diet challenge (89%-91% of baseline) and increased OTC enzyme activity compared with untreated animals (two- and four-fold for the 1:1 and 1:3 meganuclease-to-donor ratio groups, respectively). Increasing the 1:1 ratio dose so that both vectors were administered at a dose of 3×10^{13} GC/kg resulted in slightly reduced survival by day 10 of the high-protein diet challenge (90% survival) with similarly maintained body weights (91% of baseline) and a two-fold increase in OTC enzyme activity compared with untreated controls. In our previous work, we utilized a 1:3 ratio of meganuclease to donor vectors. The work described here supports this 1:3 ratio as the optimal ratio to efficiently knock-in the human OTC minigene and protect against a high-protein diet in a mouse model of OTCD.

488 DNA Double-Strand Break-Free CRISPR Interference Delays Huntington's Disease Progression in Mice

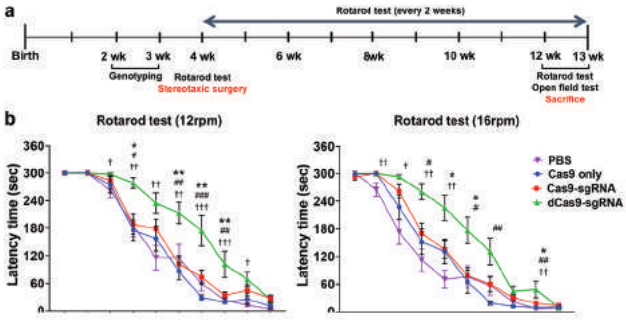
Jung Hwa Seo[1], Jeong Hong Shin[2], Junwon Lee[3], Daesik Kim[4], Hye-Yeon Hwang[4], Bae-Geun Nam[1], Jinu Lee[5], Hyongbum (Henry) Kim[2], Sung-Rae Cho[1]

[1]Department and Research Institute of Rehabilitation Medicine, Yonsei University College of Medicine, Seoul, Korea, Republic of,[2]Department of Pharmacology, Yonsei University College of Medicine, Seoul, Korea, Republic of,[3]Department of Ophthalmology, Institute of Vision Research, Yonsei University College of Medicine, Seoul, Korea, Republic of,[4]Department of Precision Medicine, Sungkyunkwan University School of Medicine, Suwon, Korea, Republic of,[5]College of Pharmacy, Yonsei Institute of Pharmaceutical Sciences, Yonsei University, Incheon, Korea, Republic of

Huntington's disease (HD) is caused by a CAG repeat expansion in the huntingtin (*HTT*) gene. CRISPR-Cas9 nuclease causes double-strand breaks (DSBs) in the targeted DNA that induces toxicity, whereas CRISPR interference (CRISPRi) using dead Cas9 (dCas9) suppresses the target gene expression without DSBs. Delivery of dCas9-sgRNA targeting CAG repeat region did not damage the targeted DNA in HEK293T cells containing CAG repeats. When this study investigated whether CRISPRi can suppress mutant HTT (*mHTT*), CRISPRi resulted in reduced expression of mHTT with relative preservation of the wild-type HTT in human HD fibroblasts.



Although both dCas9 and Cas9 treatments reduced mHTT by sgRNA targeting the CAG repeat region, CRISPRi delayed behavioral deterioration and protected striatal neurons against cell death in HD mice.



Collectively, CRISPRi can delay disease progression by suppressing *mHtt,* suggesting DNA DSB-free CRISPRi is a potential therapy for HD that can compensate for the shortcoming of CRISPR-Cas9 nuclease.This study was supported by a grant from the Korean Health Technology R&D Project through the Korea Health Industry Development Institute (KHIDI), funded by the Ministry of Health & Welfare, Republic of Korea (grant no. HI21C1314, HI22C1588 to S.-R.C.) and the Korean Fund for Regenerative Medicine(KFRM) grant funded by the Korea government (the Ministry of Science and ICT, the Ministry of Health & Welfare) (grant no. 21A0202L1, 21C0715L1 to S.-R.C.).

489 Analysis of Lentiviral Vector-Transduced Hepatocytes from *In Vivo* Gene Transfer Studies

Efrain Guzman

Oxford Biomedica, Oxford, United Kingdom

Lentiviral vectors (LVV) are well suited for the in vivo correction of inborn errors of metabolism in which the liver is the main target for the long-term expression of the therapeutic transgene. However, several challenges remain, such as 1) efficient transduction of target cells within the liver and, 2) achieving therapeutic levels of the transgene. Oxford Biomedica has carried out a series of gene transfer studies to resolve these challenges. Self-inactivating (SIN) third generation LVV have been used extensively for the ex vivo generation of CAR-T cells in the immuno-oncology field and in numerous clinical trials to introduce genes into haematopoietic stem cells for the correction of primary immunodeficiencies and haemoglobinopathies. In addition, in vivo delivery of LVV to the eye has been demonstrated to be safe to generate long-term multi-year stable expression of the therapeutic transgene. The systemic delivery of LVV in animal models has been demonstrated to be safe and efficacious but the systemic delivery of LVV is yet to be demonstrated in humans. We and others have observed species-specific differences in transduction of target cells by LVV. To overcome these differences, we used a mouse model in which human hepatocytes are engrafted into immune deficient FRG mice and repopulate the mouse liver and demonstrated that LVV are more efficient in transducing human hepatocytes in vivo compared to murine hepatocytes. Additionally, hepatocyte-specific promoter (HSP)-driven transgene expression was significantly higher in LVV-transduced human hepatocytes than in AAV-transduced human hepatocytes in this FRG model indicating the potential for high level sustained expression from LVV when administered directly in vivo. Site integration analysis of LVV-transduced C57BL/6 mouse livers revealed a polyclonal integration profile as is typical of LVV, demonstrating the safety of in vivo delivery of third generation LVV. Lastly, single nucleus RNA sequencing (snRNAseq) of livers from LVV-treated mice revealed numerous liver-resident cell subsets which are difficult to identify using histological methods, including various hepatocytes subtypes, hepatocyte progenitors, Kupffer cells, and at least two endothelial cell subsets. Mapping of LVV-encoded transgene transcription driven by HSP is ongoing and will help identify which liver-resident cell subsets transcribe the transgene of interest with great accuracy, enabling the evaluation of cell-targeting technologies. These studies underpin the successful development of LVV for in vivo gene therapy applications for the long-term expression of therapeutic transgenes in humans. Oxford Biomedica is developing a 4th generation LVV system which aims to be able to carry larger transgene/s, with higher expression, additional safety features and higher titres than the current 3rd generation LVV in both ex vivo and in vivo gene therapy applications.

490 Engineered Zinc Finger Transcriptional Regulators Specifically Reduce Prion Expression and Extend Survival in an Aggressive Prion Disease Model

Bryan Zeitler[1], Meredith A. Mortberg[2], Victoria Shih-Wei Chou[1], Mohad Mehrabian[1], Kimberly Marlen[1], Michael Howard[2], Samantha Graffam[2], Kenney Lenz[2], Tyler Caron[2], Qi Yu[1], Jing Hu[1], Sarah Hinkley[1], Alicia Goodwin[1], Asa Hatami[1], Alaric Falcon[1], Toufan Parman[1], Jason D. Fontenot[1], Amy Pooler[1], Eric Vallabh Minikel[2], Sonia M. Vallabh[2]

[1]Sangamo Therapeutics, Inc., Richmond, CA,[2]Broad Institute of MIT and Harvard, Cambridge, MA

Prion disease is a rapidly progressing, invariably fatal neurodegenerative disorder caused by misfolding of the cellular prion protein, PrP, encoded by the *PRNP* gene. Most cases are sporadic or caused by inherited dominant mutations in *PRNP*. There are currently no approved or clinical-stage disease-modifying therapies for the prevention or treatment of prion disease. *Prnp* null animals are completely resistant to prion inoculation, and lowering endogenous PrP levels by 50% either genetically or with antisense oligonucleotides can approximately double the lifespan of prion-infected mice. Here, we investigated a single-administration epigenetic regulation approach using AAV-delivered zinc finger transcriptional repressors (ZF-Rs) to achieve sustained and widespread reduction of PrP in the brain and rapid pharmacological effect. Engineered ZF-Rs targeting the transcription regulatory elements of either mouse *Prnp* or human *PRNP* were fused to the human KRAB repression domain and screened in mouse Neuro2A or human SK-N-MC cells, respectively. RT-qPCR analysis identified dozens of highly potent ZF-Rs that reduced prion mRNA by 50-99%. Selected ZF-Rs potently reduced prion mRNA levels in cultured primary mouse cortical and human iPSC-derived neurons with no detectable off-target activity. ZF-Rs under the control of the human Synapsin promoter reduced bulk prion protein mRNA and protein levels by >50% across the brain when administrated to adult mice. Single-cell RNAscope analysis revealed potent *Prnp* knockdown in transduced neurons. PrP was also significantly reduced in mouse

cerebrospinal fluid following AAV-ZF-R administration. Top candidate ZF-Rs were then tested in a prion inoculation mouse model. Wildtype mice were intracerebrally injected with the Rocky Mountain Laboratory (RML) strain of prions (PrP^{Sc}), leading to prion disease symptoms and inevitable mortality approximately 160 days post inoculation (dpi). To evaluate the efficacy of our AAV-ZF-R approach at timepoints relevant to human disease, RML-infected mice were treated with a single dose of ZF-Rs at 60 dpi, near the onset of plasma neurofilament light chain (NfL) rise, or at 122 dpi, near the onset of symptoms and body weight loss. While control groups reached terminal endpoint at 160±8 dpi (mean±sd), a majority of AAV-ZF-R treated mice (n=10/19) were alive at 360 dpi, with attendant improvements in body weight and plasma NfL. In total, 5/19 mice treated with PrP-lowering AAV-ZF-Rs survived to the scheduled necropsy date (500 dpi). Notably, RML-induced increases in plasma NfL levels were arrested following ZF-R treatment at both intervention points. Immunohistochemical staining of brain slices from surviving ZF-R-treated animals revealed a striking reduction in PrP pathology compared to untreated mice. These results support the continued development of a genomic medicine using ZF-Rs for the potential treatment of prion disease.

491 Implementation of Oxford Biomedica Technologies to Improve the Safety and Effectiveness of Lentiviral-Based Liver Gene Transfer

Federico Zambon, Joe Holley, Lydia Phipps, Efrain Guzman, Jordan Wright, Daniel Farley, Kyriacos Mitrophanous, Yatish Lad

Oxford Biomedica, Oxford, United Kingdom

Liver gene therapy with lentiviral vectors (LVs) holds great potential to provide long-term expression of key enzymes to treat metabolic disorders with a single administration. One key aspect for the success of liver gene therapy is the quality and safety of the LVs. Viral genome (vRNA) splicing and transgene protein contamination in the final product could limit the effectiveness of such therapy. Even when transgene expression during vector production is not detrimental to the out-put titre, the protein could end up in the final drug substance, either incorporated into the virion itself or co-purified with it. This is an issue for liver gene therapy based on intravenous administration of LVs because the transgene present in the vector preparation as a result of the production process could elicit an undesired immune reaction. Over the years, Oxford Biomedica (OXB) has developed key technologies that can address this challenge. Initial *in vitro* data showed that transgene expression in LV producing cells (HEK293T) was occurring even when a liver-specific promoter was adopted. Sequencing data suggested this was the result of aberrant vRNA splicing from the native HIV major splice donor (MSD) that bypasses the rev-response element (RRE) and the liver-specific transcription binding sites on the internal promoter. Splicing of the vRNA and transgene expression were greatly reduced using an inactivated MSD HIV backbone, alongside the OXB U1 technology, which rescues the reduction in titre caused by the MSD-mutation. Any residual transgene expression during vector production was completely abolished by implementing the OXB TRiP System™ (doi: 10.1038/ncomms14834) to work with the liver-specific promoter, with no detrimental effect on production titres. These innovative LV technologies, including the inactivated MSD, U1 technology™ and TRiP System™, were validated in target cells *in vitro*. The results showed that integration efficiency and expression levels were comparable to the original vector, with no vRNA splicing or transgene expression during vector production. These data show how the implementation of OXB innovative technologies can improve the quality and safety of lentiviral vectors for the in vivo delivery of therapeutic transgenes to the liver.

492 Tissue-Specific Gene Editing or Gene Expression Modulation Platform for Safer *In Vivo* Therapeutics

Poulami Chaudhuri

Helex, New York, NY

Precision and safety remain critical concerns for in vivo gene editing-based therapeutics. It is critical for therapeutic development to ensure editing in the target site in the target tissue type with no unintended edits in the genome, and in off-tissues. Recent FDA clinical holds on in vivo gene editing based therapeutics cite the challenges of off-tissue editing, germline editing amongst others. Hundred percent targeted delivery is still an ongoing challenge that is to be solved for. Meanwhile, current gene editing drug designs are incorporating cell/tissue specific promoters to achieve cell specific editing. These come with their own set of challenges such as constantly activated Cas (or other editor) enzymes that cause off targets over the life of patients. Helex's proprietary technology leverages the differential spatial organisations and epigenetic imprints of the genome in various cell/tissue types to introduce precision to editing and prevent off-tissue editing. Helex's Hele-GUIDE platform enables "Double Lock Safety" system where targeted vector delivery (first lock) is supported by tissue-specific Helex gRNA(s) (second lock) to prevent editing in off-tissues despite unwanted vector biodistribution. The AI driven Hele-GUIDE platform identifies unique sequences within the gene or in the gene context (e.g regulators) to edit or modulate the target genes in a tissue-specific manner. The target sequences on the gene are uniquely accessible only in the target tissues compared to off-tissues using a 3D spatial mapping of the chromatin and other epigenetic imprints that favor restricted editing in target tissues. The Hele-GUIDE platform then designs the most suitable gRNAs for the select unique targets considering good on target activity with minimal off-target profiles in both target tissues and off-tissues.
Figure1: Hele-GUIDE driven identification of unique hotspots on the genome for cell/ tissue specific editing

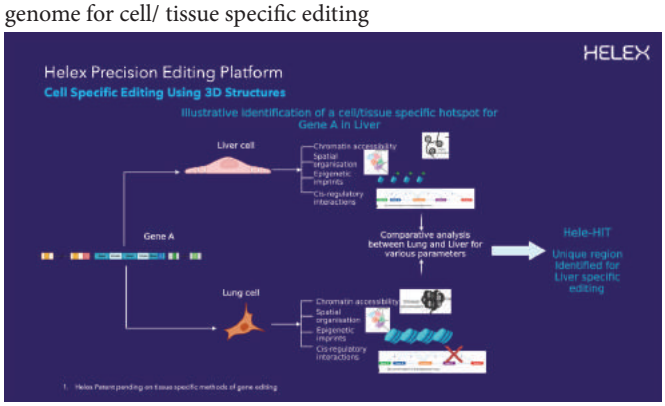


Figure 2: Hele-GUIDE driven identification of unique cell/ tissue specific regulators for specific target gene expression modulation

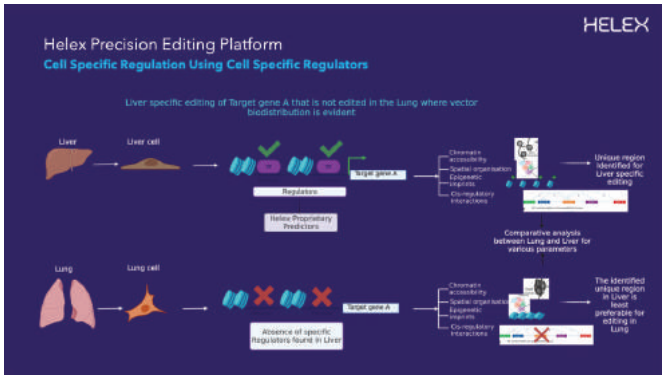

We have experimentally validated Hele-GUIDE predicted tissue specific targets and their constituent gRNAs for two therapeutically relevant targets- TTR and ANGPTL3. We achieved targeted knock down of the target genes in liver cells (TTR ~50%, ANGPTL3 ~35%) with no editing of target genes in lung, colon cells when all cell types were transfected with the same RNP (gRNA and Cas9) complex via lipofectamine. We have been able to achieve liver specific editing in mice models when the tissue specific RNP complexes were systemically administered via lipid nanoparticles as mode of delivery with biodistribution to liver, spleen, lung, colon and other tissues. Hele-GUIDEs proprietary library comprises of 500+ tissue specific targets spanning over 200 therapeutic indications across the liver and retina that can be leveraged for in vivo gene editing/ gene modulation therapeutics. These results hold promise and great scope for the use of cell specific 3D spatial organization of the genome and epigenetic parameters for gene editing drug design to develop more effective, safer and reliable therapeutics.

493 Precise Genome Editing to Correct MECP2 Mutations in Rett Syndrome

Swati Bijlani[1], Ka Ming Pang[1], Sampath Rangasamy[2], Lakshmi V. Bugga[1], Vinodh Narayanan[2], Saswati Chatterjee[1]

[1]City of Hope, Duarte, CA,[2]Translational Genomics Research Institute, Phoenix, AZ

Rett Syndrome (RTT) is a neurodevelopmental disorder that affects brain development and leads to a progressive loss of movement and intellectual ability. It is caused by mutations in the X-linked MECP2 gene, resulting in a deficiency of the functional MECP2 protein in neurons. MeCP2 is a methyl CpG-binding nuclear protein that acts as a methylation reader which regulates expression of thousands of genes. RTT is almost exclusively observed in heterozygous females, while males with hemizygous MECP2 mutations rarely survive. MeCP2 is universally expressed, but the highest expression levels are observed in neurons. Over 300 distinct MECP2 mutations have been reported in RTT patients, with ~90% located in Exons 3 and 4. Gene therapy of RTT has proven challenging due to a stringent requirement for physiologic regulation of expression, with either too much or too little being toxic. Here we evaluated the possibility of using a genome editing strategy to revert MECP2 mutations back to the wild-type sequence, thus preserving all gene regulatory elements and maintaining physiologic expression levels. The stem cell-derived adeno-associated virus, AAVHSC, have been shown to mediate high-fidelity, precise homologous recombination in the absence of exogenous nucleases. We designed AAVHSC genome editing vectors to correct mutations in Exons 3 and 4 of the MECP2 gene and to insert a promoterless Venus open reading frame (ORF) immediately downstream of the coding region of Exon 4. The MECP2 editing vector was packaged in AAVHSC7 and was used to transduce a panel of RTT patient derived MECP2 mutant cells. Successful editing of the MECP2 gene resulted in the insertion of a promoterless Venus ORF downstream of Exon 4, with expression being driven by the endogenous chromosomal MECP2 promoter. Flow cytometric analysis of AAVHSC-transduced cells revealed specific Venus expression, indicative of successful editing. Editing efficiencies based on Venus expression ranged from 10-20% in a panel of RTT patient-derived primary fibroblasts bearing the R282X, R106W and r.378_384delTCCCCAG MECP2 mutations. For immortalized patient-derived B lymphoblastoid cells, up to 10% of cells were found to be specifically edited. Editing was confirmed at the sequence level, following targeted integration analyses employing insert-specific and chromosome-specific primers. Sanger sequencing of amplicons confirmed that the MECP2 gene was precisely edited. No ITR sequences or insertion / deletion mutations were detected in the edited genomes. Sequence analyses revealed correction of the MECP2 S134C mutation in the genome of edited S134C male RTT cells, which only contain a single mutant X chromosome. Our results clearly demonstrated the capacity of AAVHSC to successfully and accurately correct MECP2 mutations. Editing of the MECP2 gene in female cells, which have both a wild type and a mutant copy of the gene, was confirmed by linkage to unique single nucleotide polymorphisms (SNP) identified in proximity to the edited locus. SNP analyses also enabled mapping of homologous recombination-related crossover events in edited genomes. Interestingly, a higher frequency of recombination was observed closer to the center of the homology region as compared with the periphery. Protein analyses is currently underway to evaluate whether correction of MECP2 mutations restores wild type MeCP2 protein expression. In vivo genome editing studies evaluating correction of a murine Mecp2 mutation is also underway in a mouse model of RTT. In conclusion, we have demonstrated successful correction of mutations in the MECP2 gene associated with RTT using the precise and nuclease-free homologous recombination based AAVHSC genome editing platform.

494 CRISPR/Cas9 Mediated Specific Ablation of *Vegfa* in Retinal Pigment Epithelium Efficiently Regresses Choroidal Neovascularization

Han Jeong[1,2], Gang Cui[1], Jinkyu Park[1], Suk Ho Byeon[1,2], Junwon Lee[3]

[1]Institute of Vision Research, Department of Ophthalmology, Severance Eye Hospital, Yonsei University College of Medicine, Seoul, Korea, Republic of,[2]Brain Korea 21 Project for Medical Science, Yonsei University, Seoul, Korea, Republic of,[3]Institute of Human Barrier Research, Department of Ophthalmology, Gangnam Severance Hospital, Yonsei University College of Medicine, Seoul, Korea, Republic of

PURPOSE: The CRISPR/Cas9 system easily edits target genes in various organisms and is used to treat human diseases. In most

therapeutic CRISPR studies, ubiquitously expressed promoters, such as CMV, CAG, and EF1α, are used; however, gene editing is sometimes necessary only in specific cell types relevant to the disease. Therefore, we aimed to develop a retinal pigment epithelium (RPE)-specific CRISPR/Cas9 system. **METHODS:** We developed a CRISPR/Cas9 system that operates only in retinal pigment epithelium (RPE) by expressing Cas9 under the RPE-specific vitelliform macular dystrophy 2 promoter (pVMD2). This RPE-specific CRISPR/pVMD2-Cas9 system was tested in human retinal organoid and mouse model. **RESULTS:** We confirmed that this system works specifically in the RPE of human retinal organoids and mouse retina. In addition, the RPE-specific *Vegfa* ablation using the novel CRISPR-pVMD2-Cas9 system caused regression of choroidal neovascularization (CNV) without unwanted knock-out in the neural retina in laser-induced CNV mice, which is a widely used animal model of neovascular age-related macular degeneration. RPE-specific *Vegfa* knock-out (KO) and ubiquitous *Vegfa* KO were comparable in the efficient regression of CNV. **CONCLUSIONS:** The promoter substituted, cell type-specific CRISPR/Cas9 systems can be used in specific 'target cell' therapy, which edits genes while reducing unwanted off-'target cell' effects.

495 An Engineered xCas12i with High Activity, High Specificity and Broad PAM Range

Hainan Zhang[1], Xiangfeng Kong[1], Mingxing Xue[1], Jing Hu[1], Zikang Wang[1], Yinghui Wei[1], Guoling Li[1], Dong Yang[1], Meiling Zhang[2], Yingsi Zhou[1], Hui Yang[1,3]

[1]HuidaGene Therapeutics Co., Ltd., Shanghai, China,[2]Center for Reproductive Medicine, International Peace Maternity and Child Health Hospital, School of Medicine, Shanghai Jiao Tong University, Shanghai, China,[3]Center for Excellence in Brain Science and Intelligence Technology, Chinese Academy of Sciences, Shanghai, China

Background: Cas12i is characterized by the capability of autonomously processing precursor crRNA to form short mature crRNA and mediates cleavage of dsDNA with a single RuvC domain. Thus, Cas12i is an ideal gene-editing delivery tool via a single AAV. Although Cas12i enables multiplex high-fidelity genome-editing, the natural variants of Cas12i (Cas12i1 and Cas12i2) have shown low editing efficiency thus limiting their utility for therapeutic gene-editing. Here we report the development and usage of a bioinformatic pipeline to annotate Cas12i proteins, CRISPR arrays, and predicted PAM preferences. **Methods**: Fluorescent reporter system was used to assess the activity of the Cas12i proteins by fluorescence intensity. Then, we performed an arginine scanning mutagenesis in the PI, REC-I, and RuvC-II domains of newly discovered Cas12i proteins. To assess the feasibility of engineered Cas12i variants or base-editor for gene-editing *in vivo*, we delivered LNP-packaged mRNA and crRNA to the liver of C57 mice by tail intravenous injection. Finally, we explored the efficiency of engineered Cas12i variant-mediated editing via a single AAV vector in a humanized Duchenne muscular dystrophy (DMD) mouse model, in which mouse exon 51 was replaced by human exon 51 followed by deletion of mouse exon 52. **Results**: We discovered 10 new CRISPR/Cas12i systems, including xCas12i, showing higher fluorescence activity than SpCas9 and LbCas12a. Engineered xCas12i variant, hfCas12Max, exhibits higher efficiency than several current Cas proteins, broadens PAM (5'-TN or 5'-TNN PAM), and exhibits high specificity in mammalian cells (Fig. 1A-C). Additionally, engineered dxCas12i-based editors exhibit high base-editing activity. Through delivering hfCas12Max RNP targeting *TRAC* in primary human T cells, crRNA-2 and crRNA-3 generated ~90% editing and reduced to 2-3% level of TRAC expression along with ~80% viability in CD3+ T cells (Fig. 1D). By targeting the exon 3 of the transthyretin (*Ttr*) gene by gene and base-editing in mice, we detected ~70%, equivalent to saturation, editing efficiencies in murine liver using targeted deep sequence analysis (Fig. 1E). Furthermore, TadA8e-dxCas12i-v4.3 achieved ~25% A-to-G editing efficiency of A13 in the *Ttr* locus in murine liver through LNP delivery. After systemic delivery of a single all-in-one AAV vector containing hfCas12Max and a crRNA targeting the splice donor site of human exon 51 to the DMD mouse model, the dystrophin expression was efficiently restored as well as histopathology and grip strength were ameliorated. In further exploration to neurodegenerative diseases including amyotrophic lateral sclerosis (ALS) and Huntington's disease (HD), hfCas12Max-mediated knockdown efficiency of toxic proteins exceeded 80%. **Conclusions**: These results indicate that hfCas12Max mediates robust editing activity and high specificity. hfCas12Max is a versatile platform for genome- or base-editing in mammalian cells or mice and could be useful in the future for *in-/ex-vivo* therapeutic applications, showing significant potential for disease modeling and therapies.

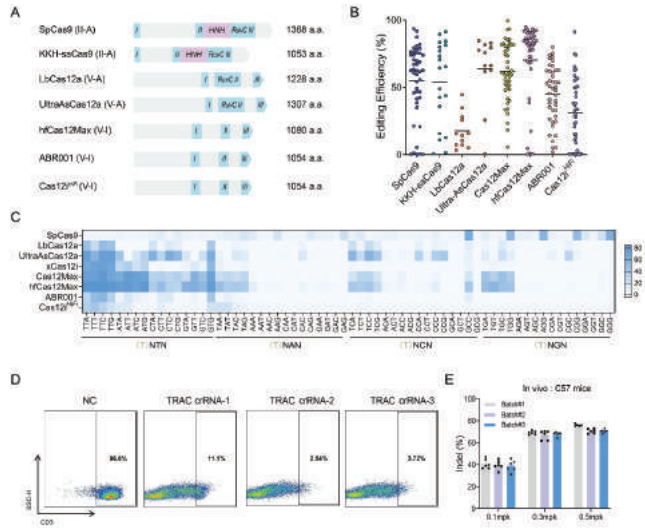

Figure 1. hfCas12Max, an engineered natural variant xCas12i, mediated high-efficient genome editing in mammalian cells, *ex vivo* and *in vivo*. A, Domains and sizes of several CRISPR Cas proteins. **B**, Comparison of indel activity from Cas12Max, hfCas12Max, LbCas12a, Ultra AsCas12a, SpCas9, KKH-saCas9, ABR001 and Cas12i^{HiFi} at *TTR* locus. hfCas12Max showed higher gene-editing efficiency than other Cas proteins. Each dot represents one of three repeats of single target site. **C**, hfCas12Max exhibited a broader PAM recognition profile than other Cas proteins, including 5'-TN and 5'-TNN PAMs. **D**, Representative flow cytometric analysis of edited CD3+ T cell 5 days after RNP delivery. NC represents blank control, untreated with RNP. **E**, Indel rates of LNP packaging with hfCas12Max mRNA and targeted *Ttr* crRNA at three doses (0.1, 0.3 and 0.5 mpk) in C57 mice (n=6).

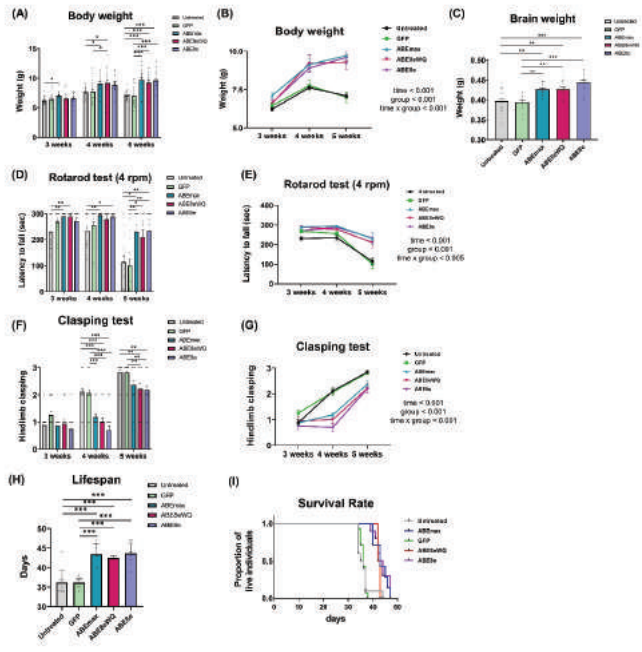
496 Adenine Base Editing of Galactosylceramidase Gene in a Mouse Model of Krabbe's Disease

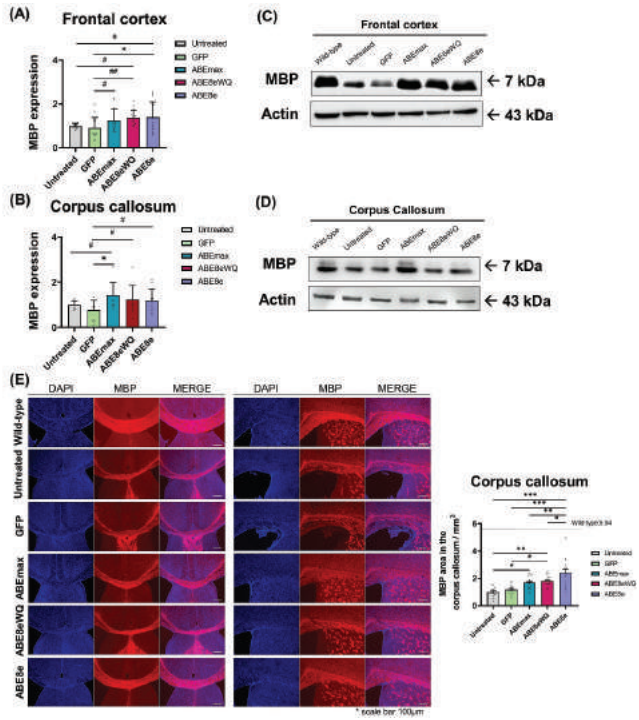
Joohee Kim[1], Bae-geun Nam[1], Sung-Ah Hong[2], Ah-reum Baek[1], Sangsu Bae[2], Sung-Rae Cho[1]

[1]Department and Research Institute of Rehabilitation Medicine, Yonsei University College of Medicine, Seoul, Korea, Republic of,[2]Genomic Medicine Institute, Medical Research Center,, Seoul National University College of Medicine, Seoul, Korea, Republic of

Cure for globoid cell leukodystrophy, Krabbe disease (KD) has long been in demand. A base editing has emerged as a promising treatment. Unlike CRISPR-Cas9 repair system, adenine base editor (ABE) can correct target sequences without DNA templates which prevents double-stranded DNA breaks. ABE has emerged as an exclusive therapeutic candidate among base editing systems with the possibility to correct a mutant gene for the recovery of the lost enzyme function. When the ABE gene was separated into two adeno-associated virus (AAV) vectors, in vitro transfection experiment of the ABE gene showed no significant difference between the unseparated and split genes. High-throughput sequencing showed 37 and 56% of the base editing efficiency. In qRT-PCR, mRNA expression levels of split-ABE pairs were largely shown in the corpus callosum and frontal cortex where also showed 0.5 and 3% of the base editing efficiency. The ABE treatments significantly ameliorated neurobehavioral functions in rotarod and clasping tests as well as body weight. Finally, brain weight and life span were significantly alleviated compared to untreated and GFP groups.



The brain of ABE-treated mice exhibited myelin recovery in qRT-PCR, Western blot, immunohistochemistry and transmission electron microscopy in addition to reduced globoid cell pathology in Luxol fast blue/periodic acid-Schiff staining and preserved axonal integrity in diffusion tensor imaging of the brain MRI.



These data indicated the novelty of a base editing technology using ABEs as a fundamental treatment option for KD, potentially extending a promising challenge for various genetic diseases.This study was supported by a grant from the Korean Health Technology R&D Project through the Korea Health Industry Development Institute (KHIDI), funded by the Ministry of Health & Welfare, Republic of Korea (grant no. HI21C1314, HI22C1588 to S.-R.C.) and the Korean Fund for Regenerative Medicine(KFRM) grant funded by the Korea government (the Ministry of Science and ICT, the Ministry of Health & Welfare) (grant no. 21A0202L1, 21C0715L1 to S.-R.C.).

497 Molecular Characterization of CRISPR-Based Targeted Gene Insertion of *Factor 9* as a Potential Treatment for Hemophilia B

Poulami Samai[1], Allen Lin[1], Rachel Sattler[1], Karole D'Orazio[1], Kalyani Nambiar[1], KehDih Lai[1], Yong Kim[1], Catherine Moroski-Erkul[2], Cindy Shaw[2], Jonathan A. Phillips[2], David Gutstein[1], Dan Chalothorn[1], Leah Sabin[1], Lori Morton[1], Christos Kyratsous[1]

[1]Regeneron Pharmaceuticals, Tarrytown, NY,[2]Intellia Therapeutics, Cambridge, MA

CRISPR/Cas9-mediated genome editing is an emerging approach to treat human diseases by addressing their underlying genetic cause. We have developed CRISPR-based therapeutic platforms to either reduce or restore expression of genes involved in human disease. One such platform is a CRISPR-based gene insertion approach, which involves the targeted insertion of a promoterless expression cassette into the *Albumin* locus of liver hepatocytes using a lipid nanoparticle (LNP) and adeno-associated virus (AAV) delivery system to allow robust and durable therapeutic protein expression from the liver. We have applied this approach to hemophilia B, an X-linked genetic

disorder characterized by reduced coagulation Factor IX (FIX) activity. In adult hemophilia B mice, we have established that liver insertion-derived FIX protein is functionally indistinguishable from purified human (h) FIX, and treatment with our development candidate rescues hemostasis in hemophilia B mice. To further characterize our insertion platform, we have developed a suite of molecular biology assays that quantitatively characterize *in vivo* DNA insertion and subsequent RNA transcription. We applied our suite of assays to characterize the insertion outcomes in adult hemophilia B mice that received hFIX-AAV and Cas9-guide RNA (gRNA) LNP. At the DNA level, AAV-LNP treatment resulted in dose-dependent increases in insertion events (quantified by droplet digital PCR) and indels at the *Albumin* locus (quantified by targeted amplicon sequencing). At the RNA level, AAV-LNP treatment resulted in dose-dependent increases of ALB-hFIX fusion transcripts (quantified by reverse transcriptase quantitative PCR [RT-qPCR] and by whole transcriptome RNA sequencing). In addition, at the RNA level, AAV-LNP treatment resulted in dose-dependent increases in the percentage of cells expressing ALB-hFIX fusion transcripts (measured by BaseScope *in situ* hybridization assays). By characterizing the effects of our AAV-LNP treatment at the DNA, RNA, and protein levels, we can correlate the extent of gene insertion to FIX expression (RNA and protein). This will aid us in using this model for dose selection and gain mechanistic understanding of our platform. Our targeted gene insertion approach has the potential to become a durable solution to several monogenic diseases.

498 Targeted Delivery of Genome Editors Complexed with Guide RNA Using ARMMs for Non-Viral *In Vivo* Delivery

Qiyu Wang, Shu-Lin Liu, Ryan Kleeck, Chris Chatzinakos, Komal Vyas, Chou-Wei Chang, Wendy Zhao, Carson Semple, Lucy Sun, Pearl Moharil, Zahra Baghbantaraghdari, Jennifer Badji, Kristin Luther, Adam Francoeur, Joseph F. Nabhan

Vesigen Therapeutics, Cambridge, MA

In vivo gene editing therapies offer the transformative potential to cure, ameliorate, or prevent an array of diseases. However, broader therapeutic applications, beyond targeting hepatocytes or *ex vivo* gene editing, have been limited by the inability to efficiently and safely deliver gene editing technologies to disease-affected tissues and cell types. We have engineered the human vesicles ARMMs (ARrestin-domain 1 Mediated Microvesicles) as a safe, targeted, and re-dosable therapeutic platform for the delivery of CRISPR/Cas9 gene editing complexes *in vivo*. We utilize the protein ARRDC1, which is the principal driver of ARMM formation, as a recruitment handle to actively load engineered vesicles. That CRISPR/Cas9 ribonucleoprotein-loaded ARMMs are engineered versions of naturally existing vesicles enables this delivery system to overcome various limitations of existing delivery technologies, such as toxicity, low specificity, instability, and immunogenicity. We have developed a scalable cell-based production system to readily load the CRISPR/Cas9 protein complexed to guide RNA (gRNA) into ARMMs and achieve high loading efficiencies, unparalleled by other platforms. Functional delivery of Cas9/gRNA complexes by ARMMs was first demonstrated *in vitro* with multiple gRNA sequences targeting several genomic loci in a range of human and murine cell types, including primary and post-mitotic cells. *In vivo* administration of ARMMs yielded 60-70% editing after a single dose. These results highlight the therapeutic potential of ARMMs-based delivery of CRISPR/Cas9 in disease modification.

499 CRISPR PERSIST-On Enables Heritable and Fine-Tunable Human Gene Activation

Y. Esther Tak[1,2], Jonathan Y. Hsu[1,3], Justine Shih[1], Hayley T. Schultz[1], Ivy T. Nguyen[1], Kin Chung Lam[1,4], Luca Pinello[1,2,5], J. Keith Joung[1,2]

[1]Molecular Pathology Unit, Massachusetts General Hospital, Charlestown, MA,[2]Pathology, Harvard Medical School, Boston, MA,[3]Massachusetts Institute of Technology, Cambridge, MA,[4]Harvard Medical School, Boston, MA,[5]Cell Circuits and Epigenomics Program, Broad Institute of MIT and Harvard, Cambridge, MA

Current technologies for upregulation of endogenous genes use targeted artificial transcriptional activators but stable gene activation requires persistent expression of these synthetic factors. Although general "hit-and-run" strategies exist for inducing long-term silencing of endogenous genes using targeted artificial transcriptional repressors, to our knowledge no equivalent approach for gene activation has been described to date. To address this, here we show stable gene activation can be achieved using a strategy we call Precision Editing of Regulatory Sequences to Induce Stable Transcription-On (**PERSIST-On**). This approach leverages the activities of endogenous transcription factors (**EndoTF**s) that are normally expressed in human cells and can be used to induce stable long-term gene activation, which we show is durable for at least five months. We also show how PERSIST-On can be modulated in two different ways to fine tune the magnitude of gene activation observed. Taken together, our results delineate a generalizable platform for inducing heritable and fine-tunable gene activation in a hit-and-run fashion, thereby enabling a wide range of research and therapeutic applications that require stable long-term upregulation of a target gene.

500 Expansion of CD33-Edited CD34$^+$ Cells by Gemtuzumab Ozogamicin for *In Vivo* HSC Gene Therapy of Hemoglobinopathies

Aphrodite Georgakopoulou[1], Sucheol Gil[1], Hans-Peter Kiem[2], Andre Lieber[1], Chang Li[1]

[1]University of Washington, Seattle, WA,[2]Fred Hutch, Seattle, WA

We have previously developed a new *in vivo* HSC gene therapy approach that involves HSCs mobilization and intravenous injection of helper-dependent adenovirus (HDAd5/35++) vectors that target receptors present on primitive HSCs. HSCs transduced in the periphery return to the bone marrow and spleen and persist there long-term. The approach has recently been used for *in vivo* editing of HSCs to reactive γ-globin or correct the Sickle Cell Disease mutation. In order to achieve therapeutically relevant editing levels, the current approach required several rounds of *in vivo* selection with low-dose chemotherapy drugs. Roland Walter and Hans-Peter Kiem developed a new system that could potentially be used for *in vivo* selection of edited HSCs and expansion of edited erythroid cells. It consists of a CRISPR-Cas9 to knock-out the exon 2 of CD33 gene in HSPCs and gemtuzumab ozogamicin (GO),

an immunotoxin that targets non-transduced, CD33$^+$ HSPCs. Notably, CD33 is dispensable for normal hematopoiesis. Here we developed a multiplex adenine base editing approach, by using a HDAd5/35++ vector to simultaneously: *i)* mutate the splice acceptor site to eliminate the second exon of CD33 (which encodes for the GO target epitope) and *ii)* inactivate a BCL11a repressor site within the HBG1/2 promoters to reactivate γ-globin (HDAd-ABE8e-sgHBG-sgCD33). Transduction of a CD33$^+$ myeloid cell line (ML-1 cells) followed by GO selection resulted in nearly 100% editing of both target sites and >98% CD33$^{\Delta E2}$ cells at day 14, indicating that editing/selection system worked efficiently. More than 80% of CD34$^+$ cells express medium or high levels of CD33, a marker for common myeloid/progenitor cells. We therefore hypothesized that knockout introduction of CD33$^{\Delta E2}$ in these cells by the base editor vector would allow for GO-mediated expansion of edited erythroid cells with reactivated γ-globin. In a first study, CD34$^+$ cells were transduced with the HDAd-ABE8e-sgHBG-sgCD33 vector and cultured for 7 days in low cytokine medium, supplemented with the small molecules SR1 and Ly, which are known to preserve the stemness of CD34$^+$ cells in culture (as reflected by the percentage of CD34$^+$/CD38$^-$/CD90$^+$ cells), thus allowing for target site editing to occur before the start of GO selection. On day 7, cells were subjected to increasing concentrations of GO and then incubated in erythroid differentiation medium for 18 days, or myeloid differentiation medium for 14 days. Editing of the target CD33 and HBG1/2 sites was measured before GO treatment and after GO treatment/*in vitro* differentiation. Preselection editing frequency at day 7 after HDAd transduction were ~3% for the CD33 and HBG1/2 sites, respectively. The relatively low editing rate could be HSC donor related. *In vitro* selection of HDAd-ABE8e-sgHBG-sgCD33-transduced CD34$^+$ cells with GO resulted in 10% and 30% edited CD33 and HBG1/2 alleles, respectively, at the end of erythroid differentiation. This led to an increase of HbF expressing erythroid cells (HDAd transduced: 80% vs non-transduced: 43% HbF$^+$ cells). (Notably, the erythroid differentiation medium actives γ-globin expression to some degree.) A similar increase in editing rates after GO treatment was observed after incubation in myeloid differentiation medium. After 14 days of myeloid differentiation, ~10% of cells were CD33$^{\Delta E2}$, compared to ~2% of non-transduced cells that underwent GO treatment and myeloid differentiation, indicating the expansion of myeloid cells where the base editor had knocked-out the CD33 exon 2. Optimization of the editing efficacy and GO concentrations for selection of double edited CD34$^+$ cells *in vitro* (with additional CD34$^+$ cell donors) and *in vivo,* in humanized mice, are ongoing. Overall, these data indicate that CD33-based selection of edited HSPCs could improve our *in vivo* HSC gene therapy approach.

501 *In Vivo* Transduction of Mobilized Human CD34$^+$ Cells in a Humanized Mouse Model with HDAd5/35++ and HDAd6/35++ Vectors

Aphrodite Georgakopoulou[1], Hongjie Wang[1], Hans-Peter Kiem[2], Chang Li[1], Andre Lieber[1]

[1]University of Washington, Seattle, WA,[2]Fred Hutch, Seattle, WA

We have previously developed a minimally invasive and readily translatable approach for *in vivo* HSC gene delivery without leukapheresis, myeloablation, and HSC transplantation. It involves injections of G-CSF/AMD3100 to mobilize HSCs from the bone marrow into the peripheral blood stream and the intravenous injection of integrating, helper-dependent adenovirus vector systems based on HDAd5/35++ and them, recently developed, HDAd6/35++ platforms. Both vector platforms target CD46, a receptor that is expressed on primitive HSCs. Transgene integration is achieved using a hyperactive *Sleeping Beauty* transposase (SB100x). Current vectors also contain an mgmt^{P140K} expression cassette which allows for *in vivo* selection of transduced HSCs with low-dose O^{6}BG/BCNU. The efficacy and safety of the system has been shown in studies with human CD46-transgenic mice and rhesus macaques. The generation of a humanized mouse model and successful *in vivo* transduction of CD34$^+$ cells are important for the development of new *in vivo* selection approaches that cannot be tested in human CD46tg mice, such as the use of immunotoxins specifically targeting human HSCs receptors or expansion of HSCs using epitope engineering of receptors present on human HSCs. We therefore generated a xenografted mouse model, by transplanting CD34$^+$ cells from healthy donors into NBSGW mice to establish human hemopoiesis. Six weeks post transplantation, CD34$^+$ cells from the chimeric murine bone marrow were successfully mobilized to the periphery by administration of G-CSF (250μg/kg for 6 days) and AMD3100 (5mg/kg for 4 days). The mobilization resulted in 37,448±7,818 circulating human CD34$^+$ cells forty minutes after the last AMD3100 injection. At this time point, mice were intravenously injected with GFP-expressing HDAd5/35++ or HDAd6/35++ vectors. Three days post transduction, no differences between HDAd5/35++-GFP and HDAd6/35++-transduced cohorts were observed in multi-lineage engraftment rates of human cells in bone marrow and spleen. Importantly, the *in vivo* transduction with both HDAd vector resulted in (on average) 10% and 2% GFP marking of CD34$^+$ cells in the bone marrow and spleen, respectively, at day 3 after HDAd injection. GFP marking in non-mobilized animals was not above background. This study shows that *i)* CD34$^+$ cells can be efficiently mobilized in humanized mice, *ii)* mobilized CD34$^+$ cells can be transduced with intravenously injected HDAd vectors targeting CD46, and *iii)* that transduced cells return to the bone marrow and spleen. A 10% marking rate in bone marrow CD34$^+$ cells is a solid basis for testing new in vivo HSC selection/expansion approaches in humanized mice.

502 Engraftment of Hepatocytes Gene-Edited *Ex Vivo* for the Treatment of Inherited Metabolic Liver Disease

Ilayda Ates[1], Tanner Rathbone[1], Callie Stuart[1], Angela Major[2], Mercedes Barzi[3], Shanthi Srinivasan[4], Karl-Dimiter Bissig[3], Renee N. Cottle[1]

[1]Bioengineering, Clemson University, Clemson, SC,[2]Texas Children's Hospital, Houston, TX,[3]Duke University, Durham, NC,[4]Emory University, Atlanta, GA

Background Inherited metabolic diseases (IMD) of the liver occur once in 800 live births and are typically caused by autosomal recessive single-gene mutations resulting in organ intoxication and premature death if untreated. An example of an IMD of the liver is hereditary tyrosinemia type I (HT-1) caused by non-functional mutations in the gene encoding the enzyme fumarylacetoacetate hydrolase (FAH). Liver transplantation represents the only curative therapy for IMDs of the liver; however, the limitations, including severe organ shortages, the life-long requirement for immunosuppressant drugs, and the high risk of mortality, highlight the urgent need for novel therapies. A novel

therapeutic approach consists of ex vivo gene editing using CRISPR-Cas9 nucleases to disrupt the gene encoding 4-hydroxyphenylpyruvate dioxygenase (HPD), an enzyme upstream in the metabolic pathway, in hepatocytes isolated from the patient's resected liver. The gene-edited hepatocytes would be subsequently transplanted into the liver to correct the disease phenotype. Although a promising tool for treating IMDs of the liver, the major challenge of CRISPR-Cas9 is its delivery into hepatocytes. Adeno-associated virus vectors (AAV) are the standard delivery method for introducing CRISPR-Cas reagents, but AAVs are associated with severe safety and efficacy concerns having the potential to hamper the advancement of gene editing therapies in the clinic. Here, we investigate the delivery of CRISPR-Cas9 into hepatocytes using electroporation and evaluate the engraftment of edited hepatocytes in the liver.**Methods** After perfusing the liver using a 3-step enzymatic degradation method to isolate hepatocytes from wild-type C57BL/6 or Fah -/- mice, we used electroporation to deliver Hpd-aiming CRISPR-Cas9 RNPs into hepatocytes. Gene-edited hepatocytes were injected via the spleen into Fah-/- recipient mice. NTBC was cycled on and off to promote engraftment.**Results** In preliminary studies, we optimized the delivery of CRISPR-Cas9 nucleases targeting the Hpd and observed up to 70% on-target activity with 100% survival and complete liver repopulation following splenic injection. We then investigated the effects of CRISPR editing on engraftment as well as the effect of using a cytokine media cocktail after electroporation. In mice transplanted with gene-edited wild-type hepatocytes incubated in cytokine media, we observed up to 47% engraftment, while no cytokine group showed no engraftment (<2%). All the transplant mice were rescued from HT-1. Next, we used CRISPR-Cas9 to disrupt Hpd ex vivo to reprogram the metabolic pathway. We observed an average of 35% engraftment for Hpd-Cas9 RNP and 28% for Hpd-Cas9 mRNA. Hpd protein concentration decreased significantly by 3-fold in both treatment groups. When the viable hepatocyte number was increased, the engraftment level was further boosted to up to 75%. Moreover, we showed that the Hpd knock-down using CRISPR-Cas9 protects Fah-/- mice from liver failure.**Conclusions** The cytokine media is found to be critical for the engraftment capacities of primary hepatocytes after electroporation. Our results indicate that hepatocytes edited using CRISPR-Cas9 delivered by electroporation have the capacity to engraft in the liver and correct acute liver failure a HT-1 mouse model.

503 Glycosaminoglycan-Binding Enhanced Transduction (GET) Peptide Nanoparticles for Cystic Fibrosis Gene Therapy

Daiheon Lee[1], Hoda Eltaher[2], James Dixon[2], Jung Soo Suk[1]

[1]Johns Hopkins University, School of Medicine, Baltimore, MD,[2]University of Nottingham, Nottingham, United Kingdom

Cystic fibrosis (CF), one of the most common genetic diseases, is resulted from a mutation in the gene encoding the CF transmembrane conductance regulator protein. It causes lung epithelial ionic dysregulation and ultimately lung function decline. Given the monogenic nature of CF and the direct accessibility of the lung airways, inhaled gene therapy has been considered attractive and straightforward. However, early clinical trials failed to show a meaningful outcome due to the limited ability of gene vectors to overcome biological barriers, including airway mucus, and to achieve therapeutically relevant gene transfer efficacy. We previously demonstrated that arginine-rich GET peptide (FLR) nanoparticles (NPs) enhanced intracellular delivery of various therapeutic cargos, including nucleic acids. We then showed that surface shielding with polyethylene glycol (PEG) facilitated the penetration of FLR NPs through human lung airway mucus and enhanced transfection efficiency in mouse lungs following intratracheal administration. To further improve the performance of our NPs, we have engineered a mucus-penetrating formulation that includes polyhistidine (FLH) to enhance endosome escape via the proton sponge effect (PEG-FLR/FLH) and compared with previous formulations (FLR and PEG-FLR). All three formulations exhibited similar particle hydrodynamic diameters of ~50 nm (**A**) and the positive surface charge inherent to FLR was neutralized by PEGylation (**B**). The particle morphology and diameter were also monitored by transmission electron microscopy (**C**). We next conducted in vitro studies where we found that PEG-FLR/FLH, despite the surface shielding of the positive charge that promotes cellular uptake, provided greater transfection efficiency compared to branched PEI (bPEI) without significant cytotoxicity (**D**). Our multiple particle tracking analysis revealed that both PEGylated formulations, due to the ability to minimize adhesive interactions with mucus constituents, exhibited markedly greater mobility in CF sputum compared to FLR NPs and polystyrene beads (**E-F**), in agreement with our previous reports. Finally, we conducted an in vivo study where we treated healthy inbred mice with either PEG-FLR or PEG-FLR/FLH carrying luciferase-expressing plasmids via intratracheal administration and evaluated transfection efficiency. The PEG-FLR/FLH provided significantly greater transgene expression compared to PEG-FLR, most likely due to the ability of FLH to promote endosome escape. Encouraged by these outcomes, we are currently pursuing further mechanistic studies and testing our NPs using a mouse model with thickened mucus barrier as shown in the lungs of patients with CF.

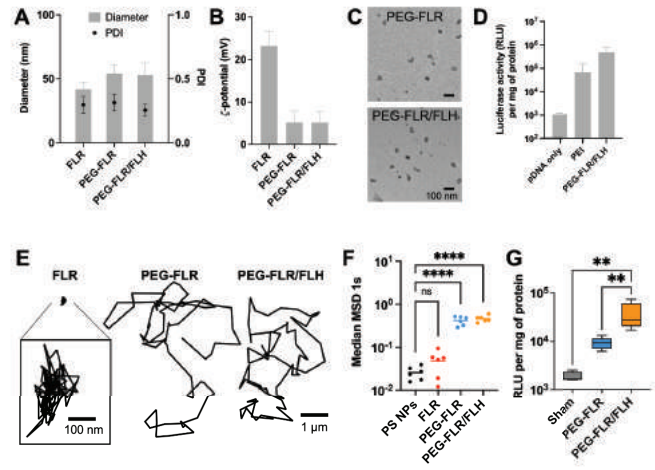


Figure 1. PEG-FLR/FLH provides efficient mucus penetration and lung transfection. Different non-PEGylated or PEGylated peptide-based gene delivery nanoparticles (NPs) were prepared and compared. (**A**) Hydrodynamic diameter, (**B**) zeta-potential, and (**C**) transmission electron micrographs of NPs. (**D**) In vitro transfection efficiency of NPs. (**E, F**) Multiple particle tracking analysis show the ability of NPs to penetrate CF sputum ex vivo. (**E**) Representative trajectories of different NPs moving within CF sputum samples and (**F**) Quantitative analysis. Median mean square displacement (MSD) values

are directly proportional to the particle diffusion rates. (**G**) In vivo luciferase transgene expression in the lung mediated by intratracheal administered NPs.

504 Development and Characterization of New Reporter Mouse Models for *In Vivo* Gene Editing

Kathy J. Snow[1], Caleb Heffner[1], Yaned Gaitan[1], Ethan Saville[1], Lawrence Bechtel[1], Tiffany L. Davis[1], Wolfgang Wurst[2], Ralf Kuehn[3], Stephen A. Murray[1], David E. Bergstrom[1]

[1]The Jackson Laboratory, Bar Harbor, ME,[2]Helmholtz Centre Munich, Neuherberg, Germany,[3]Max Delbruck Center for Molecular Medicine, Berlin, Germany

With the evolution and expansion of therapeutic CRISPR/Cas9 gene editing technologies, reliable, efficient small animal models are needed to evaluate the function of these new tools *in vivo*. To improve on existing reporters such as Ai9, JAX's Small Animal Testing Center (SCGE Consortium) has developed several new gene editing reporter alleles based on a "traffic light" reporter design. The new reporters can be used to detect a variety of DNA repair outcomes following editing with a single guide, including non-homologous end joining (NHEJ), homology-directed repair (HDR) and base editing. These models include PAM sites for multiple Cas9 variants, and in some cases have been designed to bias repair outcomes to improve the rate of reporter activation following an editing event. Each reporter line has been characterized for both baseline reporter functionality in cultured mouse embryos, and has been validated in for *in vivo* somatic gene editing applications through extensive characterization of a standard panel of adult tissues. Together, these new models provide a valuable resource for improved detection of genome editing events and expands the breadth of nucleases and editing outcomes that can be tested *in vivo*.

505 Base Editing Correction of DMD in Human iPSC-Derived Cardiomyocytes and Dystrophic Mice

Chen Zhang, Yuan Zhou, Haiwen Li, Yuanbojiao Zuo, Renzhi Han

Indiana University School of Medicine, Indianapolis, IN

Duchenne muscular dystrophy (DMD) is a devastating muscular disease that is caused by mutations in the *DMD* gene. Gene editing has shown great promise in correcting the genetic base for DMD. In this study, we used base editing to correct a nonsense mutation or to induce exon skipping in order to rescue dystrophin expression. Firstly, we rationally improved the NG-targeting adenine base editor (iABE-NGA) and demonstrated the high efficiency of precisely editing in adult dystrophic mice. Systemic delivery of AAV9-iABE-NGA resulted in dystrophin restoration and functional improvement. At 10 months after AAV9-iABE-NGA treatment, a near complete rescue of dystrophin was measured in *mdx*^{4cv} mouse hearts with up to 15% rescue in skeletal muscle fibers. The off-target activities remained low, and no obvious toxicity was detected. To broaden the applicability of base editing therapeutic approach for DMD caused by large deletions (~68% of all cases), we further explored the feasibility of base editing to induce exon skipping in DMD cardiomyocytes derived from human induced pluripotent stem cells (hiPSCs). We generated a DMD hiPSC line with a large deletion spanning exons 48 through 54 (ΔE48-54) using CRISPR-Cas9 gene editing. Dystrophin expression was disrupted in DMD hiPSC-derived cardiomyocytes (iCMs) as detected by RT-PCR, Western blot, and immunofluorescence staining. Co-transfection of ABE and a guide RNA (gRNA) targeting the splice acceptor led to efficient conversion of AG to GG (35.9% ± 5.7%) and enabled exon 55 skipping. Complete AG to GG conversion in a single clone restored dystrophin expression (42.5% ± 11% of wild type [WT]) in DMD iCMs. Moreover, we demonstrated the efficiency of inducing exons 6, 7, 8, 43, 44, 46, and 53 skipping in iCMs. These results highlight base editing with iABE-NGA as a promising therapeutic approach for DMD.

506 Epigenetic Editing of the CDKL5 Gene in Mouse and Human Cells

Julian Halmai, Jennifer Waldo, David Cameron, Casiana Gonzalez, Mandeep Singh, Jill Silverman, Kyle D. Fink

UC Davis, Sacramento, CA

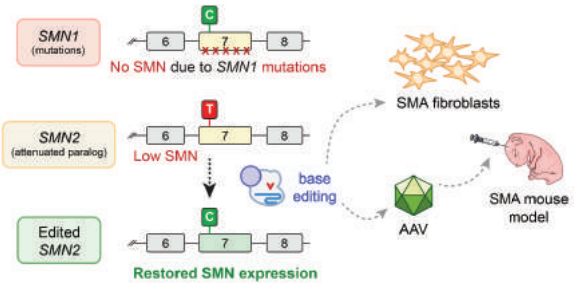
CDKL5 deficiency disorder (CDD) is an early infantile epilepsy and X-linked intellectual disability caused by de novo mutations in the CDKL5 gene. In female somatic cells, one copy of CDKL5 becomes epigenetically silenced by X chromosome inactivation (XCI). In cells expressing the mutant allele, reactivation of wildtype *CDKL5* could present a paradigm shift in the treatment of X-linked disorders by partially or fully restoring disease-associated phenotypes. In 2021, a landmark paper demonstrated that conditional restoration of *Cdkl5* using a genetic mouse model could reverse functional deficits across multiple domains even in adult mice. These results demonstrate the utility of restoration of *Cdkl5* as a treatment for CDD. We have previously demonstrated that targeted *CDKL5* reactivation is feasible in human neuronal-like cells using a dCas9 epigenetic editor. In addition, we have demonstrated that AAV delivery of such epigenetic editors is possible in the mouse brain. Our studies found that AAV particles containing epigenetic editors both result in significant *Cdkl5* upregulation and targeted removal of methylation from the mouse *Cdkl5* promoter. Our experiments utilize an improved AAV cassette that reduce viral packaging size through the use of a split dCas9, small promoters and a synthetic polyA signal and the use of a sgRNA-tRNA cassette that allows expression from a single U6 promoter. Ongoing studies address rescue of phosphorylation substrates EB2 and MAP1S. In addition, lentiviral delivery of our novel dCas9 editors to patient-derived neuronal stem cells and induced neurons has been used to measure *CDKL5* promoter methylation changes and gene reactivation. In addition, long-term exposure of lentiviral particles has been used to address rescue of the known CDKL5 phosphorylation substrates. This approach holds great promise for those affected by CDD.

507 PAMless Base Editors as a Genetic Treatment for Spinal Muscular Atrophy

Christiano R. R. Alves[1], Ha L. Leillani[2], Rebecca Yaworski[3], Cicera R. Lazzarotto[4], Kathleen Christie[1], Aoife Reilly[3], Ariane Beauvais[3], Roman M. Doll[5], Demitri de la Cruz[2], Casey A. Maguire[6], Kathryn J. Swoboda[1], Shengdar Q. Tsai[7], Rashmikant Kothary[8], Benjamin P. Kleinstiver[1]

[1]Massachusetts General Hospital & Harvard Medical School, Boston, MA,[2]Massachusetts General Hospital, Boston, MA,[3]Ottawa Hospital Research Institute, University of Ottawa, Ottawa, ON, Canada,[4]St. Jude Children's Research Hospital, Memphis, TN,[5]Massachusetts General Hospital, Heidelberg University, German Cancer Research Center (DKFZ), Boston, MA,[6]The Massachusetts General Hospital, Charlestown, MA,[7]St. Jude Children's Research Hospital, Memphis, TN,[8]Ottawa Health Institute, Ottawa, ON, Canada

Spinal muscular atrophy (SMA) is a devastating neuromuscular disease caused by mutations in the SMN1 gene. Despite the development of various therapies, outcomes can remain suboptimal in SMA infants and the duration of such therapies are uncertain. SMN2 is a paralogous gene that mainly differs from SMN1 by a C•G-to-T•A transition in exon 7, resulting in the skipping of exon 7 in most SMN2 transcripts and production of only low levels of survival motor neuron (SMN) protein. Genome editing technologies targeted to the SMN2 exon 7 mutation could offer a therapeutic strategy to restore SMN protein expression to normal levels irrespective of the patient SMN1 mutation. Here, we optimized a base editing approach to precisely edit SMN2, reverting the exon 7 mutation via an A•T-to-G•C base edit. We tested a range of different adenosine base editors (ABEs) comprised of engineered TadA domains and CRISPR-Cas9 enzymes, and observed the most specific editing (with minimal bystander editing) when using the PAMless enzyme ABE8e-SpRY. In SMA patient-derived fibroblasts, we observed up to 99% intended editing with concomitant increases in SMN2 exon 7 transcript expression and SMN protein levels. We generated and characterized ABEs fused to high-fidelity Cas9 variants which reduced potential off-target editing in HEK 293Ts, and also observed only very low-level off-target editing in SMA fibroblasts. Delivery of these optimized ABEs in vivo via dual adeno-associated virus (AAV) vectors resulted in precise SMN2 editing in an SMA mouse model. This base editing approach to correct SMN2 should provide a long-lasting genetic treatment for SMA with advantages compared to current nucleic acid, small molecule, or exogenous gene replacement therapies. More broadly, our work highlights the potential of PAMless SpRY base editors to install edits efficiently and safely.



508 Nanopore Sequencing Identifies Miscellaneous Insertion Events after Double-Cut Donor-Mediated *In Vivo* CRISPR Editing

Juanjuan Zhao[1], Xinyu Sun[1], Zongze Zhao[2], Mengdi Yin[1], Mei Zhao[1], Feng Zhang[1], Siang Li[1], Saining Tian[1], Wei Wen[1], An Gong[2], Tao Cheng[1], Jianping Zhang[1], Xiaobing Zhang[1]

[1]State Key Laboratory of Experimental Hematology, Haihe Laboratory of Cell Ecosystem, Institute of Hematology & Blood Diseases Hospital, Peking Union Medical College, Tianjin, China,[2]College of Computer Science and Technology, China University of Petroleum (East China), Qingdao, China

CRISPR-Cas9-enabled precise insertion of a large transgene in target cells is transformative to in vivo gene therapy of numerous diseases, such as hemophilia A. Expression of B-domain-deleted F8 by hepatocytes has clinically demonstrated to be effective to this hemostasis disorder, while the safety concerns of gene editing still hamper its wide application. Multiple approaches developed before addressed off-target effects and large deletions using Illumina or nanopore sequencing (NP-seq). However, on-target integration of a large fragment has yet to be comprehensively documented, particularly in *in vivo* editing, where template integration is often inefficient. To address this challenge, we developed an approach to characterize the complexity of inserted sequences at a CRISPR-targeted locus. Previously, in a hemophilia A mouse model, we showed that hydrodynamic injection of an F8 double-cut donor and CRISPR plasmids induced integration of BDDF8 at Alb locus at an efficiency of ~1% and restored the F8 to normal levels. This model allowed us to investigate the insertions in the liver. Optimizing long-range PCR allowed us to amplify 5-10 kb flanking the *Alb* target site. Still, NP-seq showed only ~0.05% of reads with donor insertion due to biased amplification of short background sequence. Therefore, we treated DNA with the RNP complex of Cas9-sgAlb and observed a 10-fold enrichment of reads with donor insertion. We designed primers amplifying a ~400-bp background to deplete the unwanted alleles further. Two rounds of 0.4x Magbeads purification of the 1st PCR product led to over 100-fold depletion of short fragments. However, we observed 5-10 times higher read numbers with plasmid backbone (BB; ~2 kb) than the F8 cassette (~6 kb). To attenuate the preferential BB amplification, we treated 1st PCR product with a BB-targeting RNP and observed more balanced events. To enable pooled NP-seq, we used primers with 12-bp indel-correcting barcodes for 2nd PCR. We also developed an algorithm to retrieve data from pooled NP-seq data, with an over 50% recovery and less than 0.1% false discovery rate (FDR), and a pipeline termed GREPore-seq for demultiplexing, quality control, and data visualization. Using the optimized protocol, ~80% of reads contained inserts. As expected, most insertions were BB or F8 in forward or reverse orientation due to intracellular linearization of the double-cut donor. We also observed the insertion of 2 or 3 pieces at the DNA break site, albeit at low frequencies. Among the possible 80 patterns of two and three fragments of donor plasmid integrations, we detected 55. Besides, the insertion of Cas9-sgRNA plasmid fragments was found in ~0.01% of reads. Consistent with previous work, we also found that ~0.01% of inserts originated from mouse chromosomes, and ~0.002% of events might be mediated by LINE-1 reverse transcriptase. Together, our data demonstrate that CRISPR cleavage enables the effective insertion of donor sequences, but a trace amount of genomic fragments and LINE sequences are

incorporated at DSB sites. Reassuringly, no abnormalities in the liver and other organs had been observed in over 100 mice that had been followed up on for 1 year. In conclusion, for the first time, our study unveils the complex CRISPR-mediated on-target insertion outcome after in vivo gene editing therapy. This robust, affordable Insert-seq approach will find its application in AAV gene therapy for identifying the integration spectrum of AAV.

509 Prime Editing Leads to Phenotypic Correction in a Novel Mouse Model of Fanconi Anemia

Lu Liu[1], Astrid Glaser[1], Kirsten Fairfax[2], Debora Arcieri Casoloari[3], Elissah Granger[1], Wayne Crismani[1], Richard D' Andrea[3], Thomas Gonda[3], Jörg Heierhorst[1], Andrew J Deans[1]

[1]St Vincent's Institute of Medical Research, Melbourne, Australia,[2]Menzies Institute for Medical Research, Tasmania, Australia,[3]University of South Australia, Adelaide, Australia

Fanconi anemia (FA), resulting from germline mutations in DNA repair genes of the FA/BRCA pathway, is the most prevalent inherited bone marrow failure disorder. The only approved treatment for FA is hematopoietic stem cell (HSC) transplant from a healthy donor, but severe post-transplantation complications are common, and in some cases lethal. To overcome these risks, *in vivo* or *ex vivo* gene editing of autologous HSCs to correct the underlying mutation has been proposed. As the defining DNA repair defect of FA cells precludes homologous recombination-dependent gene editing, we have implemented *in vitro* prime editing in primary HSCs from a novel mouse model with an human FA patient mutation (FancL^{TATdel}).Mice that are homozygous for the FancL^{TATdel} allele display abnormalities consistent with human FA, including reproductive defects, hypersensitivity to the DNA damaging agent mitomycin C, and reduced hematopoietic stem and progenitor (LSK+) cell numbers in older mice. We utilized HOXA9 immortalized myeloid cells derived from FancL^{TATdel} mice, or an EGFP reporter mouse, to optimize conditions for delivery of prime editing enzymes. Using mRNA encoded Prime editor we accomplished highly efficient gene editing (3%) and restoration of mitomycin C resistance. We next established a protocol to expand HSCs (up to 5 x10^5/mouse) from either FancL^{TATdel} adult bone marrow or fetal liver cells in serum-free media. In these *in vitro* expanded HSCs we demonstrated similar editing efficiency (3%) with higher resistance to mitomycin *in vitro* following selection (enriched to 44% of the whole population). We also achieved high levels of *in vitro* editing in other cell types, such as primary and immortalized fibroblasts. In all cases, restoration of just a single allele can restore normal FA/BRCA1 pathway function.Overall, our findings illustrate that a causative FA mutation associated with loss of the FA/BRCA pathway does not prohibit prime editing-mediated gene correction. Corrected cells behave as wild-type in all *in vitro* assays tested, and *in vivo* transplantation experiments are ongoing. The FancL^{TATdel} mouse model is the first model of FA with an human patient mutation, and will be a useful pre-clinical model to further explore the potential of gene editing in the treatment of bone marrow failure syndromes.

510 Circular Single-Stranded DNA is a Superior Homology-Directed Repair Donor Template for Efficient Genome Engineering

Keqiang Xie, Jakob Starzyk, Ishita Majumdar, Katerina Rincones, Thao Tran, Sarah Niemi, Richard Shan, Howard Wu

Full Circles Therapeutics, Inc., Cambridge, MA

The toolbox for genome editing in basic research and therapeutic applications is rapidly expanding. While efficient targeted gene ablation using nuclease editors has been demonstrated from bench to bedside, precise transgene integration remains a technical challenge. AAV6 has been a prevalent donor carrier for homology-directed repair (HDR) mediated genome engineering but has reported safety issues, manufacturing constraints, and restricted applications due to its 4.5 Kb packaging limit. Non-viral targeted genetic knock-ins rely primarily on double-stranded DNA (dsDNA) and linear single-stranded DNA (lssDNA) donors. Both dsDNA and lssDNA have been previously demonstrated to have low efficiency and cytotoxicity. Here, we developed a non-viral genome writing catalyst (GATALYST^{TM}) system which allows production of ultrapure, minicircle single-stranded DNAs (cssDNAs) up to ~20 Kb as donor templates for highly efficient precision transgene integration. cssDNA donors enable knock-in efficiency of up to 70% in induced pluripotent stem cells (iPSCs), superior efficiency in multiple clinically relevant primary cell types, and at multiple genomic loci implicated for clinical applications with various nuclease editor systems. When applied to immune cell engineering, cssDNA engineered CAR-T cells exhibit more potent and durable anti-tumor efficacy than those engineered from AAV6 viral vectors. The exceptional precision and efficiency, improved safety, payload flexibility, and scalable manufacturability of cssDNA unlocks the full potential of genome engineering with broad applications in therapeutic development, disease modeling and other research areas.

511 lgRNA-Guided Precise CRISPR Gene Editing for the Cure of Chronic HBV Infection

Minghong Zhong[1], Qiong Zhao[2], Xiaoyun Lin[1], Ranga Srinivasan[1], Ju-Tao Guo[2]

[1]GeneLancet Biosciences, Inc., Doylestown, PA,[2]Baruch S. Blumberg Institute, Doylestown, PA

Prior studies reported in the literature support the possibility of eliminating hepatitis B virus (HBV) covalently closed circular DNA (cccDNA) by the clustered regularly interspaced short palindromic repeats (CRISPR) gene editing for the cure for chronic hepatitis B. However, the achievement of this therapeutic goal requires further improvement of the CRISPR editors and hepatocyte-targeted delivery technologies. Specifically, the cure of chronic HBV infection requires high in vivo editing efficiency to eliminate or inactivate the vast majority of cccDNA to allow the ultimate clearance or complete control of residual viral infection by human immune responses. The off-target editing, as well as on-targeting cleavage of integrated HBV DNA in cellular chromosomes, introduce unintended genetic changes in patients. In addition, due to the relatively low editing efficiency, multiple doses of current CRISPR/Cas therapeutics are most likely required for significant reduction of the cccDNA pool in the liver, which may be limited by the immunogenicity of the CRISPR

ribonucleoprotein (RNP) complexes and of their delivery vehicles such as adeno-associated viruses (AAV). Improvement of guide RNAs is of crucial importance for advancing CRISPR gene editing for the treatment of diseases, including chronic HBV infection. Chemically ligated guide RNA (lgRNA) is a next-generation single-molecule guide RNA (sgRNA) for precise gene editing by CRISPR-associated proteins (Cas). LgRNAs are produced by robust, convergent, and scalable chemical synthesis via efficient chemical ligations of short RNA segments readily accessible by solid phase synthesis. By this method, 196-mer lgRNAs were synthesized. This new technology not only makes manufacturing long RNAs cost-effective but also gives access to high-quality validated full-length products with much fewer synthetic errors at the critical spacer segment than classic sgRNA. Obviously, it enables cost-effective global chemical modifications for better efficacy, selectivity, and stability, as well as targeted delivery by molecular tagging and other formulation technologies. Thus far, we have synthesized and evaluated more than 50 ultra-pure chemically modified lgRNAs. CRISPR-Cas9 guided by these lgRNAs efficiently cleaved target DNAs in vitro and edited HBV cccDNA as well as integrated HBV DNA in human hepatoma cells supporting HBV replication and gene expression. Particularly, our cell-based studies showed that a single transfection of one single lgRNA edited more than 80% of cccDNA and integrated HBV DNA and reduced the levels of HBV surface antigen (HBsAg) and e antigen (HBeAg) by approximately 90%, targeting at various regions of HBV genome respectively. One highly potent lgRNA was identified (99% reduction in both HBsAg and HBeAg levels). Progress in the development of an lgRNA-guided STAR (Search-Tag-Amend-Release) editing platform to overcome the existing barriers to HBV DNA editing therapeutics will also be presented.

512 Environment Social Governance Solution for Fluorescence-Labeled ssDNA Fragment Analysis Using Denature Microfluidics Capillary Electrophoresis, an Application for CRISPR Enzyme Study

Yali Sun, Zhi-xiang Lu, Anis Khimani, Yanhong Tong
PerkinElmer Health Science Inc., Waltham, MA

For research use only. Not for use in diagnostic procedures. **Introduction:** Capillary electrophoresis (CE) and microfluidic CE (MCE) have been widely used in nucleic acid fragment analysis. In studies of nucleic acid modification enzymes such as CRISPR enzymes, PCR amplification analysis, where one strand of nucleic acid substrate needs to be analyzed, denaturing CE has been the common method. We have demonstrated the formamide denaturing MCE to characterize CRISPR-Cas9 genome-editing efficiency using fluorescence-labeled fragments as the substrate. Although formamide is a standard nucleic acid denaturing chemical, it is a reproductive toxin and is regulated as "danger" in Safety Data Sheet (SDS), with stringent exposure limits by EU regulatory guidelines. Besides, artifact peaks due to incomplete denaturation often occur in denaturing CE, which interfere with the accuracy of fluorescence-labeled ssDNA analysis. This study was designed to evaluate an environment green denaturing chemical and a new method for reducing artifact peaks in MCE. **Method and Result:** PerkinElmers platforms, LabChip® GXII Touch™ (Part# CLS138160), FFA 120 reagent (Part#: CLS158081), and DNA 5K/RNA/CZE HT LabChip (Part#:760435) were used in the study. The artifact peaks were observed in MCE with DMSO as the denaturing reagent (Figure 1). Mainly two peaks are observed for the 3 tested PCR products (120bp, 200bp, 500bp) prepared with one primer labeled by Cy5 at 5' end (Figure 1A). The slower-migrating peak is the ssDNA product, and the faster-migrated peak is the dsDNA product. After the Lambda exonuclease treatment of digesting the strand without fluorescence labeling and purification, only the slower-migrating ssDNA peak is detected (Figure 1B). The dsDNA artifact peaks can be reduced by adding chelators e.g. EDTA (Figure 2). The peak percentage of dsDNA artifact is reduced substantially with the increase of EDTA. When the EDTA amount is equal to or higher than the magnesium concentration in the sample (4mM), there is no obvious difference (over 5%) of heat treatment on further reducing artifacts. **Conclusion:** This study proves that DMSO, which is nontoxic, and recyclable, can be used as a denaturing reagent for MCE system and the dsDNA artifact peaks can be reduced by adding a certain amount of EDTA into the sample without the need for additional heat denature. As an Environment · Social · Governance (ESG) solution, it has direct, positive impact on the environment and reduces hazardous waste from daily research.

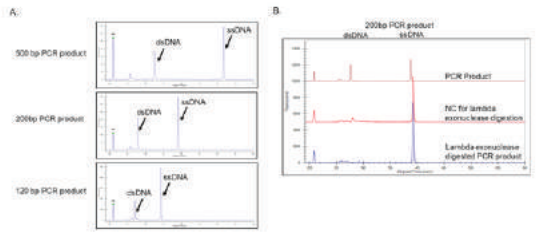


Figure 1: dsDNA artifact peaks in DMSO-mediated denaturing MCE system. A. 3 PCR products; B. 200bp PCR product with different treatments.

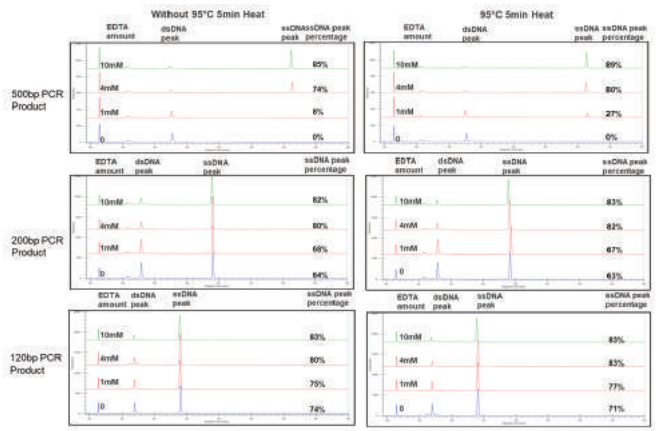

Figure 2. EDTA reduces dsDNA artifacts in DMSO-mediated denaturing MCE without the need for 95°C heat denature.

513 Pin-point™ Base Editing System: A Versatile Editing Platform Driving Cell Therapies

Anastasia Lomova Kaufman[1], Bronwyn Joubert[2], Robert Blassberg[2], Jennifer Harbottle[2], Olga Mielczarek[2], Paul Russel[2], Jesse Stombaugh[1], John Lambourne[2], Kevin Hemphill[1], Matthew Perkett[1], Žaklina Strezoska[1], Anja van Brabant Smith[1], Immacolata Porreca[2]

[1]Horizon Discovery, a PerkinElmer Company, Lafayette, CO,[2]Horizon Discovery, a PerkinElmer Company, Cambridge, United Kingdom

Gene editing technologies have successfully been used to improve the next generation of cell and gene therapies. However, standard gene editing platforms such as CRISPR-Cas9 trigger concerning cell toxicity and off-target effects due to the formation of DNA double-strand breaks (DSBs) that could hinder wider clinical applications. Base editing offers an ability to correct disease-causing mutations or knock out genes in a multiplexed manner, without introduction of DSBs. The first cohort of base editing therapeutics entered clinical trials only a few years after the development of the technology. Horizon's modular Pin-point base editing system, uses a nickase Cas9 with an aptameric guide RNA to recruit a deaminase to the site of interest, facilitating highly efficient and precise nucleotide conversion. We optimized design and delivery conditions of chemically modified synthetic guide RNAs and enzymatic mRNA to apply multiplex editing with our Pin-point base editing system to the development of engineered CAR-T cells. We target a set of therapeutically relevant loci for the development of allogeneic CAR-T cells achieving high knockout efficiency and editing purity at all sites simultaneously with a safer editing profile and enhanced cell viability compared to traditional nuclease systems. Our technology also enables robust simultaneous targeted knock-in and multiplex knockout without the requirement of additional sequence-targeting components. The ability to perform complex genome editing in multiple cell types (such as T cells, iPSCs, HSCs) safely, efficiently, and precisely opens the door to the application of the Pin-point system in a range of advanced cell therapies.

514 CRISPR/dCas9 Mediated Epigenetic Modifications in CASK-Related Disorders

Casiana E. Gonzalez, Julian Halmai, Kyle D. Fink

Center for Interventional Genetics, MIND Institute, Stem Cell Program and Gene Therapy Center, UC Davis, Sacramento, CA

CASK-related disorders are caused by mutations in an important regulatory gene in the brain, calcium/calmodulin-dependent serine protein kinase (CASK) and can result in microcephaly with pontine and cerebellar hypoplasia (MICPCH), in addition to intellectual disability, and seizure activity. CASK-related Intellectual Disabilities (CASK-ID) predominantly affect the female population and are classified as X-linked neurodevelopmental disorders. CASK-ID is typically the result of a *de novo* loss of function mutation. As females have two X-chromosomes, disease causing mutations present with a 50/50 expression of mutant and wildtype, due to the mosaicism caused by random X-chromosome inactivation (XCI). This mosaicism presents an interesting therapeutic option of reactivating the intact allele in affected neurons.Previously, the Fink lab has shown the ability to target *CDKL5* in human neuron-like cells and reactivate the XCI-silenced allele using our CRISPR/dCas9 epigenetic approach. Our current goals are to optimize this approach with a smaller split-CRISPR orthologue, sadCas9, to meet the packaging limit of an Adeno-associated Virus (AAV). We also aim to apply this epigenetic rescue technology in disease relevant cell lines and eventually in patient-derived iPSC neurons. We aim to accomplish this through cloning and testing sadCas9 with identified guide RNAs to target the *CASK* promoter. Constructs will be tested for optimal targeting efficacy and assessed through gRNA screens measured via RT-qPCR. Additionally, epigenetic modifications from our approach will be analyzed through bisulfite sequencing. Currently, the lead guide RNAs were evaluated in HEK293Ts and fibroblasts that contain a coding SNP to measure reactivation.Our results show the ability to target *CASK* and assess gene expression changes with sadCas9 and paired epigenetic modifier. This shows the potential for sadCas9 to be utilized for epigenetic editing and the potential for a therapeutically relevant delivery of the CRISPR/dCas9 system. This project will allow for a therapeutic platform that can be more readily packaged in an AAV delivery method and applied to CASK-related disorders.

515 Molecular Dynamics of Genome Editing with CRISPR/Cas9 and rAAV6 Virus in Human HSPCs to Treat Sickle Cell Disease

Liwen Xu[1], Premanjali Lahiri[2], Jason Skowronski[3], Neehar Bhatia[4], Annalisa Lattanzi[5], Matthew H. Porteus[6]

[1]Pediatrics, Stanford Univ. School of Medicine, Stanford, CA,[2]Graphite Bio, Sunnyvale, CA,[3]Graphite Bio, South San Fransisco, CA,[4]Stanford Laboratory of Cell and Gene Medicine, Palo Alto, CA,[5]Genentech, South San Francisco, CA,[6]Stanford University School of Medicine, Stanford, CA

Since the discovery of CRISPR/Cas9 system in 2012 as a tool to make DNA double-strand breaks, genome editing has exploded as a research tool. Moreover, gene therapy with CRISPR/Cas9 has risen as a promising and powerful therapeutic approach for many diseases which previously were untreatable or for which suboptimal treatments were available, particularly in genetic disorders. Currently, an increasing body of clinical trials have been opened worldwide with CRISPR/Cas9 system operating a variety of genomic modifications, and promising results of safety and efficacy have been achieved in some of these clinical trials. A better understanding of molecular changes and cellular responses during and after CRISPR/Cas9 genome editing *ex vivo* in clinically relevant cells is vital to ensure the progress and success of this technology. Sickle cell disease (SCD) is the most common serious monogenic disease with 300,000 births annually worldwide. It is an autosomal recessive disease resulting from a single nucleotide variant in codon six of the β-globin (HBB) gene. Currently, the only curative treatment of SCD is allogeneic hematopoietic stem cell transplantation (allo-HSCT). However, HLA-matched donors are limited, and graft-vs-host disease (GVHD) may occur after allo-HSCT. *Ex vivo* gene correction in autologous hematopoietic stem/progenitor cells (HSPCs) with CRISPR/Cas9 and rAAV6 (a recombinant adeno-associated virus serotype 6) virus as DNA donor template to treat SCD has now entered early-phase clinical investigation with the aim of proving feasibility, safety and efficacy of editing the disease-causing mutation in HBB gene with CRISPR/Cas9 and rAAV6 (NCT04819841). To better understand the molecular mechanism of genome editing with CRISPR/Cas9 and

rAAV6, and to ensure the safety of genome edited drug products, we developed sensitive assays for detecting changes of manufacturing reagents and for cellular responses during and post genome editing. In this study we demonstrated 1) The remarkable stability and activity preservation of the rAAV6 donor template virus after multiple freeze/thaw cycles or storage at 4°C or storage at room temperature. 2) Better genome editing outcomes when frozen mobilized peripheral blood HSPCs were pre-stimulated for 72 hours compared to 48 hours with better cell survival and higher number of gene corrected cells without compromising stem cell properties and engraftment efficiency. 3) The transient activation of p53 pathway in human HSPCs invoked by all genome editing machinery components peaking at 6 hours post genome editing treatment and remaining partially activated at 48 hours post genome editing. 4) Dynamic changes of rAAV6 capsid and Cas9 proteins during and after HBB gene editing with no detectable residual rAAV6 capsid proteins and a trace amount of residual Cas9 protein in the cells at the completion of manufacturing. These findings will be beneficial to better understanding the molecular mechanism of *ex vivo* genome editing in HSPCs, and they will also provide important insights into the development and application of CRISPR/Cas9/rAAV6 genome editing and highlight some of the current safety and efficacy properties of the process.

516 Newly Discovered and Engineered CRISPR-Associated Nucleases as a Robust, Efficient, Allele- and Target-Specific Editing Tool

Milit Marom[1], Shira Warszawski[1], Liat Rockah[1], Nir Hecht[1], Nir Shpak[1], Rivkah Rogawski[1], Shir Weber[1], Veronica Moskovicz[1], Bar Dagan[1], Dotan Omer[1], Roy Sirkis[1], David C. Dale[2], Asael Herman[1], Rafi Emmanuel[1], Lior Izhar[1]

[1]Emendo Biotherapeutics, Rehovot, Israel,[2]Department of Medicine, University of Washington, Seattle, WA

CRISPR-based gene editing holds great promise for curing various medical conditions. However, several limitations in current CRISPR-Cas systems restrict harnessing the full potential of genome-wide editing. First, commonly used nucleases share a narrow repertoire of PAM recognition motifs, limiting the range of genomic targets. Second, editing efficiency is occasionally insufficient to achieve the desired goal. Third, off-target effects remain a major concern in most CRISPR-Cas systems. In particular, achieving allele-specific editing, required for treating diseases caused by dominant negative mutations, is a highly challenging goal. To address these challenges, we first used *in silico* analysis of metagenomic databases, and discovered a large number of novel nucleases that are active in mammalian cells. Importantly, these nucleases have diverse PAM recognition domains, thereby enabling gene-editing of genomic sequences that are inaccessible by commonly used nucleases. Our unique engineering platform enabled us to further optimize one of our leading nucleases, which already showed intrinsic high fidelity and activity when tested in mammalian cells. This resulted in improved variants that perform highly efficient, allele-specific editing - up to a single nucleotide difference - with no detectable off-targets. These proprietary engineered variants are currently under clinical development for an *ex vivo* gene editing strategy for severe congenital neutropenia (SCN), which involves specific excision of the disease-causing mutant allele of the *ELANE* gene. Our results demonstrated that monoallelic *ELANE* knockout, using our engineered nuclease, alleviated the major SCN related abnormality in patient-derived hematopoietic stem cells, and resulted in maturation of the edited cells into active neutrophils. Thus, our nuclease discovery and engineering platforms establish a comprehensive approach that offers efficient, high fidelity gene editing at unique targets. This strategy could potentially be available to broad patient populations suffering from a range of genetic disorders.

517 Generative Machine Learning Enables De Novo Guide RNA Design for Precise RNA Editing

Yue Jiang[1], Lina Bagepalli[2], Bora Banjanin[1], Katie Rupp[1], Yiannis Savva[1], Brian Booth[2], Ron Hause[1]

[1]Shape Therapeutics, Seattle, WA,[2]Shape Therapeutics, Brookline, MA

RNA editing mediated by adenosine deaminase acting on RNA (ADAR) unlocks a diverse set of molecular and therapeutic modalities, including the correction of pathogenic G-to-A mutations that underlie many monogenic diseases. The recruitment of endogenous ADAR enzymes by guide RNAs (gRNAs) antisense to a target transcript can allow for precise adenosine-to-inosine (A-to-I, effectively A-to-G) editing at the RNA level. However, the therapeutic potential of this process has been limited due to two factors: ADAR's natural preference to edit adenosines within certain sequence contexts, and its proclivity to edit multiple adenosines in a given dsRNA substrate. Here, we demonstrate the power of combining high-throughput screening (HTS) and generative machine learning (ML) to rapidly engineer novel gRNAs *de novo* to any target of interest. To expand the potential of RNA editing, we sought to design a gRNA capable of recruiting ADAR to selectively edit multiple adenosines. The introduction of three separate A-to-I edits spanning four nucleotides within the coding sequence of APP leads to amino acid substitutions K670G and M671V, which are predicted to decrease BACE1 cleavage and decrease accumulation of amyloid plaques, accumulation of which is a hallmark of Alzheimer's disease. Two of the target adenosines have a 5' guanosine neighbor, a strong editing dispreference of ADAR, adding to the design challenge. Despite an initial screening of nearly 58,000 gRNAs, none were able to edit all three sites simultaneously. However, input optimization on a convolutional neural network (CNN) generated novel gRNAs predicted to have >30% editing across all three sites in tandem, which were then experimentally validated (Figure 1). This generative approach yielded gRNAs with improved tandem editing compared with more traditional sample-and-score "exhaustive" ML approaches. Next we extended generative ML to gRNAs targeting any novel adenosine of interest. We constructed a library of >50,000 gRNAs targeting >5,600 clinically relevant adenosines, with a median of nine gRNAs per target. A target-stratified CNN achieved strong predictive power for editing in genes withheld from the validation set (Figure 2). The model further validated on a separate, single target empirical data set of >20K gRNAs (rho = 0.5-0.7) and allowed us to establish a "target editability" score to flag hard-to-edit adenosines for generative gRNA design prioritization. Overall, our results demonstrate the effectiveness of HTS coupled with generative ML for designing gRNAs for ADAR editing of novel targets.

Ongoing efforts include incorporating transformer architectures of DNA and RNA structure. The ability to rapidly program precise and safe ADAR gRNAs has the potential to significantly advance the development of therapies for monogenic diseases.

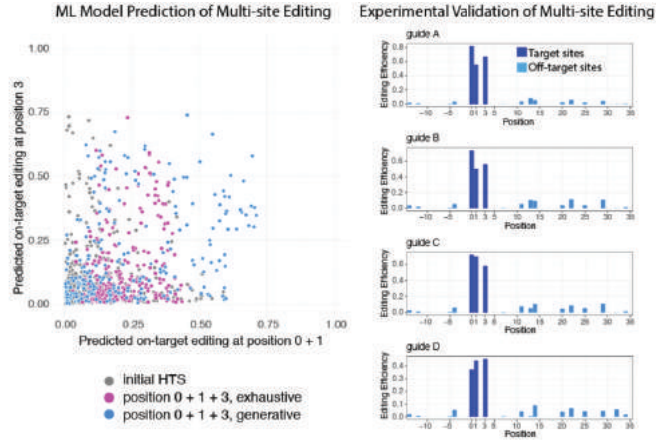

Figure 1 Generative designs identified gRNAs that were predicted and validated to achieve position 0, +1, and +3 co-editing of APP.

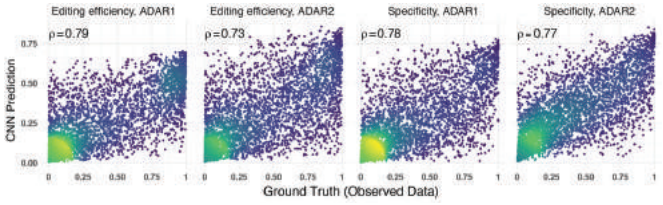

Figure 2 Target-stratified CNNs predict ADAR editing across diverse, withheld targets.

518 Development of Minicircle-Based Non-Viral Delivery of Cytosine Base Editors

Melissa M. Evans[1,2], Shirley Liu[1,2], Timothy J. Scholl[1,2], John A. Ronald[1,2]

[1]Medical Biophysics, Western University, London, ON, Canada,[2]Robarts Research Institute, London, ON, Canada

Introduction: CRISPR/Cas has revolutionized genome editing over the past decade. Cytosine base editors (CBEs) can edit DNA without double strand breaks by converting a cytosine (C) base to a thymidine (T) using a cytosine deaminase enzyme linked to Cas9 nickase[1]. A major limitation of all CRISPR technologies is how to safely and effectively deliver them to tissues of interest. The most commonly used delivery tool for BEs are adeno associated viruses (AAVs)[2]. With limited capacity and immunogenicity concerns at high doses, alternative methods for CBE delivery should be explored[2]. Non-viral minicircles (MCs) are derivatives of plasmids that lack a prokaryotic backbone, making them smaller with improved delivery and safety profiles[3]. In this study, we explored the use of MCs for CBE delivery[3]. **Methods:** We engineered parental plasmids (PPs) and MCs containing a third generation CBE or a Cas9 (control) plus appropriate guideRNA (PP-CBE, MC-CBE, PP-Cas9, MC-Cas9). To evaluate BE activity, we employed a previously described activatable reporter gene tool, the Gene On (GO) system[4]. In this, green fluorescent protein (GFP^{GO}) or firefly luciferase ($LUC2^{GO}$) are encoded with a mutated start codon to prevent translation. When the mutation is corrected by a CBE, it allows for direct visualization of BE activity. HeLa cells were transduced with GFP^{GO} or $LUC2^{GO}$ lentiviral vectors to produce stable cells expressing the mutated reporter genes (a constitutive red fluorescent protein was used for FACS). Hela cells were transfected with either PP-CBE, MC-CBE, PP-Cas9, or MC-Cas9. For GFP^{GO} cells, the fluorescent expression of GFP was measured continually for 72 hours using the Incucyte® Live-Cell Analysis Systems. For $LUC2^{GO}$ cells, activity was assessed 48 hours post transfection by bioluminescence imaging (BLI) using a Newton imaging system. **Results:** Substantially more GFP^{GO} cells expressed GFP after transfection with MC-CBE (10.5%) compared to PP-CBE (3%) after 72 hours, and the kinetics of the reaction shows MC-CBE activation occurs more rapidly (Fig 1B). Additionally, transfection of cells with PP-Cas9 and MC-Cas9 showed minimal GFP expression. $LUC2^{GO}$ cells transfected with MC-CBE had significantly higher BLI signal than cells transfected with PP-CBE, PP-Cas9, and MC-Cas9 ($p<0.01$) (Fig 1D). **Conclusions:** Our data supports improved base editing efficiency in cancer cells using MCs encoding both a CBE and gRNA over traditional plasmids. MCs provide an alternative to viral delivery systems and have been associated with excellent safety profiles that might expedite clinical translation. We are currently evaluating the use of MCs to deliver CBEs targeted to genes of interest across a range of cancer cell types both in vitro and in vivo, and for targeted CBE delivery to tissues of interest such as the lungs and liver.

519 Allele-Specific CRISPR Gene Therapy for Epidermolysis Bullosa Simplex Dowling-Meara with Single-Base Precision

Yohan An[1], Hyomin Lee[2], Junho Hur[3]

[1]Biomedical Science, Graduate School of Biomedical Science & Engineering, Hanyang University, Seoul, Korea, Republic of,[2]Medicine, Major in Medical Genetics Hanyang University, Hanyang University, Seoul, Korea, Republic of,[3]Genetics, College of Medicine, Hanyang University, Seoul, Korea, Republic of

Epidermolysis bullosa (EB) is a group of rare skin diseases typified by blisters that primarily affect the skin after mechanical trauma. The Dowling-Meara variant of epidermolysis bullosa simplex (EBS-DM) is one of the most severe types of EBS. The major genetic causes of EBS-DM include dominant-negative mutations within either the

KRT5 (*12q13.13*) or *KRT14* (*17q12.q21*) genes. The keratin proteins are highly abundant in the cytoplasm of basal keratinocytes in the epidermis, providing cytoskeletal scaffold within the epithelial cells for protection against mechanical and non-mechanical stresses. These mutations cause keratin 5 and keratin 14 filament network structures to become fragile, which leads to epidermal cytolysis and blistering which are symptoms of EBS-DM. Currently, there are no approved therapy that can cure this disease. Only symptomatic care is available. In this regard, gene therapy might be a potential option for corrective therapy for these patients. To this end, we developed a CRISPR/Cas9 based near-cognate sgRNA method to specifically target the *KRT5* and *KRT14* point mutations to disrupt the dominant-negative mutant form of keratin. We found that this near-cognate sgRNA method efficiently induced genome editing of the mutant alleles without significant effect on the normal keratin alleles. In conclusion, we developed allele-specific CRISPR/Cas9 methods to target *KRT5* and *KRT14* specific mutations associated with EBS-DM.

520 Enhancing the Precision of Designer Site-Specific Recombinases: Methods for Surveying Sequence Specificity and Mitigating Potential Off-Target Effects

Jenna Hoersten, Maciej Paszkowski-Rogacz, Felix Lansing, Frank Buchholz

Medical Faculty, Medical Systems Biology, TU Dresden, Dresden, Germany

The specific targeting and editing of site-specific recombinases (SSRs) provide an appealing option for gene editing therapies where precision is crucial. Recent developments to engineer and evolve Cre/loxP-type SSRs, have made it possible to shift the specificity of Cre from its native target preference, the palindromic loxP site, to catalyze recombination of a range of DNA substrates, including non-palindromic sites. By taking advantage of the modular nature of the complex, each molecule can be designed to have its own unique specificity, and when expressed together, can form a functional heterotetramer capable of performing DNA-editing reactions on non-palindromic sites from the human genome. Although the ability to combine these evolved molecules into functional complexes drastically broadens the targeting possibilities of SSRs as heterocomplexes, it also carries a risk of unspecific reactions performed by homotetramers formed by individual subunits. To investigate the therapeutic potential of these novel recombinases, it is necessary to profile their general specificity to detect potential off-targets and then apply methods to mitigate any non-specific activity. We developed a high-throughput assay to measure the activity of designer-SSRs on a large set of over 5,000 rationally designed, non-randomized DNA target sequences, which allows building a machine learning model for accurately predicting off-target activity on all possible DNA sequences. The assay is carried out in *E. coli* to minimize experimentation and eliminate artifacts, and employs widely accessible Illumina sequencing as the final readout. We demonstrated the capabilities of this assay by profiling a designer Cre-like complex consisting of two subunits with unique specificities. Although the evolved complex showed high specificity to the on-target sequence, one of the subunits had measurable non-specific behavior when expressed alone. To reduce this effect, we transformed the complex into a functionally obligate system by mutating a single residue in each subunit. The mutated subunits became inactive when expressed alone, and a functional heterotetrametric complex was formed only when the subunits were expressed together. By screening the mutated subunit on a library composed of its potential off-targets, we confirmed its improved specificity. By constructing a DNA specificity model of a SSR, we could determine the best method to mitigate off-targets and improve its specificity, to ultimately use the designer-recombinase complex on a therapeutic target in human cells. Not only do these results facilitate the development of safe and effective therapeutic designer-recombinases but the profiles can also be used to advance our understanding of SSR catalysis.

521 CRISPR-Powered Graphene Electronics-A New Generation of Bioelectronics for CRISPR Quality Control

Kiana Aran

Keck Graduate Institute, Cardeabio, CRISPR QC, Claremont, CA

The discovery of CRISPR technology has revolutionized the fields of transcriptional activation and repression, genome editing, gene-based therapeutics, and diagnostics. The applications of this technology have been rapidly expanding as researchers continue to discover new Cas enzymes, engineer high fidelity Cas orthologs, and modify and synthesize guide RNAs to efficiently direct these Cas enzymes to their targets. In this talk, we will introduce the first-generation DNA biosensors that combine CRISPR technology with the ultra-sensitivity of graphene-based field effect transistors (gFETs) to detect target DNA sequences within the whole genome without the need for DNA amplification. This technology, termed CRISPR-Chip™, utilizes the genome searching capability of Cas and reprogrammable RNA molecule to unzip the double-stranded DNA and bind to its target. This binding event causes a change in graphene conductivity which can be detected in real-time within the gFET construct. CRISPR-Chip was first utilized to detect target genes within clinical samples obtained from patients with Duchenne Muscular Dystrophy (Cover of Nature BME-2019), and single cell point mutations in Sickle cell disease and ALS without the need for amplification (Nature BME 2021), within less than 30 minutes. The applications of this technology platform go beyond diagnostics. CRISPR-Chip can provide insight into the factors that impact editing outcomes and greater insights on the mechanism of CRISPR and can lead to safe and more effective utilization of this gene editing technology for therapeutic applications.

522 Large Knock-In in Primary T Cells with Optimized Cas9 HDR Methods and Design

Rolf Turk, Bernice Thommandru, Jessica Woodley, Karthik Murugan, Thomas Osborne, Mollie Schubert, Garrett Rettig

Integrated DNA Technologies, Coralville, IA

Knock-in of large transgenes in primary T lymphocytes has previously relied on methods that insert via random integration, not allowing for precise editing and making the genome susceptible to insertional mutagenesis (off-target effects, chromosomal rearrangements, translocations, etc.). As such, there is a need for precision gene editing for introduction of stably expressed transgenes such as chimeric antigen receptor (CAR) variants. CRISPR-Cas9 is an expedient tool for

precision editing and can mediate targeted HDR-based insertion. Here we present optimized reagents, donor design, and delivery methods for CRISPR HDR in primary T cells with chemically synthesized short HDR donors for small inserts and PCR-based long HDR donors for knock-in of up to 2kb. These methods and reagents together in primary human T cells achieve high-efficiency precise genome editing with low off-target integration.

523 Reducing the Inherent Auto-Inhibitory Interaction within the pegRNA Enhances Prime Editing Efficiency

Karthikeyan Ponnienselvan, Pengpeng Liu, Thomas Nyalile, Sarah Oikemus, Stacy A. Maitland, Nathan D. Lawson, Jeremy Luban, Scot A. Wolfe

UMass Chan Medical School, Worcester, MA

Prime editing systems have enabled the incorporation of precise edits within a genome without introducing double strand breaks. Previous studies defined an optimal primer binding site (PBS) length for the pegRNA of ~13 nucleotides depending on the local sequence composition. However, characterization of optimal PBS length has been based on prime editing outcomes using plasmid or lentiviral expression systems. Here we report that the inherent complementarity between the PBS and spacer sequence within the pegRNA affects pegRNA binding efficiency and target recognition. Because RNA-RNA duplexes are typically more stable than RNA-DNA duplexes and due to the intramolecular nature of the association between the spacer and PBS regions of the pegRNA, the formation of a PBS-spacer RNA duplex can preclude the formation of an R-loop by the prime editor at its target site. Finding the correct balance between PBS length and pegRNA sequence composition is critical to maximize prime editing activity by reducing the inherent "auto-inhibition" within the pegRNA sequence composition. We demonstrate that reducing the complementarity between the PBS and spacer sequences by reducing PBS length can broadly improve prime editing activity in the context of prime editor protein complexed with synthetic, end-protected pegRNAs across multiple target sites and multiple cell types. The difference in PBS length requirement between plasmid expression systems and PE RNPs loaded with synthetic, end-protected pegRNAs appears to originate from the susceptibility of transcriptionally produced pegRNAs to 3' end degradation. By small RNA sequencing, we observe that while the majority of the transcriptionally produced pegRNAs are full length, the pegRNA species that are bound by the prime editor protein are enriched for 3' truncated species. In the case of end-protected pegRNAs, we demonstrate that shorter PBS lengths with a PBS-target strand melting temperature near 37°C are optimal. Additionally, a transient cold shock treatment of the cells post PE-pegRNA delivery further increases prime editing outcomes. Finally, we show that prime editor ribonucleoprotein complexes programmed with pegRNAs designed using these refined parameters efficiently correct disease-related genetic mutations in patient-derived fibroblasts and install precise edits in primary human T cells and zebrafish.

524 Cytosine Base Editing of Surfactant Protein C Mutation Restores Genotype and Phenotype in Human and Murine Models

Valerie L. Luks[1], Ana Maria Dumitru[1], Brandon White[1], Rohan Palanki[1], Apeksha Dave[1], Mohamad Gabriel Alameh[2], Michael F. Beers[3], Katzen Jeremy[3], William H. Peranteau[4]

[1]Division of Pediatric General, Thoracic and Fetal Surgery, Children's Hospital of Philadelphia, Philadelphia, PA,[2]Department of Immunology, University of Pennsylvania, Philadelphia, PA,[3]Department of Pulmonary, Allergy, and Critical Care, University of Pennsylvania, Philadelphia, PA,[4]Division of Pediatric General, Thoracic and Fetal Surgery, The Children's Hospital of Philadelphia, Philadelphia, PA

RATIONALE Mutations in the surfactant protein C (*SPC*) gene can lead to lethal neonatal respiratory distress syndrome or pediatric interstitial lung disease. The most common *SPC* mutation is a thymine-to-cytosine base change that leads to a substitution of threonine to isoleucine at codon 73 (I73T), resulting in mistrafficking of proSPC protein and blockage of cellular macroautophagy. Cytosine base editing allows for safe, site-specific conversion of cytosine to thymine without double stranded breaks. Here, we demonstrate *in vitro* genotypic and phenotypic correction of the SPC I73T mutation by cytosine base editing in both human and mouse *SPC*. METHODS Human embryonic kidney cells (HEK293) constitutively expressing either mutant (huSPC-I73T) or wildtype (huSPC-WT) human SPC cDNA were treated via nucleofection with a combination of cytosine base editor (CBE) mRNA and custom guide RNAs (sgRNA) specific to the I73T mutation site. Gene editing efficiency was determined by Sanger sequencing, and the top performing sgRNA/CBE were used to assess phenotype rescue. Differences in proSPC trafficking before and after correction were analyzed by Western blot of HEK293 cell lysate and immunofluorescent microscopy of fixed cells. Correction of macroautophagy blockage was assessed by Western blotting for LC3B, a marker of autophagosome turnover. A similar guide screen was conducted in HEK293 cells expressing the murine SPC mutation (muSPC-I73T) prior to encapsulation of the top performing murine sgRNA and CBE mRNA into lipid nanoparticles (LNPs) for non-viral delivery to cells. RESULTS Nucleofection of hSPC-I73T cells achieved up to 95% correction of the I73T mutation. Western blot confirmed mistrafficking of SPC protein in unedited huSPC-I73T cells as demonstrated by an inappropriate accumulation of intermediate isoforms of proSPC. After cytosine base editing, aberrant proSPC banding proSPC was resolved. Immunofluorescent microscopy of fixed, unedited huSPC-I73T cells demonstrated abnormal accumulation of immature SPC protein in the plasma membrane and throughout the cytoplasm. After cytosine base editing of huSPC-I73T cells, immunofluorescent microscopy showed punctate patterning of proSPC without plasma membrane accumulation, consistent with the appearance of huSPC-WT cells and correction of the trafficking defect. In addition, cytosine base editing of huSPC-I73T cells resulted in reduction of intracellular LC3B accumulation, suggesting resolution of the macroautophagy defect present in unedited cells. In muSPC-I73T cells, nucleofection with the top sgRNA/CBE mRNA achieved 60% correction of the I73T mutation. Although further characterization of base edited muSPC-I73T was not pursued since these cells lack a disease phenotype, a translatable LNP gene delivery platform encapsulating the sgRNA and CBE mRNA

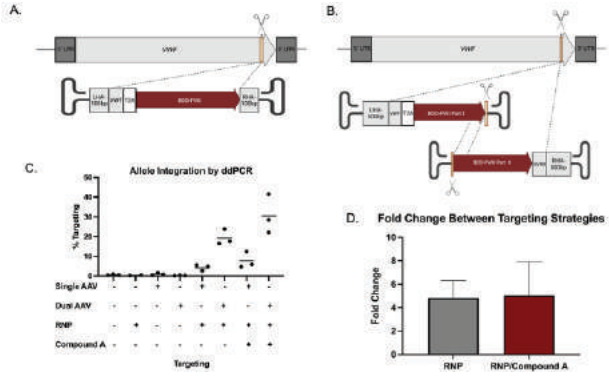
was engineered and applied to achieve 30% correction of the murine I73T mutation. CONCLUSION Cytosine base editing is a promising therapeutic strategy for genetic diseases caused by point mutations, including the SPC family of congenital diseases. In this study, we demonstrate correction of the SPC I73T mutation with subsequent return to physiologic protein trafficking and macroautophagy in human cells. This discovery provides the framework for future in vivo base editing studies with LNPs to ultimately develop a novel therapy for pediatric patients with SPC mutation disease.

525 Engineering a Potential Curative Treatment for Hemophilia A Using an AAV Dual Targeting Strategy

Nicole Marie Johnston[1], Alvaro Amorin[1], Loan Nguygen[1], Hana Ghanim[1], Matthew H. Porteus[2]

[1]Stanford University, Stanford, CA,[2]Stanford University School of Medicine, Stanford, CA

Hemophilia A is an X-linked bleeding disorder that effects 12 in every 100000 assigned male at birth within the United States. Within this subpopulation almost half have the severe phenotype, with less than 1% Factor VIII activity, correlating to spontaneous bleeding among other symptoms. Current treatments can be costly and needed across the lifetime of the patient with no FDA approved cure available. Here we report an efficient CRISPR/Cas9 editing strategy using an AAV6 donor template which expresses a B domain deleted Factor VIII (BDD-FVIII) gene cassette to provide a potential curative treatment for Hemophilia A. In our approach we selected the von Willebrand Factor gene locus, an endogenous platelet locus within the hematopoietic lineage, for protein expression limited to the megakaryocyte/platelet cell type. Our novel strategy uses a dual AAV cassette targeting approach. This strategy follows the idea that a dual targeted construct integrates simultaneously for an increase in the targeting efficiency at the locus. Our dual vector system has integration at a frequency of 20-30% compared to the single AAV vector with integration of 5-10%. The targeted cells show Factor VIII expression in CD41+/CD42a+ in vitro differentiated megakaryocytes and maintain multilineage differentiation potential in-vitro.



526 SPOT-ON is a Cas9 Nuclease with No Detectable Off-Targets and Reduced Chromosomal Translocations *In Vivo*

Sandra Wimberger, Dmitrii Degtev, Burcu Bestas, Alexandra Madsen, Aleksandar Zdravkovic, Michelle Porritt, Pinar Akcakaya, Marcello Maresca, Grzegorz Sienski

AstraZeneca, Mölndal, Sweden

The CRISPR-Cas9 systems have revolutionized the field of genome medicines. However, only a few Cas9 enzymes work efficiently in the in vivo setting and even fewer made it to clinical trials. While the first enzyme, SpCas9 has been successful in early trials, its aberrant activity raises safety concerns due to off-target editing. Here, we describe the discovery of a new Cas9 member of the Type II-B family from the human gut microbiome metagenomic database, which we named SpOT-ON. We characterized SpOT-ON biochemically and showed that its gene editing activity in vitro and in vivo is comparable to SpCas9. Remarkably, SpOT-ON displayed intrinsic high-fidelity and undetectable levels of off-target editing evaluated by conventional methods and high-sensitive DUPLEX-sequencing. Genome editing with SpOT-ON results in reduced levels of genomic translocation compared to SpCas9. Overall, SpOT-ON could serve as an alternative to SpCas9 for clinical use with a significantly improved safety profile. At the ASGCT Annual Meeting, we will present the discovery and engineering of SpOT-ON and our latest efforts to further improve its editing properties. Furthermore, we will share the results of in vivo studies using SpOT-ON at AstraZeneca.

527 Characterization and Quantification of CRISPR/Cas9-Induced Genomic Alterations and AAV Targeted Integration in Human HSPC

Alexandra Tachtsidi[1,2], Guillaume Corre[1,2], Laurie Lacombe[1,2], Mario Amendola[1,2,3]

[1]Genethon, Evry, France,[2]Université Paris-Saclay, Univ Evry, Inserm, Genethon, Integrare Research Unit UMR_S951, Evry, France,[3]Department of Clinical and Experimental Medicine, University of Foggia, Foggia, Italy

CRISPR/Cas9 technology has revolutionized our ability of genome editing and is a very promising tool for gene therapy. However, recent studies show that it can result into extensive on-target damage (extended deletions, chromosomal truncations, chromothripsis) in edited human cell lines, primary cells or human embryos. In addition, little is yet known about the CRISPR mediated targeted integration outcomes in primary cells. Here, we carry out a detailed analysis of the genomic events occurring upon CRISPR/Cas9-based gene editing, alone or in combination with the targeted integration of a therapeutic viral vector in HUDEP-2 cell line and clinically relevant Hematopoietic Stem/Progenitor Cells (HSPCs). To that end, we perform long read sequencing of a targeted genomic region of interest (ROI), using the Oxford Nanopore Technology (ONT) and the recently developed Cas9-based enrichment procedure. This approach allows us to enrich for our ROI avoiding PCR amplification biases. We choose to target α-globin locus, as we have previously shown it is a genomic safe harbour site for editing and targeted integration in human HSPCs, with Cas9 (nuclease and nickase)-gRNA ribonucleoprotein complexes alone or in addition with an adeno-associated virus (AAV) encoding for β-globin

gene, flanked by homology arms for homologous recombination. Noteworthy, our single gRNA targets both HBA1 and HBA2 genes and can result in HBA2 deletion which allows us to simultaneously assess the editing occurring after gRNA single cut as well as the genomic deletion. We perform Cas9-enrichment of a 14kb ROI to be able to recover most possible editing events with statistical significance (~100X coverage) and we establish a bioinformatical pipeline to process the generated data and explore the structural variations. We first focus on the effect of gRNA cut. We show that large unintended deletions (> 500bp) at the gRNA site as well as the deletion of the HBA2 locus occur at higher frequencies in HSPC (40%) than in HUDEP-2 cells (25%). These events are decreased with the use of Cas9 nickase. Then, we analyse cells with targeted DNA integration. We observe that AAV integration efficiency is also cell type dependent, with higher efficiency obtained in HSPCs (70%) than HUDEP-2 (20%), suggesting that these widely used cell lines are not ideal as model for genome editing. Interestingly, most of the integrations are HDR mediated but cases of AAV ITRs on-target-trapping are detected probably due to non-homologous end joining. Unexpectedly, we reveal the existence of complex rearrangements of integrated AAV genomes, concretely concatemers accounting for 20% of the AAV integrations. ITRs are also detected in AAV concatemers integration (on the junctions of the copies). We confirm our results by independent approaches as ddPCR, for the quantification of HBA2 deletion and of HDR mediated AAV on-target integration frequency, and FACS analysis for the quantification of on and off-target integration of the GFP-cassette. We are currently studying the effect of commonly used drugs affecting DNA repair on the editing and integration outcomes. In addition, we are performing ONT sequencing on edited single cell clones to further confirm our observations in bulk populations. Similar analyses are on-going for additional genomic targets and vectors. Our findings provide a clear understanding of the on-target genomic alterations occurring upon CRISPR editing and targeted integration of AAV vectors in the HSPCs, using Cas9 nuclease, nickase and drugs acting on DNA repair. This knowledge is important for future clinical applications of the CRISPR gene editing tool.

528 LNPs for Editing NASH Patient Liver Derived Organoids

Tobias D. Raabe[1], Sarah McCarron[2], Mohamad-Gabriel Alameh[3], Drew Weissman[3], Brooke Bathon[4]

[1]Department of Medicine, Division of Translational Medicine and Human Genetics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA,[2]Vertex Pharmaceuticals, Boston, MA,[3]Institute for RNA Innovation, University of Pennsylvania, Philadelphia, PA,[4]Dept. of Nutrition, School of Public Health, The University of North Carolina at Chapel Hill, Chapel Hill, NC

Background: Patient derived organoids (PDOs) that partially recapitulate the 3D structure(s) of an organ or tissue are increasingly seen as crucial tools to model diseases and develop human relevant therapeutics because they are direct descendants of a patients adult stem cells located in the diseased organ or tissue. The relative lack of fast and efficient gene editing technologies for PDOs, which usually do not divide after their final differentiation, is still a serious drawback preventing their full implementation. LNPs complexed with Cas9 mRNA/gRNA have recently emerged as powerful gene editing tools for animals and humans but despite their promise have not yet been systematically used for editing PDOs. LNPs are uniquely capable to deliver mRNA of up to 12kB into non-dividing cells and allow unperturbed safe repeat applications in organoid culture as well as the clinic as they induce the immune system to manageable levels. For many types of PDOs it is not yet clear how well LNP mRNA complexes work, in part since it is unknown under what conditions PDOs can take up the LNPs at an efficiency that is similar to the parental tissue. **Rationale:** For proof of principle that LNP mRNA complexes can efficiently target PDOs, we decided to set out with targeting non-alcoholic steatohepatitis (NASH) patient liver derived organoids (NASH-PDOs). We have recently described NASH-PDOs derivation from human NASH explant livers and their surprisingly high utility in modeling human NASH (McCarron et al. Hepatology, 2021). NASH is a common liver disorder, but genetically complex and heavily influenced by non-genetic factors including nutrition, exercise and infection, making it difficult to define therapeutic targets. Thus, establishing LNP mRNA complex - mediated gene editing in NASH-PDOs would dramatically improve their ability to functionally probe candidate NASH genes and pathways. **Results:** Using GFP mRNA LNPs in a 96 well 3D culture format with IF microscopy as output we have developed a method resulting in > 90% efficient targeting of total cells in the terminally differentiated non-dividing NASH-PDOs 2-3 days after addition of the LNP GFP mRNA complexes. This is an order of magnitude better than any other known targeting method for most types of PDO. These NASH-PDOs mostly contain hepatocyte- and cholangiocyte - like cells which are both transfected by the GFP mRNA LNPs. **Conclusions:** Our GFP mRNA LNP based results suggest that LNP mediated Cas9 mRNA/gRNA gene editing or mRNA mediated transgene over expression will be highly efficient in non-dividing terminally differentiated NASH-PDOs. We are currently employing Cas9 mRNA based gene editing using this system. We are also working on developing selective LNP targeting strategies for NASH liver derived macrophages, myofibroblasts and endothelial cells, all of which play important roles in NASH pathogenesis. Since these cells are involved in all types of liver diseases the implications for such liver cell type specific LNP-mediated targeting could be far reaching.

529 Impact of Three-Dimensional Spatial Genome Organization on Gene Editing and Its Use in Gene Editing Drug Design for Higher Safety

Shoko Iwai[1], Kuljeet Sandhu[2], Rakesh Kappagantu[1], Rohini Kalvakuntla[1], Anirudh Nishtala[1], Poulami Chaudhuri[1]

[1]Helex Inc., New York, NY,[2]Biological Sciences, IISER Mohali, Punjab, India

CRISPR-Cas technology is promising in providing targeted gene editing and modulation of the gene expression for therapeutic outcomes. However, there are still technical challenges to be addressed to bring it widely into medical applications including potential off-target effects. The off-target effects include unintended genome edits and rearrangements by the repair mechanism, which could lead to serious deleterious outcomes including carcinogenesis. While the application of CRISPR-Cas in clinical settings is rapidly advancing, our understanding of how the editing technology interacts with the genome and its consequences- both short and long term is relatively under explored.

The three-dimensional (3D) spatial organization of chromatin plays a critical role in gene regulation and function. Multiple studies reported inter- and intra-chromosomal physical contacts between loci is required to coordinate regulation of multiple genes within specific transcriptional activities. Furthermore, those spatial organization and regulation of the genes are tissue and cell specific. To date, several approaches have been taken to accurately predict off-target effects mainly based on sequence and/or epigenetics data, however, none of them have examined the 3D spatial organization of chromatin and consequent regulatory effects in the context of CRISPR-Cas gene editing with tissue and cell-specific angle. Here, we evaluated how 3D spatial organization affects CRISPR-Cas off-target editing activity, potential translocations and potential regulatory pathway modifications. We compared contact frequency measured by Hi-C assay of the genomic loci between experimentally validated edits and mismatch based predicted off-targets in HeLa cells. Contact frequency between experimentally validated edits were significantly higher than between experimentally validated and predicted but experimentally not validated edits ($p<0.05$), suggesting that chances of editing at off-target site are increased when the loci are in higher contact frequency with the genomic loci with edits. Chromosomal translocations associated with CRISPR-Cas editing bring critical structural and molecular changes in the cell, however it is experimentally expensive to capture the entire effects. Thus, we calculated gene homology between high-contact loci to evaluate the risk of possible translocations in silico. Contact frequency of the translocation sites were also examined. The presented results underscore the importance of considering 3D spatial genome organization and proximity in a tissue and cell-specific manner to understand and reliably predict off targets, and their critical regulatory functional consequences. The approach is essential in developing precision medicine to deliver safer gene editing therapy.

530 ARRDC1-Mediated Microvesicles (ARMMs) as a Novel Non-Viral Modality for Efficient Functional Delivery of Adenine and Cytidine Base Editor Proteins Complexed with Guide RNA

Wendy Zhao[1], Qiyu Wang[1], Kelcee Everette[2], Zahra Baghbantaraghdari[1], Jennifer A. Badji[1], Yashodhan Chinchore[1], Morgan G. Stykel[1], Chris Chatzinakos[1], Nedyalka Valkov[1], Bhavesh Gurwani[1], Ryan von Kleeck[1], Carson Semple[1], Chou-Wei Chang[1], Komal Vyas[1], Meirui an[2], Lily Widdup[2], David R. Liu[3], Joseph F. Nabhan[1]

[1]Vesigen Therapeutics, Cambridge, MA,[2]Harvard University, Cambridge, MA,[3]Harvard University and HHMI, Cambridge, MA

Significant advances have been made over the past 10 years in the discovery and development of novel genome editing proteins to precisely and safely modify genetic sequence. However, the application of these technologies and the ability to articulate novel *in vivo* therapeutic strategies has been limited by the absence of appropriate delivery vehicles that permit: 1) efficient encapsulation of editors, particularly larger Cas-derived editors complexed with guide RNA (gRNA); 2) transient functional delivery of the genome editing machinery to target cell types; and 3) the ability to re-dose. Here, we report an approach to engineer a class of human vesicles called ARMMs (ARrdc1-Mediated Microvesicles) to load and deliver adenine and cytosine base editors (ABEs and CBEs, respectively) complexed with targeting gRNAs in cultured mammalian cells and *in vivo*. Cas-derived base editors, typically composed of an engineered Cas protein fused to natural or laboratory-evolved deaminase enzymes, have emerged as powerful tools to specifically edit genetic sequence without introduction of double-stranded breaks. We used a suspension producer cell line to produce and engineer ARMMs intraluminally loaded with ABE or CBE complexed with gRNA. ARMMs purified from producer cell cultures were analyzed for ABE, CBE, and gRNA content. Approximately 10-15 complexes were loaded per ARMM indicating a high level of compacting of complexes within ARMMs. We then treated a range of cell types, including primary and post-mitotic cells, with ARMMs loaded with base editors complexed to gRNA. ARMMs mediated dose-dependent editing of targeted genomic loci, achieving near-complete editing levels at higher multiplicities of ARMMs to cells. *In vivo* evaluation of ARMMs in mice yielded increasing levels of editing with repeat administration, reaching ~ 60% editing in a challenging-to-target cell type after two doses. These results suggest ARMMs as a promising non-viral delivery vehicle for base editors.

531 Precise Temporal Regulation (Titratable and Reversible) of Gene Editing with a Small Cas9 Nuclease by an FDA-Approved Small Molecule Drug, Using cytoDRiVE® Technology

Grace Olinger, Andrew McNeal, Najmia Amirina-Nave, Kerri Sheahan, Bulent Arman Aksoy, Dexue Sun, Andres Alvarado, Dhruv Sethi, Jan ter Meulen, Mara C. Inniss

Obsidian Therapeutics, Cambridge, MA

Gene editing has the potential to revolutionize the treatment of many genetic diseases and several *in vivo* gene editing therapies have recently entered the clinic. To increase their safety and efficacy, precise spatial and temporal on-target editing with minimal off-target editing is highly desirable and will require tight intrinsic or extrinsic control of the gene editor. To this end, we have developed small drug-responsive domains (DRDs) as part of our cytoDRiVE® platform that can be fused to Cas9 nuclease enabling precise control of its expression and activity by exposure to a clinically approved small molecule drug. The small size of these DRDs requires minimal vector space and will allow delivery of DRD-Cas9 and guide RNA in a single AAV vector. We show that the DRD-Cas9 fusions have extremely low editing activity in the absence of drug which increases to near constitutive levels of activity upon treatment with activating drug for a panel of guide RNA targets. In addition, we show that fusion of DRDs to Cas9 does not affect target specificity or repair patterns of the nuclease. This level of control demonstrated *in vitro* by our cytoDRiVE® platform supports potential future clinical utility in cell and gene therapies, where tight regulation of DRD-Cas9 would give the physician control of Cas9 activity in the patient. Pausing or stopping administration of the activating drug once edits have been made could limit off target editing activity and reduce the risk of genotoxicity.

532 Altered Kinetics of Immunoreceptor Internalization Following Activation as a Mechanism for Enhanced Anti-Tumor Function of KIR-Based Chimeric Antigen Receptors

Qian Zhang[1], Tyra Wentz[1], Jingyi Yang[1], Morgan Hresko[1], Alina Boesteanu[1], Danielle Cook[1], Yibo Yin[1], Chong Xu[1], Laura A. Johnson[1], Michael C. Milone[2]

[1]University of Pennsylvania, Philadelphia, PA,[2]University of Pennsylvania, Moorestown, NJ

We previously described a chimeric killer immunoglobulin-like receptor (KIR-CAR) approach to modifying T cell antigenic specificity that mimics the multichain design of natural immunoreceptors. T cells modified to express a mesothelin-specific KIR-CAR with the natural ITAM-containing adaptor, DAP12 demonstrate significantly enhanced anti-tumor activity in a pre-clinical model of mesothelioma when compared with traditional CD3z-based CAR designs such as those used in tisagenlecleucel or axicabtagene ciloleucel. We have extended these observations to show that T cells expressing a KIR-CAR specific for EGFRvIII also have significantly enhanced antitumor activity in two different orthotropic xenograft models of glioblastoma (GBM), U87-vIII and primary GBM D270, when compared with 2nd generation, 4-1BB-costimulated, CD3z-based CAR T cells previously used in a clinical trial at our institution (NCT02209376). Our prior studies demonstrated that a transient loss of CD3z-based CAR expression is associated with CAR T cell hypofunction in vivo in tumor-infiltrating lymphocytes. We hypothesized that the retention of function in KIR-CAR TIL is related to a reduced rate of receptor internalization following receptor activation, compared with standard CD3z-based CAR T. In order to evaluate CAR internalization kinetics, we utilized a surface protein tagging method using the SpyCatcher-SpyTag™ system in which the CAR ectodomain is comprised of a Myc-tagged-SpyCatcher domain and the antigenic specificity of the CAR is conferred by addition of a fluorescently-labeled SpyTag-DARPin fusion protein (SpyDARPin) that specifically binds the SpyCatcher domain covalently via its SpyTag and recognizes the EGFR antigen. A SpyCatcher KIR-CAR (SpyKIR-CAR) or CD3z-CAR with CD28 costimulatory domain (Spy-CAR) were expressed in CD3/28 activated primary human T cells by lentiviral transduction, and their expression confirmed by flow cytometry using an antibody to the myc-tag. Addition of the SpyDARPin exhibited uniform labeling at the plasma membrane as assessed by image cytometry and confocal microscopy. Functional testing demonstrated that the Spy-KIR-CAR and Spy-CARs exhibited comparable cytokine secretion in response to EGFR+ target cells and similar cytotoxicity against EGFR+ U87 glioma target cells in the presence of SpyDARPin. No cytokine secretion or cytotoxicity was observed with SpyCAR and SpyKIR-CAR T cells in the absence of the SpyDARPin. The kinetics of SpyCAR or SpyKIR-CAR fluorescence loss were similar in the absence of EGFR ligand with a half-life of 2 days, consistent with normal membrane protein turnover by pinocytosis. Upon ligand-induced activation, the SpyCAR fluorescence rapidly reduced to background levels of unlabeled SpyCAR cells within 8 hours of activation. In contrast, the mean SpyKIR-CAR fluorescence, while exhibiting a 20% reduction in mean baseline fluorescence at 8 hours, remained increased 4-fold above the background fluorescence. Confocal imaging confirmed the retention of labeled KIR-CAR at the plasma membrane over the time frame in which the labeled SpyCAR at the plasma membrane is lost. We also observed that a substaintial proportion of intracellular CARs appeared to colocalize with lysosomes in the activated SpyCAR T cells, but not SpyKIR CAR T cells. These observed differences in internalization kinetics between the KIR-CAR and CD3z-CAR when coupled with metabolic stress of the tumor microenvironment may explain the ability of KIR-CAR TIL to retain CAR expression and function. Our data also suggests that the retained surface expression of KIR-CAR may be at least partially responsible for the improved antitumor function observed in vivo in solid tumor models.

533 Outcomes from the First NIST Genome Editing Consortium Interlab Study

Samantha Maragh[1], Sierra Miller[1], Ayah Shevchenko[1], Simona Patange[1], Justin Zook[1], Nate Olson[1], Jamie Almeida[1], Hua-Jun He[2], Natalia Kolmakova[1], Patricia Kiesler[1], NIST Genome Editing Consortium[1]

[1]NIST, Gaithersburg, MD,[2]NIST: National Institute of Standards and Technology, Gaithersburg, MD

Genome editing is being actively pursued globally to transform medicine and bioscience to enable previously impossible advances in cell & gene therapy. Moving the promise of these technologies into production and medical practice requires robust quantitative assays, with associated controls and data tools. **The U.S. National Institute of Standards and Technology (NIST) Genome Editing Consortium (GEC) convenes experts** across academia, industry, and government to collaboratively address precompetitive genome editing measurements and standards needed to increase confidence in evaluating genome editing and utilizing these technologies in research and commercial products. As a result of NIST GEC led efforts there is now a first international standard for genome editing terminology: International Standards Organization- ISO 5058-1:2021 Biotechnology — Genome editing — Part 1: Vocabulary **This presentation will detail the design and results of this first NIST GEC Interlab Study**. The NIST GEC has completed a first of its kind interlab study with organizations in the genome editing field to understand the performance of DNA detection technologies of interest for confirming on- and off-target genome editing. For this interlab study, NIST designed mixture schemes consisting of DNA- or cell-based control samples. These control samples were qualified with ddPCR and NGS to evaluate the accuracy of the study participants' reporting on the size, sequence, and frequency of the DNA variants. DNA variant benchmarks within control samples ranged in size from single nucleotide variants (SNV) to insertions and deletions tens of kilobases long. Variants were present within the interlab study control samples at all of 5 primary frequency bins: 0%, >30%, 5 - 10%, 0.5 -2%, and 0.1 - 0.25%; with two optional samples of ~0.01% and ~0.001%. Participants were provided 5 required samples and a core list of 39 genomic positions of interest to be analyzed by any type of DNA detection process being utilized by the interlab participant. Interlab participants were blinded as to variant sequence and variant frequency within each sample and at each position of interest. **14 Interlab participants returned their assessments** of the samples they were given, including metadata describing the assay and data analysis approach, raw data files, and a list of variants detected- complete with variant positions, sequences, and frequencies. One to two technologies were assessed per participant, with 1-4 replicates per technology.

Technologies assessed include: bulk DNA short read NGS, bulk DNA long read NGS, single cell targeted NGS, genome wide DNA imaging, targeted DNA probe imaging, and capillary electrophoresis fragment analysis. NIST evaluated the results from individual technologies for accuracy of variant detection and frequency prediction. While no one technology had the capability to detect all of the variants at all of the frequencies and sizes, combined results from all of the technologies evaluated, confirmed the ability to measure a subset of variants down to 0.001% and variant sizes from SNV to >100kb. Trends in performance were identified as well as instances where variant signal was present but not reported by the bioinformatics process. **The NIST GEC is working on** a database where all datasets, metadata, and results could be made publicly accessible. Further in-progress NIST GEC work includes development of metadata norms and clonal engineered cell lines to be used as DNA/cell based controls supporting greater assay confidence for the genome editing community and development of genome edited cell based therapies.

534 Discovery and Engineering of a Miniature CRISPR-Cas Type V-L System

Lauren E. Alfonse, Alexa Ornstein, Erin Doherty, Jenna M. Rachman, Tomoaki Sasaki, Blake McMahon, Quinton Wessells, Anthony J. Garrity, Gabrielle Z. Munoz, Zachary Maben, Mishti Bose, Paul Yan, Amy Biasella, David R. Cheng, Tia DiTommaso, John E. Murphy, Gregory R. Hoffman

Arbor Biotechnologies, Cambridge, MA

Employing a metagenomic search, we identified a family of miniature CRISPR-Cas type V-L systems capable of RNA-guided dsDNA target cleavage without a tracrRNA. A bacterial depletion screen revealed several active systems which were subsequently shown to have low-level editing in mammalian cells. Among the systems with activity in mammalian cells, we selected a 745aa nuclease effector as a candidate for engineering. An unbiased mutational scanning approach was applied to identify single substitutions that increase indel activity in mammalian cells. Indel-enhancing single substitutions were then screened in combination, with a combinatorially engineered variant demonstrating indel editing activity comparable to SpCas9 in HEK293T cells and SaCas9 in primary cells. Structure determination via cryo-EM revealed the domain organization and nuclease mechanism of the ternary complex. Due to its small size and robust editing levels, this novel miniature CRISPR-Cas type V-L system is an attractive therapeutic candidate for single- or dual-guide excision via all-in-one AAV delivery.

535 Alpha-Synuclein Gene Dosage Human Stem Cell Model is a Powerful Tool to Study Neuronal Differentiation and Cellular Stress in Parkinson's Disease

Faria Zafar[1,2]

[1]Pathology, Stanford School of Medicine, Santa Clara, CA,[2]Pathology, Stanford School of Medicine, Stanford, CA

Background: The accumulation and aggregation of alpha-synuclein protein (a-syn) is a critical event in Parkinson's disease pathophysiology, impairing neuronal function and contributing to dopaminergic neuronal cell death. Clinical cases with alpha-synuclein (*SNCA*) multiplications or deletions indicate that gene expression levels are essential for neurodegeneration and neurodevelopment (M. Torres *et. al.* 2020). The goal of the study is to combine induced pluripotent stem cell (iPSC) technology with gene editing to establish isogenic cellular tools which express dosage dependent *SNCA* gene copy numbers (Zafar *et. al.* 2022). **Methods:** Here, we developed an isogenic *SNCA* gene dosage model using clustered regularly interspaced short palindromic repeats - CRISPR/Cas9 - gene editing to introduce frameshift mutations into exon 2 of the *SNCA* coding region in iPSCs from a patient with an *SNCA* triplication. We generated and characterized clones with different frameshift mutations relating to 4 knock-out (KO), 3 KO, 2 KO, 1 KO, and 0 KO. The characterization included genotyping, pluripotency test, spontaneous *in vitro* differentiation, karyotyping, and off-target nuclease analysis. Isogenic lines with 0 KO, 2 KO, and 4 KO were differentiated into cortical neuronal precursors for 20 days and mature neurons for 40 days in vitro (DIV). Precursors were characterized for key neuronal and cortical markers using SYBR green array, functional assays to measure lysosomal activity, and oxidative stress. **Results:** Genotyping of each frameshift mutation into exon 2 of the *SNCA* was confirmed by fragment analysis using capillary electrophoresis of fluorescently labeled PCR product. Immunocytochemistry of pluripotency test (*OCT4* and *SSEA4*) and SYBR green array for multilineage differentiation potential for each clone was confirmed with five genes per germ line. Bionano optical mapping resulted in normal karyotypes with no structural variance and with duplicated *SNCA* gene structure as the parental line. The absence of off-target binding sites of Cas9 is confirmed with Sanger sequencing. After the cortical neuron differentiation at 13 DIV, 16 DIV, and 20 DIV, we observed significant downregulation in general neuronal, cortical, and synaptic markers in the 4 KO line. Differentiated dopaminergic precursors in this model showed a reduction of oxidative and lysosomal activity in an (*SNCA*) gene-dose dependent manner. **Conclusion:** This isogenic *SNCA* gene dosage panel will be beneficial to address the physiological and detrimental effects of varying a-syn expression levels.

536 Extru-seq: A Method for Predicting Genome-Wide Cas9 Off-Target Sites with Advantages of Both Cell-Based and *In Vitro* Approaches

Jungjoon Lee[1], Jeonghun Kwon[1], Minyoung Kim[1], Woochang Hwang[2], Anna Jo[1], Gue-Ho Hwang[2], Minhee Jung[1], Un Gi Kim[1], Gang Cui[3], Heonseok Kim[4], Joon-Ho Eom[5], Junho Hur[2], Junwon Lee[3], Youngho Kim[1], Jin-Soo Kim[6], Sangsu Bae[7]

[1]Toolgen, Seoul, Korea, Republic of,[2]Hanyang University, Seoul, Korea, Republic of,[3]Yonsei University College of Medicine, Seoul, Korea, Republic of,[4]Staford University, Stanford, CA,[5]National Institute of Food and Drug Safety Evaluation, Cheongju, Korea, Republic of,[6]Center for Genome Engineering, Institute for Basic Science, Seoul, Korea, Republic of,[7]Seoul National University, Seoul, Korea, Republic of

We present a novel genome-wide off-target prediction method named Extru-seq and compare it with cell-based (GUIDE-seq), in vitro (Digenome-seq), and in silico methods using promiscuous guide RNAs with large numbers of valid off-target sites. Extru-seq demonstrates a high validation rate and retention of information about the intracellular environment, both beneficial characteristics of cell-based methods. Extru-seq also shows a low miss rate and could easily be performed in clinically relevant cell types with little optimization, which are major positive features of the in vitro methods. In summary, Extru-seq shows beneficial features of cell-based and in vitro methods.

537 A Novel Method for Generating Unprecedented Ultra-High-Sequence Diversity Libraries of Plasmids and Recombinant Viruses (with Validation) for High-Throughput Screening and Targeted Therapy

Praveensingh B. Hajeri, Masato Yamamoto

Department of Surgery, University of Minnesota, Minneapolis, MN

Background: A typical drug discovery pipeline needs good libraries of potential therapeutic candidates with high-sequence diversity. The probability of finding a good hit primarily depends on the quantity (diversity) and quality (distribution) of candidates in libraries used for screening. They include libraries of peptides, single-chain antibodies, nanobodies, CRISPRs, shRNAs, phage display, yeast display, Ribosome display, DARPins, BiKEs, TriKEs, CAR-T cells, and recombinant viruses (including adenoviruses, lentiviruses, AAVs, and other oncolytic viruses, etc.). Screening them for specific interaction with the target of interest to narrow down to fewer candidates, which can be further validated, are the basic steps in the generic discovery pipeline. ***Current limitations:*** Generating high-sequence diversity libraries is very challenging. Several published studies and industries claim to have very high diversity libraries ranging over 10^9 sequence diversity. However, most of those libraries lack validation by stringent experimental standards, and the diversity claimed is mainly based on sequencing a small number of candidates in the library and statistical extrapolations. Most of the time, we found that those who claim very high diversity (over 10^8) did not validate their libraries with stringent next-generation sequencing (NGS) based methods, and those who used stringent NGS methods for validation usually do not claim such big diversity. Therefore, there is an imminent need for a method to generate genuine high-sequence-diversity libraries of high quality. ***Methods and results:*** We have developed a novel method to generate such libraries with very high sequence diversity and validated them with stringent NGS-based methods. Compared to other established methods, our libraries are at least 100 to 1000 times better in diversity (quantity) and have a more uniform and unbiased distribution (quality). Through benchmarking studies, we validated total diversity, duplication rate, sequence bias, and the ability to scale up. As a proof of concept, we generated libraries of plasmids (shuttle vectors to make recombinant adenoviruses) and recombinant adenoviruses with high sequence diversity in a structural protein (Fiber). We also used them for screening against a cancer-specific cell-surface protein. ***Applications:*** Our methods can generate quantitatively and qualitatively better (100-1000 times) libraries. They can be used in high-throughput screening against targets of interest to narrow down to fewer candidates. Smaller libraries resulting after serial and multiple rounds of screening can serve as a dataset for machine training to aid AI-based design. Our unbiased, high-diversity libraries provide a high-quality dataset to improve Ai-based design criteria. We expect our libraries may help in avoiding AI-based design altogether in some cases.

538 An RNA Switch-Regulated All-in-One AAV-CRISPR-Cas System for *In Vivo* Inducible Gene Editing

Guocai Zhong[1,2,3], Chengzhi Du[4], Haimin Wang[1]

[1]Gene Therapy Center, UMass Chan Medical School, Worcester, MA,[2]RNA Therapeutics Institute, UMass Chan Medical School, Worcester, MA,[3]Department of Biochemistry and Molecular Biotechnology, UMass Chan Medical School, Worcester, MA,[4]Shenzhen Bay Laboratory, Shenzhen, China

In vivo CRISPR-Cas gene editing has enormous potential for treating a range of human diseases. AAV vector is an efficient delivery vehicle for *in vivo* gene editing in diverse tissues. However, a single dose AAV delivered to terminally differentiated cells could provide persistent transgene expression for years to decades, which could lead to persistent off-target editing, long-lasting expression of an immunogenic Cas effector protein, and high level of double-strand break-associated integration of AAV vector DNA into chromosomal DNA. These potential safety issues significantly increase the risk and undercut the efficacy, and thus limit the application of this approach. An inducible CRISPR-Cas expression system has the potential to address these safety issues. We previously developed an RNA on switch system that efficiently regulates AAV transgene expression with up to 200-fold dynamic range in mice. In this system, a transgene is kept in off state by an optimized self-cleaving hammerhead ribozyme (T3H38), and can be conditionally switched on by a steric-blocking morpholino antisense oligonucleotide (v-M8) complementary to the ribozyme**.** Here, we utilized this efficient RNA switch to develop an inducible CRISPR/Cas system. We first tried directly introducing the T3H38 ribozyme to the 3′-UTR of a Cas9/Cas12a gene. Surprisingly, although the ribozyme efficiently lowered the expression of Cas9/Cas12a protein to almost undetectable level, gene-editing activity was much less impacted. More importantly, the difference between regulated and constitutive gene editing got smaller over time. This time-dependent leaky editing kinetics represent a key challenge for developing an inducible gene-

editing system. Then, by leveraging our previous finding that Cpf1/Cas12a can specifically bind and process its own CRISPR RNA from Pol-II transcripts, we engineered a four-level-regulated inducible CRISPR/Cas12a system that can be delivered by a single AAV vector. In this system, Cas12a protein expression, as well as CRISPR RNA expression, folding, and processing, are simultaneously regulated by the T3H38 ribozyme and a newly designed CRISPR-RNA-disrupting hairpin structure. We demonstrated in cell culture that, compared to a constitutive expression system, the four-level regulated system could function with 0% leaky gene editing activity in the absence of an inducer oligo and with up to 68% induced gene editing activity in the presence of a single v-M8 morpholino inducer. We then further tested the system in mice. Animals were continuously monitored for gene editing events for more than 6 weeks and minimal leaky editing activity was detected. The system was efficiently turned on when a single-dose (1.0 mg/kg) v-M8 morpholino inducer was administered. This RNA switch-regulated all-in-one AAV-CRISPR/Cas system has the potential to be used in diverse *in vivo* gene-editing applications.

539 De Novo Design of Peptide-Guided Protein Degraders with Structure-Agnostic Language Models

Garyk Brixi[1], Tianzheng Ye[2], Lauren Hong[1], Vivian Yudistyra[1], Sophie Vincoff[1], Tian-Lai Leo Chen[1], Matthew DeLisa[2], Pranam Chatterjee[1]

[1]Biomedical Engineering, Duke University, Durham, NC,[2]Chemical and Biomolecular Engineering, Cornell University, Ithaca, NY

Targeted protein degradation of pathogenic proteins represents a powerful new treatment strategy for multiple disease indications. Unfortunately, a sizable portion of these proteins are considered "undruggable" by standard small molecule-based approaches, including PROTACs and molecular glues, largely due to their disordered nature, instability, and lack of binding site accessibility. As a more modular, genetically-encoded strategy, designing functional protein-based degraders to undruggable targets presents a unique opportunity for therapeutic intervention. In this work, we integrate pre-trained language models with protein interaction databases to devise a unified, sequence-based framework to design peptide-guided degraders without structural information. We create a Structure-agnostic Language Transformer & Peptide Prioritization (SaLT&PepPr) module that efficiently down-selects peptides from known partner protein sequences for downstream screening. We experimentally fuse SaLT&PepPr-derived peptides to E3 ubiquitin ligase domains and reliably identify candidates exhibiting robust intracellular degradation of diverse pathogenic targets in human cells, including membrane proteins, disordered transcription factors, fusion oncoproteins, and other undruggable targets. We further show that our peptide-guided degraders have negligible off-target effects via whole-cell proteomics and demonstrate degradation of endogenous β-catenin and subsequent downregulation of Wnt signaling in cellular models of colorectal cancer. Finally, we encapsulate our peptide-guided degraders as mRNA in lipid nanoparticles (LNPs) and demonstrate effective in vivo delivery and target degradation in mouse models, motivating downstream clinical translation of our genetically-encoded degradation platform.

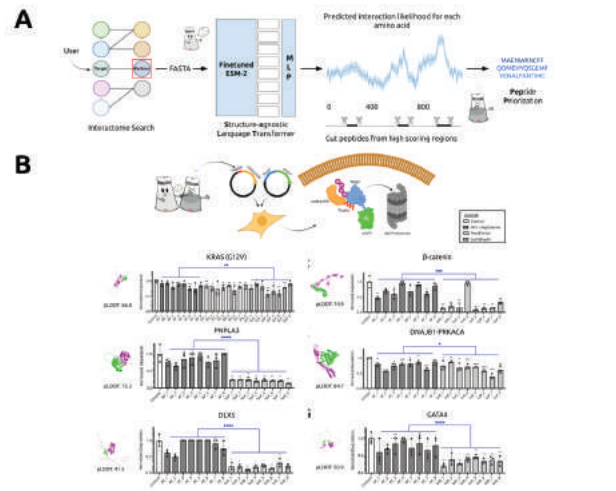

Figure. A) SaLT&PepPr model training and peptide prioritization pipeline. B) Testing of SaLT&PepPr-derived degraders vs. AlphaFold-derived degraders against diverse target substrates. AlphaFold structures are provided for each target with a pLDDT confidence score. All samples were conducted in independent triplicates (n=3). A two-tailed Student's *t* test was used to assess statistical significant degradation vs. a negative control for each sample, and a Mann-Whitney U Test was used to determine statistical significance between methods.

540 Efficient Circular RNA Engineering by End-to-End Self-Targeting and Splicing Reaction Using *Tetrahymena* Group I Intron and Study of Circular RNAs in Cells

Kyung Hyun Lee[1], Seongcheol Kim[1], Jaehwi Song[1], Seung Ryul Han[1], Jihyun Kim[1], Seong-Wook Lee[1,2]

[1]Rznomics Inc., Seongnam, Korea, Republic of,[2]Department of Bioconvergence Engineering, Research Institute of Advanced Omics, Dankook University, Yongin, Korea, Republic of

Circular RNA (circRNA) has advantages over linear mRNA which is gaining success as a new vaccine and therapeutic agent. However, new circRNA preparation method has not been developed for decades. In this study, we developed a new *in vitro* circular RNA engineering strategy by end-to-end self-targeting and splicing (STS) reaction during *in vitro* transcription using *Tetrahymena* group I intron ribozyme, providing circRNA without any extraneous fragments into circRNA sequences which may trigger unwanted innate immune responses in cells. For efficient self-circularization, we optimized group I intron ribozyme components and the optimized self-circularization RNA construct design showed the improved self-circularization efficiency which was comparable to permuted intron-exon (PIE) method. In addition, *in vitro* transcription condition for upstream process and Ion Pair-Reverse Phase HPLC (IP-RP HPLC) purification method for downstream process were optimized as well. IP-RP HPLC-purified circRNA with CVB3 IRES showed efficient protein expression in HEK293A cells comparable to circRNA prepared by PIE method. Moreover, circRNA without extraneous fragments and any modified nucleotides induced negligible innate immune responses in A549 cells. In conclusion, our new *in vitro* circRNA strategy efficiently generated circRNA *in vitro* for protein expression in cells and various applications.

541 Selection and Characterization of Truncated Vimentin Binding Aptamers

Hongyu Wang[1], Andrea M. Costello[2], Xin Li[2], David E. Volk[2], Anil K. Pillai[3]

[1]Department of Diagnostic and Interventional Imaging, McGovern Medical School, University of Texas Health Science Center at Houston, Houston, TX,[2]Institute of Molecular Medicine, McGovern Medical School, University of Texas Health Science Center at Houston, Houston, TX,[3]Department of Radiology, University of Texas Southwestern Medical Center, Dallas, TX

Vimentin is an extracellular matrix protein expressed in normal mesenchymal cells to maintain cellular integrity. Vimentin is overexpressed in various epithelial cancers, including prostate cancer, gastrointestinal tumors, central nervous system tumors, ovarian cancer, breast cancer, malignant melanoma, and lung cancer. Overexpression of vimentin has been associated with increased capacity for migration and invasion of the tumor cells. Recently, vimentin has been recognized as a marker for epithelial-mesenchymal transition (EMT). Based on its overexpression in cancer and its association with tumor growth and metastasis, vimentin also serves as an attractive potential target for cancer therapy. Aptamers are small single-stranded DNA or RNA ligands with high affinity and specificity to their targets. Aptamers offer many significant advantages over monoclonal antibodies in terms of low cost, non-immunogenicity, and facile modification for various applications. Along with nucleic acid design and synthesis techniques, aptamers have been rapidly developed for detecting and manipulating molecular changes, biomarker discovery, and targeted therapies. We have identified two phosphorothioated aptamers, V3 and V5, with high affinity and specificity binding to vimentin through our innovative morphology-based tissue aptamer selection (Morph-X-Select) method. Based on secondary structure prediction, we identified potential binding motifs of V3 and V5 by truncating the sequences on the stem-loop regions, and generated seven truncated motifs. Those tentative binding motifs were further characterized via cell and tissue binding assays, as well as flow cytometric analysis. By screening the binding affinity of the seven truncated motifs with vimentin-expressing IGROV cells, we selected V3M2 and V5M2 based on their highest fluorescence intensity among truncations of V3 and V5 groups, respectively. Truncations on the stem-loop regions demonstrated a significantly increased binding affinity (about 50% reduction of Kd values) to vimentin protein compared to that of the full-length V3 and V5 sequences while maintaining selective binding activity. Moreover, the shortened motifs with fewer thiophosphate modifications also led to reduced non-specific binding against both target and non-target proteins compared to the full-length phosphorothioated aptamers. Future applications for the vimentin binding aptamer motifs include conjugating the aptamers to synthetic dyes for targeted imaging, precise drug delivery, and targeted therapy in various epithelial cancers.

542 Multimodal Glioma Immunotherapy Combining TLR9-Targeted STAT3 Antisense Oligodeoxynucleotides with PD1-Specific Immune Checkpoint Blockade

Chia Yang Hung[1], Chunsong Yu[1], Elaine Kang[1], Xiaowei Zhang[1], Christine Brown[1], Susanta Hui[2], Benham Badie[3], Amy Heimberger[4], Marcin Kortylewski[1]

[1]Immuno-Oncology, Beckman Research Institute at City of Hope, Duarte, CA,[2]Radiation-oncology, Beckman Research Institute at City of Hope, Duarte, CA,[3]Division of Neurosurgery, Beckman Research Institute at City of Hope, Duarte, CA,[4]Neurological Surgery, Feinberg School of Medicine, Northwestern University, Chicago, IL

Introduction: Malignant gliomas (MG) are rapidly fatal despite multimodal treatments including radiation therapy, used to treat nearly all MG patients, or even the emerging cellular immunotherapies. Therapeutic resistance in glioma is related to tolerogenic STAT3 activity in both glioma cancer stem cells (GCSs) and in the tumor-associated myeloid immune cells, such as macrophages and microglia, which dominate MG microenvironment. We previously demonstrated that STAT3 activity in GSCs and tumor-associated myeloid cells can be targeted using Toll-like Receptor-9 (TLR9)-targeted oligonucleotide therapeutics such as siRNA or antisense oligonucleotides (ASO). **Methods:** Here, we describe development of a new TLR9-targeted and double-stranded STAT3 antisense oligonucleotide (CpG-STAT3dsASO) with optimized efficacy and safety for glioma immunotherapy. **Results:** Compared to our benchmark ASO oligonucleotides, the locked nucleic acid (LNA)-modified CpG-STAT3dsASO showed enhanced target gene knockdown in human and in mouse glioma cells and also in TLR9^{+} immune cells, such as macrophages and microglia. When tested against orthotopic model of human U251 glioma, intracranial injections of CpG-STAT3dsASO (1 mg/kg/q2w) inhibited tumor growth and significantly extended survival of immunodeficient NSG mice compared to benchmark oligonucleotide. Next, we tested CpG-STAT3dsASO against syngeneic GL261 and QPP8 models in immunocompetent mice. Our results demonstrated that CpG-STAT3dsASO was more effective and significantly better tolerated than single-stranded CpG-STAT3ASO when injected intracranially, without evidence of severe acute neural toxicities within tested dosing. All tested CpG-STAT3ASO variants induced activation of intratumoral DCs, macrophages and microglia, while reducing numbers of tumor-associated macrophages (TAMs), resting microglia and regulatory T cells as assessed using flow cytometry. To Our results also suggested the elevation of several immune checkpoint molecules on tumor-infiltrating T cells likely as a result of IFN signaling. Importantly, our preliminary experiments demonstrated a synergy between systemic PD1 inhibition with different dose (0.25 and 0.5 mg/kg) CpG-STAT3dsASO local therapy. While, neither of treatments alone was curative, the combination anti-PD1/CpG-STAT3dsASO therapy resulted in complete rejection of orthotopic GL261 tumors in the majority of treated mice. Importantly, CpG-STAT3ASO treatments improved the ratio of intratumoral CD8 T cells to Tregs. To elucidate changes in the glioma microenvironment related to STAT3-inhibition/TLR9-activation, we performed an initial single-cell RNAseq analysis of transcriptomic profiles in immune cell subsets isolated from tumors after treatment using CpG-STAT3dsASO^{LNA}. Our analysis indicated the reprogramming of tumor-associated myeloid cell populations

within treated glioma with an increased ratio of CD8:regulatory T cells. We previously demonstrated that GCSs can be targeted using TLR9/STAT3 antisense oligonucleotides. Here, our results indicated that the anti-PD1/CpG-STAT3dsASO treatment also inhibited tumor growth and extended the survival of murine GCSs-QPP8 model in immunocompetent mice. **Conclusions:** We believe that further development of CpG-STAT3dsASO will pave way to clinical translation of this strategy to immunotherapy of malignant glioma.

543 miR-375 Triggers Tissue Injury by Activating the Mitochondria of Macrophages

Jinchen He[1], Yi Wang[1], Xiaofei Shen[2], Xiaojun Liu[3], Elisabet Mandon[1], Zhiqi Li[1], Hong Ma[1], Ning Huang[3], Guangping Gao[1], Jun Xie[1]

[1]UMass Chan Medical School, Worcester, MA,[2]Chengdu University of Traditional Chinese Medicine, Chengdu, China,[3]Dept of Pathophysiology, Sichuan University, Chengdu, China

Macrophage activation is central to human immune responses. MicroRNAs (miRNAs) are crucial regulators in various biological processes, including innate and adaptive immune responses. How miRNAs regulate macrophage activation is not well defined. Here, we found that lipopolysaccharide (LPS) stimulation increased miR-375 expression in multiple macrophage cell lines and mouse primary peritoneal macrophages. In an LPS-induced peritoneal inflammation mouse model, miR-375 expression was elevated in the duodenum, peritoneum, and liver. We isolated mouse primary peritoneal macrophages, infected with a lentiviral vector expressing miR-375 and reinfused into the peritoneal cavity of the recipient mice. Seven days later, recipient mice showed damaged duodenum and liver, and elevated levels of macrophages in tissues. Additionally, irregular duodenal villi, less hepatic lobules, granulocyte infiltration, and small areas of hemorrhaging were observed in the injured tissues. To investigate the impact of miR-375 on liver damage, we generated a liver-tropic scAAV9 vector expressing miR-375 under a ubiquitous cytomegalovirus enhancer/chicken β-actin (CMVen/CB) promoter and intravenously injected into adult C57BL/6 mice. Two weeks after injection, the mice showed increased aspartate transaminase (AST) and alanine transaminase (ALT) levels, and decreased body weights and liver sizes. Pathological analysis revealed severe inflammation and macrophage proliferation in the liver. In contrast, depletion of macrophages with clodronate liposome treatment suppressed the elevation of ALT/AST caused by the administration of scAAV9-miR-375 vectors. To explore the therapeutic applications, we generated an scAAV9 vector expressing an inhibitor of miR-375 and intraperitoneally injected it into adult C57BL/6 mice. Three weeks after injection, mice were challenged with LPS and sacrificed two days later. Enlarged spleens were observed in the mice treated with a control vector, but not with vector expressing the miR-375 inhibitor. Compared to control vector-treated mice, the mice that received vector expressing miR-375 inhibitor showed reduced cytokine (IFN-γ, IL-1β, IL-10, IL-17 and IP-10) and chemokine (MIP1β, MIP2 and MCP-1) levels in the serum. To understand the role of miR-375 on macrophage activation we established a stable mouse macrophage cell line that overexpresses miR-375. This cell model exhibited improved macrophage self-renewal, migration, phagocytosis, and activated mitochondria. Assessments of the metabolic capacity of the miR375 expressing macrophages using a Seahorse platform demonstrated a shift to glycolysis with a significative increase in the mitochondrial metabolic potential. This pattern is characteristic of M1 activation. The transcriptome analysis correlates with the upregulation of enzymes involved in glycolysis and in the mitochondrial biosynthesis of the building blocks for cytokines and itaconic acid. Finally, we found that miR-375 repressed *Zfp36l2* and upregulated WDR5 to stabilize cMYC to activate mitochondria. Altogether, this study revealed that miR-375 triggers tissue injury by activating the mitochondria of macrophages through a Zfp36l2-WDR5-cMYC axis. Using a miR-375 antagonist to prevent tissue injury caused by macrophage overactivation can be a possible therapeutic approach. # J.H. and Y.W. are co-first authors *N.H., G.G., and J.X are co-corresponding authors

544 Self-Delivering RNAi (INTASYL™) Compounds Targeting TIGIT or CBL-B Improve NK Cell Functional Cytotoxicity toward Tumor Cells

Melissa Maxwell, Benjamin Cuiffo, Dingxue Yan, Brianna Rivest, Andrew Boone, James Cardia, Linda Mahoney, Robert Bitterman

Phio Pharmaceuticals, Marlborough, MA

Background: NK cells are the body's first line of defense against cancer, able to recognize and kill tumor cells without prior exposure. Unlike T cells, allogeneic NK cells do not induce graft-versus-host disease. NK cell adoptive cell therapy (NK-ACT) holds promise as a true "off-the-shelf" cellular immunotherapy for cancer, with the potential to circumvent many of the hurdles associated with autologous cell therapies. NK-ACT shows promise against hematological cancers, but the cytotoxic activity of these cells needs to be enhanced to improve clinical efficacy. In particular, expression of inhibitory proteins such as TIGIT and CBL-B has been shown to inhibit NK cell-mediated cytotoxicity. Therefore, strategies to relieve TIGIT and/or CBL-B inhibition in NK-ACT products are under active exploration as means to improve the efficacy of NK-ACT. Incorporating RNAi treatment into ex vivo NK cell expansion protocols prior to ACT represents one such strategy. The INTASYL™ platform is a self-delivering RNAi technology that imparts small molecule-like properties to interfering RNAs, providing extremely efficient delivery to target cells without need for specialized formulations or drug delivery systems. This allows INTASYL to be easily incorporated into cell therapy manufacturing protocols. INTASYL compounds are potent, stable, and are rapidly taken up by cells. While durable, INTASYL-mediated gene silencing is transient, mitigating safety considerations that may arise from permanent deletion of NK cell suppressors. INTASYL compounds are able to silence both extracellular (TIGIT) and intracellular (CBL-B) proteins. **Methods:** Primary human $CD56^+$ NK cells were expanded using the ImmunoCult™ NK Cell Expansion Kit. Following the 14-day expansion protocol, cells were collected, and the cell density was adjusted to 0.5 x 10^6 cells/mL in culture media containing IL-2. Cells were seeded directly into 24-well plates containing INTASYL compounds ranging in final concentration from 0 to 5 μM. TaqMan gene expression assays were used to determine expression levels of TIGIT and CBL-B following the RNA-to-Ct 1-step protocol. Cytotoxic capabilities of the INTASYL-treated NK cells against the K562 (Chronic Myelogenous Leukemia) cancer cell line were tested in a DELFIA cell

cytotoxicity assay. Following co-culture, cell culture supernatants were analyzed by ELISA for increased secretion of IFN-γ. **Results:** INTASYL treatment results in consistent mRNA silencing without negative impact on NK cell viability. Silencing of TIGIT and CBL-B resulted in increased expression of markers of NK cell activation and increased cytotoxic capabilities of NK cells against K562 cancer cells in the DELFIA cell cytotoxicity assay. **Conclusions:** Here, we demonstrate the potential of INTASYL to improve NK cell potency in ACT. By treating NK cells with INTASYL targeting the inhibitory proteins TIGIT and CBL-B ex vivo, during NK cell expansion, the anti-tumor response of these cells was enhanced. This may result in a more effective cell therapy for solid tumors and hematological malignancies. In vivo studies are ongoing.

545 Cell-Selective STAT3 PROTAC Degrader Based on the Decoy Oligonucleotide

Jeremy Hall[1], Zhuoran Zhang[2], Dongfang Wang[3], Supriyo Bhattacharya[4], Yong Liang[5], Piotr Swiderski[5], Nagarajan Vaidehi[4], Marcin Kortylewski[3]

[1]Immuno-Oncology, Beckman Research Institute at City of Hope, Duarte, CA,[2]Immuno-Oncology, City of Hope, Duarte, CA,[3]Immuno-Oncology, City of Hope Comprehensive Cancer Center, Duarte, CA,[4]Computational Therapeutics, City of Hope Comprehensive Cancer Center, Duarte, CA,[5]DNA/RNA Synthesis Core, City of Hope Comprehensive Cancer Center, Duarte, CA

Oncogenic and/or tolerogenic transcription factors (TFs), such as STAT3 and NF- kB, are enticing but challenging targets for cancer therapy. Decoy oligodeoxynucleotides (dODNs) specific to TF DNA-binding domains were explored as highly-selective and competitive TF inhibitors. However, delivery challenges and limited potency hampered translation of decoy inhibitors. We previously demonstrated that conjugation of dODNs to single-stranded CpG ODNs facilitates targeted delivery to cells expressing scavenger receptors (SRs)/Toll-like receptor 9 (TLR9), such as myeloid cells and certain cancer cells. To improve inhibitory potency of dODNs, we converted a STAT3-specific decoy (S3dODN) into a proteolysis targeting chimera (S3dODN^{PROTAC}) capable of inducing an irreversible STAT3 protein degradation. Thalidomide molecule (Tha), a ligand for cereblon (CRBN) within a E3 ubiquitin ligase complex, was tethered to the 3' end of S3dODN. The S3dODN^{PROTAC} design was guided by computational modeling in solution to enable complexing of STAT3 proteins bound to S3dODN^{PROTAC} via CRBN to the E3 ubiquitin ligase complex. STAT3 protein degradation and decreased activity was almost completely abrogated in target myeloid cells transfected with STAT3dODN^{PROTAC} but not with equimolar amounts of unconjugated S3dODN and Tha. The competition studies verified specific contributions of decoy and thalidomide moieties in STAT3 degradation. The inhibitory effect of S3dODN^{PROTAC} in target cells was abolished in the presence of proteasome inhibitors and also by CRISPR-knockout of CRBN consistently with the putative proteolytic mechanism of STAT3 inhibition. Based on modeling studies, we have identified two lysine residues, K601 and K626 as potential ubiquitination sites in STAT3. The mutation of either site or both sites together reduced or completely abrogated S3dODN^{PROTAC}-induced STAT3 degradation, respectively. To enable targeted and formulation-free STAT3dODN^{PROTAC} delivery, we conjugated this ODN to a CpG moiety. C-S3dODN^{PROTAC} was spontaneously internalized and reduced STAT3 levels in primary mouse, myeloid cells, B cells and human Ly18 and mouse A20 B cell lymphoma cells, but not in T cells. C-S3dODN^{PROTAC}, but not the unmodified C-S3dODN, decreased STAT3 levels to 50% at 250 nM and over 85% at 2 μM dosing in mouse myeloid cells. The inhibitory effect of C-S3dODN^{PROTAC} was specific to STAT3 and it did not affect levels of the related STAT5 and STAT1 proteins. To our knowledge, this is the first demonstration that the PROTAC approach can be successfully applied to decoy-based targeting of undruggable transcription factors such as STAT3.

546 Development of a Next-Generation *Ex Vivo* Delivery Platform Using Nanoneedles for Physical Cargo Delivery into Cells

Eldon T. Chou

Mekonos Inc., Berkeley, CA

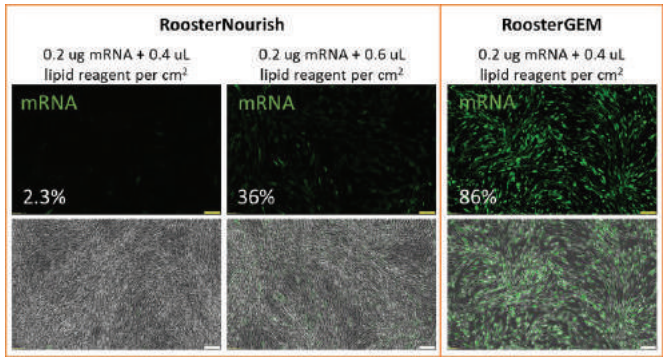
The widespread use and development of cell therapies has been limited by a deficiency of efficient and safe delivery methods. The current conventional methods of biomolecule delivery all have severe restrictions, including a lack of dose control, a lack of precision, patient safety concerns, cell viability issues, cargo size limitations, and cell type restrictions. All these limitations compound and can cause both short- and long-term cell functionality compromises that are observed either in the production of a cell therapy or downstream in the patient. At Mekonos, we are developing a next-generation delivery platform that will address the *ex vivo* delivery bottleneck and unlock the full potential of gene editing for cell therapies. Here we describe our novel cell engineering platform which utilizes a controllable array of solid silicon nanoneedles to enable direct intracellular access of multiplexed biomolecular payloads without the use of viral vectors or electroporation. The silicon nanoneedles are made using an advanced semiconductor process to develop chips that are scalable and precise, allowing us to consistently produce nanoneedles with specific heights and widths. Cells are trapped using a microfluidic system that enables precise localization of each nanoneedle tip to a single cell, enabling a controlled, consistent delivery that is not possible with other delivery methods such as electroporation. The biomolecular payloads are adsorbed onto the surface of each nanoneedle with an aptamer-based surface chemistry that ensures the controlled release of the desired biomolecule once within a cell-specific environment. Our nanoneedle delivery method has been demonstrated to be cell type and cargo agnostic, allowing us to deliver a variety of biomolecules such as nucleic acids, proteins, and RNP complexes into a variety of primary and stem cells with higher viability and efficiency than current industry standard methods. We believe that the combination of our semiconductor, microfluidic, and surface chemistry technologies will drive the future of cell therapies through scalable, hyper-precise cell engineering.

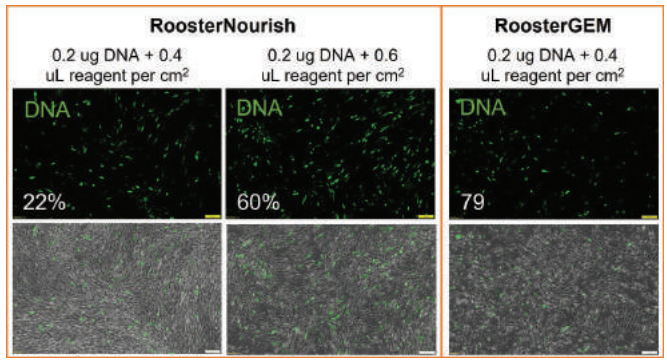
547 A GMP-Compatible Process for the Efficient Transfection of MSCS with mRNA

Mary T. Doolin[1], Therese M. Willstaedt[2], Michael Boychyn[2], Jon A. Rowley[2]

[1]RoosterBio, Inc, Frederick, MD,[2]RoosterBio Inc., Frederick, MD

Background & Aim Genetic engineering of mesenchymal stromal cells (MSCs) has emerged as a powerful player in the cell and gene therapy field due to MSCs' immunomodulatory and regenerative potential. For example, transient transfection of MSCs has been shown to enhance neovascularization *in vivo* via increased MSC survival. mRNA transfection is well suited for cellular reprogramming (i.e. gene editing) applications, as a transposase or Cas9 need only be expressed while integrating a gene of interest. We previously optimized medium formulations and mRNA transfection parameters for MSCs and demonstrated dramatic enhancement of MSC transfection efficiency. A significant challenge to the clinical implementation of mRNA-modified MSCs is to efficiently transfect MSCs within the context of GMP-compatible processes. Therefore, we aimed to develop a scalable GMP-compatible process for genetically modified MSCs that could be rapidly implemented within product development programs. Methods, Results, & Conclusion MSCs were plated in 2D flask culture for 4 days until 90% confluent and passaged into a final culture vessel using RoosterNourish medium. After 3 days, the growth medium was changed to RoosterGEM (Genetic Engineering Medium) formulated with all-GMP reagents, and MSCs were transfected using a proprietary transfection reagent developed by Mirus Bio and mRNA or plasmid DNA encoding a fluorescent protein. Cell transfection efficiency was evaluated using fluorescence microscopy and quantified via flow cytometry. The transfection reagent yielded 86% mRNA transfection efficiency and 79% DNA transfection efficiency (**Figures 1, 2**). Despite an initial overall lower cell yield in RoosterGEM compared to RoosterNourish growth medium, there were still fifteen-fold more engineered cells in the RoosterGEM process when transfected with mRNA. To ensure this process yields a viable product, we showed that mRNA-transfected MSCs can be cryopreserved and thawed successfully, maintaining their protein expression (**Figure 3**). Cells lose their fluorescence rapidly after passage, with only 20% of cells maintaining fluorescence after 3 days. Therefore, we recommend transfecting cells at the confluence and passage desired for the final application. We have also tested MSC expansion and transfection in a 3D bioreactor process, with transfection efficiency of ~50% using RoosterGEM using un-optimized conditions. Future work will optimize the transfection of MSCs with mRNA in a 3D bioreactor process.





548 Epicardial Hydrogel Delivery of Adeno-Associated Virus to Treat Heart Disease

Gabriella Kabboul[1,2], Jeremy D. Caplin[3], Christopher B. Doering[4], Andrés J. García[3], Rebecca D. Levit[2]

[1]Wallace H. Coulter Department of Biomedical Engineering, Georgia Institute of Technology & Emory University, Atlanta, GA,[2]Division of Cardiology, Department of Medicine, Emory University, Atlanta, GA,[3]Woodruff School of Mechanical Engineering & Petit Institute for Bioengineering and Bioscience, Georgia Institute of Technology, Atlanta, GA,[4]Department of Pediatrics, Aflac Cancer and Blood Disorders Center, Emory University, Atlanta, GA

Introduction: Heart disease is a leading cause of death world-wide. Despite promising preclinical studies, clinical trials using adeno-associated virus (AAV) to treat heart disease have failed due to low transduction of cardiomyocytes (<1%) and neutralizing effects of anti-AAV antibodies. Hydrogels containing non-viral therapeutics delivered to the epicardium through the pericardial space have shown efficient targeting of drugs to the heart while minimizing off-target delivery. The goal of this study is to investigate the delivery of AAV-containing hydrogels to the epicardium. We hypothesize that epicardial hydrogels encapsulating AAV will efficiently transduce cardiomyocytes *in vivo*. **Methods:** AAV9 delivering mCherry driven by the CMV promoter was encapsulated in 4-arm poly(ethylene glycol) (PEG-4MAL) hydrogels crosslinked with protease-sensitive peptide and hydrolytic crosslinker. AAV was delivered to male Sprague-Dawley rats at 2.5E11 vector genomes (vg)/rat by 50 µL epicardial gels (n=4). Control (no AAV) epicardial gels were also included (n=4). Eight animals were randomized to receive either control gel or AAV gel. Organs were collected for analysis 6 days post-treatment. Transgene expression in cardiac tissue was analyzed by quantitative PCR (qPCR) and immunohistochemistry. Masson trichrome and H&E staining were used to evaluate potential inflammation or fibrosis induced by AAV. **Results:** By qPCR, we measured fold changes in mCherry expression in the heart relative to a reference gene (PPIA) of 0.076 ± 0.050 in animals that received epicardial AAV gels (n=4). No amplification was detectable in control animals (n=4). Immunohistochemical analysis of the heart tissues from epicardial AAV gels showed mCherry expression across the epicardium and myocardium. Signal colocalized with cardiac troponin T (cTnT) as a cardiomyocyte marker. Histological staining did not show evidence of inflammation or fibrosis, and there were no significant increases in fibrosis accumulation measured by colorimetric analysis using ImageJ in heart tissues from AAV gels compared to

control gels. **Conclusion:** These results provide a basis for AAV-containing hydrogel delivery to the epicardial surface. Future work will focus on optimizing the hydrogel for AAV cargo and evaluating local and systemic immunologic response to epicardial delivery.

549 New Imidazole Core Based Helper Lipids for Non-Viral Gene Delivery Applications

Alexis Hocquigny[1], Mathieu Berchel[2], Paul-Alain Jaffrès[2], Tristan Montier[1,3]

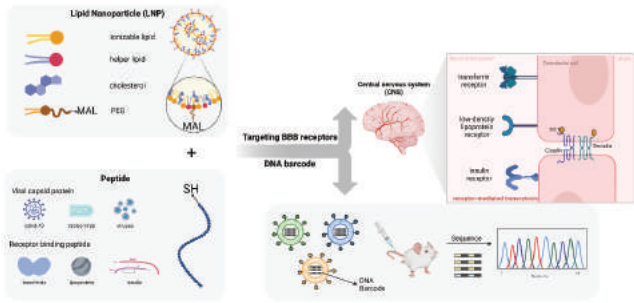
[1]Univ Brest, Inserm, UMR 1078, GGB-GTCA Team, "Gene Transfer and Combined Therapeutic Approaches", Brest, France,[2]Univ Brest, CNRS, CEMCA UMR 6521, 6 Avenue Victor Le Gorgeu, Brest, France,[3]CHU Brest, Medical Genetics and Reproductive Biology Department, Center of Reference for Rare Diseases "Neuromuscular Diseases", Brest, France

Introduction Development of efficient, reinjectable and non-toxic gene delivery systems is among the most challenging requirement to deploy the full potential of gene therapy. As an alternative to viral-based systems that are associated with immunogenic and oncogenic complications, synthetic carriers have been developed, notably based on cationic lipids and polymers. In this context, we have designed and synthesized four new helper lipids (HpLs) featuring either one or two identical imidazole or histidine moieties as polar region. These moieties can be protonated in acidic environment, destabilizing endosome membrane for an easier endosomal escape induced by causing swelling and rupture of the endosomal membranes. In this work, our goal was to improve non-viral gene transfection by associating BSV107, a cationic lipid (CL), with novel HpLs and to compare them with formulations including DOPE. To better understand the impacts of imidazole rings during gene delivery, we further studied the endosomal escape pathway implicated during transfection. **Methods** Formulations with cationic lipid BSV107 and HpLs were prepared at ratio 1:1 and their physicochemical parameters (size, zeta potential and polydispersity index) were determined by dynamic light scattering. Transfection efficiencies (expressed in relative light unit per mg of total proteins, RLU/mg) were determined using a plasmid encoding a luciferase reporter gene 24h after transfection and cell viabilities were also evaluated. Transfection assays were performed mainly on human epithelial lung cell lines with different charge ratios (2, 4 and 6) between CLs and plasmids. To explore the endosomal escape, the impact of the new HpLs was probed by using different endosome maturation inhibitors which were added to the medium two hours prior to transfection assays. **Results** Formulations including HpLs demonstrated a significantly higher transfection efficiency compared to standard CLs in the three cell lines used (10^6 RLU/mg for CLs vs. 10^7 - 10^8 for HpLs-CLs). In term of transfection efficiencies, no significant difference was observed between histidine and imidazole-based HpLs. HpLs containing two moieties (either imidazole or histidine) showed better transfection efficiencies than HpLs with only one moiety (10^7 vs 10^8 RLU/mg). Experiments performed with two rings-based HpLs-CLs demonstrated transfection efficiencies (10^8 RLU/mg) and cell viabilities (70% of untreated cells) comparable with DOPE-associated CLs. However, we noticed higher toxicities (approximately 20%) with histidine-based HpLs-CLs. In addition, the application of endosome acidification inhibitors (bafilomycin A1, a specific inhibitor of vacuolar-type H+ ATPase, for example) reduced significantly the transfection efficiency of HpLs-CLs complexes. These results highlighted the importance of acidic endosomal pH in transfection processes. **Conclusion** In this work, the synthetic vector BSV107, associated with our innovative imidazole/histidine-based HpLs, have demonstrated promising transfection efficiencies. Further optimizations are still needed to enhance biocompatibility and reduce potential toxicity. In this sense, the application of microfluidic should result in safer formulations. The role of endosomal pathway could be further characterized through cellular sub-fractionation and microscopic studies. This will help us to better understand various steps of transfection processes and to fine-tune our formulations to fit with future applications.

550 Development of Blood-Brain Barrier-Penetrating Functional Lipid Nanoparticles for Effective CNS Gene Therapy

Haram Kim, Yujin Shin, Hyeonmin Maeng, Kye Il Joo

EWHA Womans University, Seoul, Korea, Republic of



Despite many current treatment options that could treat central nervous system (CNS) diseases, there still remains a need to improve the delivery efficacy of drugs into the brain. This is because there is a blood-brain barrier (BBB) that selectively passes nutrients from the blood to maintain brain neuron function and control the brain tissue's microenvironment. Approaches to penetrating the BBB to deliver LNP into CNS for gene therapy are being conducted, but the problem is that the effectiveness is still low. In this study, we formulated LNPs capable of crossing the BBB by tailoring the composition and surface properties of LNPs to promote their binding to receptors that are present in the BBB and inducing receptor-mediated transcytosis. Furthermore, it is generally believed that the smaller size is more efficient to cross the BBB. Therefore, for effective CNS gene therapy, we prepared sub-100nm LNPs and functionally modified the particle surface with peptides capable of targeting the receptor in the BBB. This approach involves incorporating functional peptides selected from diverse proteins, including viral capsid proteins, known to efficiently penetrate the BBB. In this presentation, diverse LNP formulations with functional peptides for improving the efficacy of CNS gene therapy will be compared and discussed in more detail.

551 Demonstration of Safety and Therapeutic Effect of Cell-Derived Vesicles in Retinal Degeneration

Hui-Chong Lau[1], Jiwon Park[1], Yvette Wooff[2,3], Adrian V. Cioanc[2,3], Riccardo Natoli[2,3], Sung-Soo Park[1], Seung Wook Oh[1]

[1]BioDrone Research Institute, MDimune Inc., Seoul, Korea, Republic of,[2]Clear Vision Research, Eccles Institute of Neuroscience, John Curtin School of Medical Research, College of Health and Medicine, The Australian National University, Acton, ACT 2601, Australia,[3]School of Medicine and Psychology, College of Health and Medicine, The Australian National University, Acton, Act 2601, Australia

Introduction: Age-related macular degeneration (AMD) is the leading cause of blindness in developed countries. Despite the emergence of ophthalmic drugs, effective treatment for AMD remains elusive. It was widely reported that inflammation is the key to AMD progression. Previously, we have reported the immunomodulatory capacity of cell-derived vesicles (CDVs) in several inflammatory or degenerative diseases. Here, we present the evidence to support the potential of CDVs as a novel therapeutic for slowing the progression of AMD. The safety and therapeutic potential of CDVs were assessed by examining retinal function in an AMD mouse model. **Methods**: CDVs produced from umbilical cord mesenchymal stem cells (UCMSCs) by serial extrusion were used in this study. RNAseq was first performed to identify key miRNAs involved in anti-inflammatory functions in UCMSC-CDVs. Then, the cellular uptake of CDVs in different retinal cell types was assessed *in vitro*. *In vivo* safety and efficacy of UCMSC-CDVs were evaluated after administering CDVs by intravitreal injection into mice subjected to photo-oxidative damage for 5 days. Alteration in retinal function was measured using electroretinography (ERG), angiography, and immunohistochemistry. **Results**: Comprehensive bioinformatics analyses of RNAseq data revealed that UCMSC-CDVs were enriched with let-7 family and miR-125a, well known for their therapeutic protection in retinal degeneration. CDVs showed efficient cellular uptake in different retinal cell types. In the *in vivo* experiments, UCMSC-CDVs demonstrated a protective effect against retinal degeneration, while exhibiting no apparent toxicity in the mouse retina. Overall, UCMSC-CDVs significantly improved retinal function and reduced levels of cell death as measured by the number of photoreceptor rows and $TUNEL^+$ cells in the outer nuclear layer. Additionally, treatment of UCMSC-CDVs did not induce inflammation in the retina. **Summary/Conclusion**: Findings of this study support the use of UCMSC-CDVs as non-toxic and therapeutically efficacious vesicles in retinal degeneration. With proven productivity and versatility for various drug loading, UCMSC-CDVs can serve as effective therapeutics as well as vehicles for additional payloads in AMD and many other inflammatory diseases.

552 Development of Highly Efficient and Biocompatible Delivery Method of RNA Therapeutics Using BioDrone™ Platform Technology

Jinhee Park, Kyeongeun Park, Sung-Soo Park, Seung Wook Oh

BioDrone Research Institute, MDimune Inc, Seoul, Korea, Republic of

Introduction: The extraordinary success of CoVid-19 vaccine has accelerated an explosive expansion of mRNA therapeutics. However, synthetic vehicles such as lipid nanoparticles (LNPs) and polymers currently used for mRNA delivery exhibited considerable safety concerns. Cell-derived vesicles (CDVs) produced by serial extrusion of diverse human cells are emerging as novel delivery vehicles for RNA delivery due to their superior biocompatibility, capability to cross diverse tissue barriers, and unique scalability. Here, we present an alternative approach for mRNA delivery using CDVs to overcome the immunogenicity and toxicity issues. The therapeutic potential of CDVs carrying mRNA was evaluated *in vitro* and *in vivo*. **Methods**: mRNAs were complexed with CDVs via positively-charged lipids. Fluorescent-labeled mRNAs or reporter mRNAs such as luciferase and EGFP were used to determine the potential of CDVs for mRNA delivery. Cellular mRNA uptake and protein expression level were measured using flow cytometry, western blot, and luciferase reporter assay. The *in vivo* delivery and biodistribution of mRNA-loaded CDVs were assessed by IVIS imaging. In addition, acute toxicity and inflammatory response were evaluated by assessing a hematology profile and multiplex cytokine/chemokine panel. All the animal experiments were conducted in comparison with LNPs. **Results**: We established a method of loading mRNAs to CDVs using cationic lipids. The mRNA cargo can be loaded onto CDVs with over 90% of loading efficiency, maintaining the integrity of the vesicle structure. CDVs facilitated the delivery of mRNAs to target cells, resulting in robust protein expression. Remarkably, no significant immunogenicity was observed upon intramuscular and intravenous delivery of mRNAs by CDVs, whereas multiple immunogenic responses were evident in LNPs. **Summary/Conclusion**: Taken together, we have demonstrated the potential of CDVs as an mRNA delivery carrier. With proven safety and efficiency, the BioDrone™ technology based on CDVs will expedite the development of mRNA-based therapeutics for cancer, CNS disorders as well as many other debilitating diseases.

553 A Novel Phosphatidylserine-Based Nanoparticle Gene Delivery System for DNA & mRNA

Hui Liu

Matinas Biopharma, Bedminster, NJ

Background: A major challenge confronting modern-day gene therapy is the safe, efficient, and targeted intracellular delivery of DNA and mRNA. Currently available options include lipid nanoparticles (LNPs) and viral vectors, both of which have a number of well-documented limitations. We wish to report recent results using a novel phosphatidylserine (PS) based nanoparticle (PS-NP) gene delivery platform to deliver plasmid DNA and mRNA in vitro. **Methods:** Studies were conducted in cultured HeLa cells. Cells were transfected with 200 ug/mL of either GFP or luciferase-coding plasmid DNA or

mRNA (Tri-link) that was encapsulated in a PS-NP delivery platform. In vitro cell culture doses ranged from 4-500 ng per well, with controls of the respective nucleic acids delivered either by Lipofectamine 3000 or Lipofectamine™ MessengerMAX™Transfection efficiency was assessed by fluorescence microscopy and flow cytometry, looking at both fluorescence intensity and the percentage of GFP-positive live cells. Cytotoxicity was assessed by cell viability with ATP Glo assay. Stability of mRNA formulations was evaluated by measuring the transfection activity of the PS-NP mRNA formulations at time 0, and after 1,2,3, 5, and 10 weeks of storage at 4 ºC storage conditions. **Results:** For each of the PS-NP/oligo formulations studied, particle sizes ranged from 100 to 400 nm, with Zeta potentials from 30 to 60 mV. Efficiency - pDNA formulations were as potent as Lipofectamine 3000 controls at concentrations ranging from 4-500 ng. mRNA formulations were less active than gold-standard Lipofectamine™ MessengerMAX, but still showed substantial clinically relevant activity.Cytotoxicity testing showed virtually no cell death after 36 hours of incubation at high doses of 500 ng DNA per well, with similar survival with sequential serial dilutions down to 31 ng.Stability (and biological activity) of mRNA formulations was maintained out to 10 weeks. **Conclusions:** This unique PS-NP delivery platform represents a promising delivery alternative for gene therapy applications that require safe, efficient delivery of DNA and mRNA. Confirmatory in vivo work is ongoing.

554 Lipid Nanoparticle-Mediated Gene Editing of Human Primary T Cells and Off-Target Analysis of the CRISPR-Cas9 Indels

Meenakshi Swaminathan[1], Bernice Thommandru[2], Reka Geczy[1], Rita Zhao[1], Krystal Tan[1], Kevin Low[1], Aruna Balgi[1], Stella Park[1], Ethan Watt[1], Vaugh Thada[2], Garrett Rettig[2], Angela Zhang[1], Rolf Turk[2], Samuel Clarke[1]

[1]Precision NanoSystems, Vancouver, BC, Canada,[2]Integrated DNA Technologies, Coralville, IA

Background and Aims: TheCRISPR/Cas9 system has emerged as a powerful tool for gene editing of primarycells. In our previous work, we demonstrated a novel lipid nanoparticle (LNP)reagent for the multi-step engineering of gene-edited CAR T cells. We showedhigh cell viabilities and potent CAR-T mediated killing, even after multiplegenetic manipulations. Here, we extend this work by assessing potentialoff-target editing effects in both LNP-treated T cells and T-cells where theCRISPR reagents were delivered by electroporation. Further, we evaluatedmultiple Cas9 variants and guide RNA targets. **Methods**: LNPsencapsulating wild type or high fidelity S.p. Cas9 mRNA and various *TRAC*and *CD52* targeted guide RNAs (sgRNAs) were produced using our scalable NanoAssemblr™ microfluidicsplatform. Concurrently,electroporation was performed to deliver equivalent cargoes. Purified primary Tcells were cultured, activated, and expanded in serum-free media in plates,flasks, or small bioreactors. The LNPs were added to cells by direct additionfor gene editing. Gene expression and cell viability were measured using flowcytometry or colorimetric assays. Multi-target performance of CRISPR-Cas9editing was evaluated through rhAmpSeq™ next-generation sequencing (NGS) and indels analyzed for with CRISPRAltRations.**Results**: TCR or CD52 targeted Cas9 mRNA-LNPaddition or electroporation yielded high single and double knockoutefficiencies. High-throughput NGS analysis showed strong agreeance to flowcytometry for on-target analysis. We tested a range of sgRNA targets, wild-typeand high-fidelity Cas9 mRNAs, and determined off-target editing for all targetsand variants investigated. Similar results were obtained when comparingdifferent LNP batch sizes (micro to milligram RNA) and cell culture vessels(0.1 to 45 million cells), demonstrating scalability of both LNP production andcell treatment.**Conclusions**: The results from this study further supportthe utility RNA-LNPs for the genetic engineering of primary T cells. The simpleand gentle nature of LNP cell treatment allows for multiple genetic engineeringsteps for simultaneous expression and deletion of proteins. These LNPs can be easily manufactured fromsmall scale to rapid scale up.

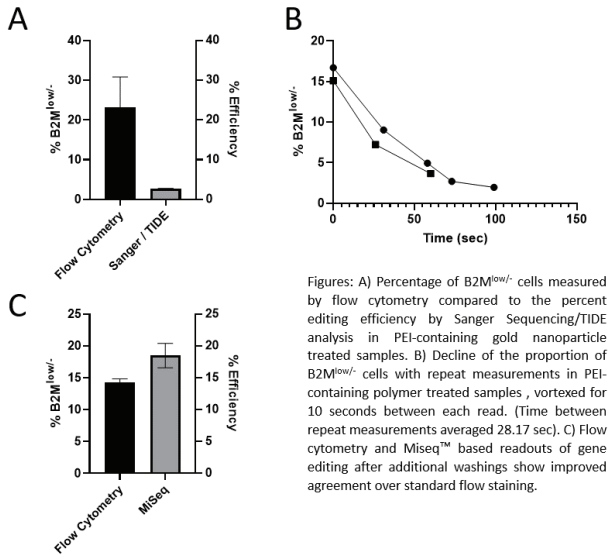
555 False Positive Gene Editing Outcomes as Measured by Protein Expression Following Polymer-Based CRISPR Delivery Due to Nonspecific Sequestration of Antibodies by PEI

Youngseo Jwa[1], Daniel D. Lane[1], Karthikeya S. V. Gottimukkala[1,2], Molly E. Cassidy[1], Jennifer E. Adair[1,2]

[1]Translational Science and Therapeutics, Fred Hutchinson Cancer Center, Seattle, WA,[2]Department of Laboratory Medicine and Pathology, University of Washington, Seattle, WA

CRISPR gene editing can create insertions and deletions (indels) in genomic DNA to alter protein expression in cells for therapeutic purposes. Current state of the art uses electroporation to deliver CRISPR plasmids or ribonucleoprotein (RNP) complexes, however these methods are complex and expensive to implement, and not easily translated *in vivo*. There are several major classes of nanoscale delivery tools being developed to enable *in vivo* CRISPR therapy base on: cationic lipids, polymers, and/or metal cores, including gold (AuNP). Both polymeric and metal core nanoparticles utilize cationic polymers as oligonucleotide carriers and intracellular release agents. Transgenic murine models have been used to evaluate biodistribution and activity of these *in vivo* CRISPR delivery tools, however, these models are not reproducible across delivery platforms/tissues. An ideal model would enable rapid and reliable readout of gene editing frequency and biodistribution, preferably as changes in functional protein expression. Here we studied the four exon human β-2-microglobulin (B2M) gene as a target for comparing CRISPR delivery strategies. As a component of the major histocompatibility I complex, the B2M protein is expressed on the surface of most tissues and cell types. Indels in the coding sequence result in loss of B2M expression, making flow cytometry a useful, rapid readout for gene editing. As proof for B2M's utility we evaluated a cationic, polyethylenimine (PEI)-containing AuNP for its ability to deliver CRISPR (Cas9) RNP into Jurkat cells. Comparing untreated Jurkat cells and electroporation controls, cells were stained for flow cytometry on a BD FACSCelesta and analyzed on FlowJo™ software (v.10.8). Gating first identified cells using forward and side light scatter, then gated on live cells (Zombie NIR™) followed by B2M Mouse anti-human, Clone: 2M2. We observed 23.13±13.34% $B2M^{low/-}$ cells across all AuNP + PEI treated samples. However, Sanger sequencing with TIDE analysis showed 2.67±0.21% gene editing, suggesting flow cytometry results were false positive. We hypothesized that PEI could interfere with antibody staining due to known electrostatic PEI-protein interactions leading to sequestration.

To test this, we repeated flow cytometry against a PEI-containing polymer and tracked its change in B2M protein expression. Repeat measurements of the same samples demonstrated an apparent decrease in proportion of B2M$^{low/-}$ cells over 5 min from 16.70% to 1.96% with repeated mixings. To fix this problem, we developed a new staining protocol with maximum volume dilution and additional washing steps to remove excess PEI prior to staining for B2M. Consequently, we observed ratiometrically stable frequencies of gene editing by both flow cytometry (14.23±1.04%) and MiSeq™ analysis (18.50±3.30%), confirming that presence of PEI could lead to false positive gene editing results. This study underscores the need to optimize analysis protocols for protein expression in intact cells when PEI-containing polymers are used for delivery of gene editing tools, and to validate gene editing outcomes by multiple methods at different points in the central dogma of biology.



Figures: A) Percentage of B2M$^{low/-}$ cells measured by flow cytometry compared to the percent editing efficiency by Sanger Sequencing/TIDE analysis in PEI-containing gold nanoparticle treated samples. B) Decline of the proportion of B2M$^{low/-}$ cells with repeat measurements in PEI-containing polymer treated samples , vortexed for 10 seconds between each read. (Time between repeat measurements averaged 28.17 sec). C) Flow cytometry and Miseq™ based readouts of gene editing after additional washings show improved agreement over standard flow staining.

556 High-Throughput Screening Platform of Lipid Nanoparticles for *In Vivo* CRISPR/Cas Gene Editing

Qing Xia[1], Bang Wang[1], Chengbiao Yang[1], Zongli Zheng[2]

[1]GenEditBio Limited, HongKong SAR, China,[2]Ming Wai Lau Centre for Reparative Medicine, Karolinska Institutet, HongKong SAR, China

Gene editing mediated by CRISPR/Cas holds great promise for gene therapy. Delivery of CRISPR/Cas systems to specific tissue by an effective way is one of the greatest challenges in *in vivo* gene editing. Lipid nanoparticle (LNP)-based mRNA delivery represents a clinically proven and effective nonviral delivery system that is gaining attractions across the fields of the nucleic acid-based therapies. Previously, thousands of novel lipid components and LNP compositions were screened either in cell culture contexts or *in vivo* to evaluate single mRNA delivery and expression. However, these screening strategies may not be applicable on CRISPR/*Cas9* mRNA-based *in vivo* gene editing, which needs codelivery of both *Cas9* mRNA and target single-guide RNA into one cell and function as one ribonucleoprotein complex. A high-throughput platform for screening LNPs dedicated to the *in vivo* delivery of functional CRISPR/Cas9 systems is in great demand. We herein present an *in vivo* high-throughput screening platform for simultaneously quantifying delivery efficiencies of up to 96 barcoded LNPs encapsulating *Cas9* mRNA and single-guide RNA (sgRNA) by single administration with pooled LNP mixture and subsequent deep sequencing. In the initial proof-of-concept experiments, we designed an array of LNPs consisting of combinations of new lipids, formulations, and encapsulation processes. The delivery efficiencies of different LNPs were tracked and quantified by their corresponding barcodes, in which the sequence *per se* has no effect on delivery and can only be detected when both *Cas9* mRNA and target sgRNA are co-delivered and function within cells. In the context of *in vivo* delivery to rat liver, several barcodes showed high enrichments, indicating that the corresponding LNPs exhibited high delivery efficiencies for CRISPR/Cas9. Indeed, the results were subsequently verified by individual LNP delivery in individual rats, indicating that this platform can efficiently identify lead LNP candidates as well as optimal formulation parameters for *in vivo* delivery of CRISPR/Cas9. We further applied this approach to nonhuman primate (cynomolgus monkey) and screened for 96 LNPs. By measuring the relative abundances of the 96 LNP barcodes, we identified new formulations and lipids that were associated with varying delivery efficiencies of CRISPR/Cas9. Interestingly, those LNPs showed high delivery and editing efficiencies in cynomolgus monkey were not always the same as those showed high efficiencies in rats, and vice versa. The result suggests that the efficiency of LNP-based mRNA delivery of CRISPR/Cas9 system may differ across different species, highlighting the significance of choosing proper *in vivo* LNP screening models for LNP-based gene editing therapies. Our screening platform employs a direct quantification of barcoded LNP harboring functional CRISPR/Cas9, enables a high-throughput and straightforward readouts of efficient LNP-*Cas9* mRNA delivery systems. The high-throughput platform could be broadly applied beyond LNPs to non-lipid nanoparticles and beyond Cas9 nucleases, thus would significantly benefit *in vivo* CRISPR/Cas therapeutic applications.

557 Edible Plant-Derived Nanovesicles to Systemic Deliver Nucleic Acid Medicine for Oral Administration

Tomohiro Umezu, Mamoru Yanagimachi, Masakatsu Takanashi, Yoshiki Murakami, Masahiko Kuroda

Tokyo Medical University, Tokyo, Japan

[Introduction] In recent years, as the functions and properties of extracellular vesicles, including exosomes, have been elucidated, the development of drug delivery systems (DDS) based on these properties has been actively conducted. On the other hand, several issues remain to be cleared in supplying extracellular vesicles for clinical application, including cost, quality, and storage. Therefore, we searched for exosomes that could be mass-produced at low cost, and found that exosome-like vesicles could be extracted from acerola juice with high efficiency. The aim of this study is to deliver siRNA of ApoB, a major protein component of Low Density Lipoprotein (LDL), to the target tissue (liver) by oral administration using plant-derived nanovesicles as DDS carriers. [Methods] Acerola juices were obtained from Nichirei Foods Inc. The exosome-like nanovesicles derived from acerola juices (AELNs) were extracted by exoEasy Maxi kit (Qiagen). Nanoparticle tracking

analysis (NTA) measurements were performed using Nanosight LM10 system (Malvern). ALENs (1×10^9 particles/ml) and ApoB siRNA (100 pmol, Ajinomoto Bio-Pharma) were mixed in 50 µl of PBS. After incubation on ice for 30 min. were used to measure the oral administration of ApoB siRNA. Oral administration was conducted with total volume 200 µL sample (including 10mg/kg of synthetic ApoB siRNA-AELN complex) by the sonde. The C57BL/6 female mice (8 weeks old, n = 5 per cohort) treated with synthetic ApoB siRNA-AELN complex were scarified and each organ was collected at 1h or 24 h after oral administration, respectively. The expression of ApoB gene in each organ were measure by qRT-PCR. [Results] The number of exosome-like nanovesicles in 8 ml of lemon juice was found to be 1×10^8 particles, whereas acerola juice contained 1×10^{12} particles of AELNs, a larger amount than other fruits. Thus, acerola was shown to be an excellent source of exosome-like nanovesicles.We found that it is possible to form a complex by mixing AELNs (2.2×10^9 particles) and synthetic miRNA (100 nM) at a certain concentration and allowing them to stand on ice for 30 minutes. Furthermore, the nucleic acid (synthetic miRNA) that formed a complex with AELNs was resistant to RNase, strong acid (pH 2), and strong alkali (pH 10). The in vivo system was used to analyze the in vivo kinetics of acerola-derived vesicle-nucleic acid drug complexes and their efficacy as nucleic acid drugs. PKH26-labeled acerola vesicles were orally administered to mice, and the pharmacokinetics were observed at 1, 3, and 6 hours after administration. Fluorescent signals were observed in the stomach, intestinal tract, liver, and kidney at 1 hour after administration. Interestingly, signals were also observed in brain tissue including the cerebrum, suggesting that the acerola vesicles also reached the central nervous system after oral administration.In addition, since orally administered nucleic acid drugs are likely to be absorbed in the portal vein, the liver is the primary target for investigation aimed at clinical application. Therefore, a complex of siRNA targeting the ApoB gene in the liver and acerola-derived vesicles was orally administered, and the knockdown efficiency of the ApoB gene in the liver tissue was analyzed by qPCR over time. The results showed that ApoB gene expression was decreased in the liver and small intestine 24 hours after oral administration, i.e., the knockdown effect by siRNA was confirmed. [Conclusions] The major features of this research are: 1) the focus on plant-derived exosomes, which are inexpensive and can be supplied stably; 2) the development of a highly safe drug (DDS formulation) by using plant-derived vesicles, which are usually edible by humans; and 3) the development of the world's first orally administrable nucleic acid medicine.

558 VecTabs Target Oxidized Phosphatidylcholine for Treating Amyotrophic Lateral Sclerosis

Andreia Gomes-Duarte[1], Svetlana Pasteuning[1], Farangis Sharifi[1], Sofia Pascoal[1], Roland van Dijk[1], Wouter Pos[1], Martino Böhne[1], Marina Sogorb-Gonzalez[1], Barbara Sanders[1], Sander Van Deventer[1,2], Pavlina S. Konstantinova[1]

[1]VectorY Therapeutics, Amsterdam, Netherlands,[2]Leiden University Medical Centre, Leiden, Netherlands

Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease characterized by the progressive loss of motor neurons, eventually leading to paralysis and premature death. It is a multifactorial disease characterized by protein aggregation, neuroinflammation, mitochondrial dysfunction, axonal defects and neuromuscular junction (NMJ) damage. Most ALS patients are diagnosed with sporadic ALS (sALS), with no apparent genetic contribution identified. Nonetheless, native TDP-43 aggregation is found in 97% of all patients. Besides TDP-43 pathology, one of the strongest metabolic abnormalities in affected ALS motor neurons is the dramatic increase of glycerophospholipids. Certain glycerophospholipids, such as phosphatidylcholines (PC), are enriched in ALS biofluids, correlated with disease progression and can be oxidized hence forming neurotoxic oxidized phosphatidylcholines (OxPCs). In fact, OxPC deposits are found in the axon segment of ALS motor neurons. Accumulating evidence has shown that cerebrospinal fluid (CSF) from sALS induces a drastic ALS phenotype in-vivo, and that this toxicity is low density lipoprotein (LDL)-mediated. Since LDL are not toxic themselves and has been associated with ALS progression, we hypothesize that OxPCs contained in OxLDL are the propagating vehicle of degeneration in sALS. Motor neuron exposure to OxPC triggered ALS-like phenotypes at transcriptomic level. Here, we describe a therapeutic strategy to target neurotoxic OxPCs in the context of ALS. We have generated a VecTab which is able to bind OxPCs and neutralize their pathological effects. OxPC VecTab prevented OxPC toxicity in iPSC motor neurons. Furthermore, biodistribution studies in large animals demonstrate robust transduction and expression of VecTabs in cortical, spinal cord, and brain stem regions following intracisternal administration. Finally, we show OxPC VecTab can potentially protect neuronal cells against OxPC toxicity.

559 Effects of Urine Stem Cell Derived Extracellular Vesicles on a Human Kidney Organoid Model of Acute Kidney Injury

Julie Bejoy[1], Eddie S. Qian[1], Rick Welch[1], Felisha M. Williams[1], Lauren E. Woodard[1,2,3]

[1]Nephrology and Hypertension, Vanderbilt University Medical Center, Nashville, TN,[2]Biomedical Engineering, Vanderbilt University, Nashville, TN,[3]VA Medical Center, Veteran Affairs, Nashville, TN

Acute kidney injury is associated with morbidity and mortality, necessitating the development of new therapies to improve patient outcomes. Technological and clinical advancements in AKI treatment have supported patient recovery, however most treatment options are supportive or supplementary and not curative. USCs are adult stem cells of renal origin that can easily be obtained through noninvasive methods. USCs are highly proliferative compared to other stem cell types. EVs from stem cells have been shown to elicit regenerative functions, while those secreted by diseased cells can serve diagnostic purposes. EVs elicit their effects with high specificity due to integral membrane proteins that interact with target cells upon contact. We thus, hypothesized that USC-EVs have the greatest potential for treating AKI because they are secreted from kidney stem cells. Here, we use a cisplatin-induced nephrotoxicity model to mimic AKI. Cisplatin is a chemotherapeutic agent used to treat several cancers including testicular, bladder, ovarian, esophageal, breast, and other cancers. Developments in kidney organoids derived from human induced pluripotent stem cells (hiPSCs) have provided an improved in vitro model for kidney diseases in recent years. Cisplatin-induced AKI kidney organoid models show tubular toxicity, suggesting their

relevance as a disease model. Our data demonstrated that in vitro treatment with USC-EVs reduced tubular injury and oxidative stress from nephrotoxicity. Additionally, our data show that USC-EVs increase staining for Ki67, a biomarker for proliferation. The results from our study suggest potential of USC-EVs in promoting cellular regeneration through proliferation.

560 ARMMs as a Versatile Non-Viral Delivery Platform for Therapeutic RNA Molecules

Nedyalka Valkov, Bhavesh Gurwani, Chris Chatzinakos, Lucy Sun, Qiyu Wang, Kristin Luther, Adam Francoeur, Yashodhan Chinchore, Sophie Kim, Alysia Bryant, Leah Gens, Joseph F. Nabhan

Vesigen Therapeutics, Cambridge, MA

One of the major challenges of RNA-based therapeutics is the efficient packaging and functional delivery of RNA molecules. Major limitations of existing delivery platforms include achieving efficient packaging and transfer of functionally active RNA cargos in recipient cells, without eliciting unwanted immune responses. Overcoming these barriers would expand the potential of RNA therapies. We engineered ARMMs (arrestin domain-containing protein 1 (ARRDC1)-mediated microvesicles), a class of extracellular vesicles that bud directly from the cell surface, to package a variety of labile RNA molecules, including shRNA, mRNA, and aptamers. Here we present data demonstrating functional delivery of various types of RNA via engineered ARMMs. We developed a system that permits active non-covalent recruitment of RNA payloads using ARRDC1, or engineered variants thereof, as an active loading handle into ARMMs. In this body of work, we demonstrate functional delivery and activity of RNA molecules by ARMMs in recipient cells. ARMMs loaded with shRNA molecules induce robust reduction of target mRNA and corresponding protein upon delivery in multiple cell types. P53 mRNA delivered via ARMMs induces activation of p53 target genes in p53-null recipient cells. Further, our data show that uptake of ARMMs loaded with RNAs is dose-dependent, without toxicity, and in contrast to other delivery systems does not trigger innate immune pathways, including those mediated by TLR7, in recipient cells. Our data support development of therapeutic strategies enabled by ARMMs-mediated intracellular delivery of RNA molecules.

561 Scalable Suspension Cell-Based Production and Purification of Engineered ARMMs as a Platform for Non-Viral Therapeutics

Steven Greenway, Alysia Bryant, Leah Gens, Adam Francoeur, Sofia Berrio, Qiyu Wang, Nedyalka Valkov, Wendy Zhao, Gary Hao, Joseph Nabhan, Kristin Luther

Vesigen Therapeutics, Cambridge, MA

A variety of human extracellular vesicles are currently being evaluated as promising platforms for non-viral delivery of therapeutic payloads. Scaling production, purification, and characterization of extracellular vesicles remains a major limitation. We are engineering a class of extracellular vesicles called ARMMs (ARRDC1-mediated microvesicles) as vehicles for delivery of protein, RNA, or ribonucleoprotein complexes. Here, we report a scalable approach for suspension cell-based production of ARMMs paired with an optimized downstream purification process. Using our cell-based production platform, we loaded ARMMs with various payloads including Cre recombinase, Cas9/guide RNA complexes, or short hairpin RNA. We evaluated production in 1 and 5 L shake flasks and in a fed batch stirred tank bioreactor. Three days following transfection of ARMMs-loading constructs, conditioned media were harvested and subjected to downstream purification processes. We evaluated multiple approaches to purify ARMMs by tangential flow filtration and mixed-mode size exclusion chromatography or monolithic anion exchange chromatography. We further subjected ARMMs loaded with Cre protein to stability testing before and after purification, followed by evaluation of potency. Our data establish robust and scalable production and purification processes for ARMMs with multiple payloads. These advances support the potential to utilize these processes for manufacturing of ARMMs to support clinical trials.

562 Novel Approach for Fluorescent Labeling of Intraluminal Protein Payloads in ARMMs as a Model Extracellular Vesicle

Wendy Zhao[1], Rebecca Lees[2], Kristin Luther[1], Zahra Baghbantaraghdari[1], Ben Peacock[2], Joseph F. Nabhan[1]

[1]Vesigen Therapeutics, Cambridge, MA,[2]NanoFCM Co., Nottingham, United Kingdom

Modern extracelullar vesicle (EV) characterization often utilizes fluorescent labelling of proteins, lipids, nucleic acids, or structural components. Labelling of internal EV proteins often requires transgenic co-expression of fluorescent proteins. Here, we present two protocols which allow targeted fluorescent labelling of lumen-side EV proteins, using ARMMs (ARRDC1-mediated microvesicles) as a model EV, and demonstrate detection efficiency as "percentage of targets labelled" through the use of nano-flow cytometry (nFCM). HEK (Human embryonic kidney) 293 suspension cells were transfected with a variety of ARMMs loading constructs and EVs were enriched from supernatant of transfected cells using size exclusion chromatography (SEC). Presence of ARMMs was confirmed by Western blotting and quantified by nFCM using a NanoAnalyzer (optical technique suitable for objects 40-1000nm diameter). Transgenic protein loading was assessed by nFCM as was subsequent fluorescent labelling. Intraluminal localization of the transgenic proteins was confirmed by anti-GFP, anti-SPOT tag, anti-FLAG tag fluorescent labelling. ARMMs loading of GFP tagged with SPOT from transgenic lines was shown to be ~70% within EVs >40nm. Fixation and/or permeabilization was shown to have limited impact on particle size and concentration, with EVs retaining a median size between 60-70nm. Incubation with anti-SPOT nanobodies following permeabilization demonstrated that up to 62% of the GFP labelled EVs could be further labelled in two unique protocols. Comparison between antibody and nanobody labelling of internal proteins demonstrated the superior detection efficiency of using smaller targeting reagents, such as nanobodies. Length of incubation, fixative concentration and starting EV concentration were all shown to impact efficiency of detection of EV payloads. Here, we describe a novel approach to test the efficiency of immunodetection of intraluminal payloads in EVs and demonstrate consistency with

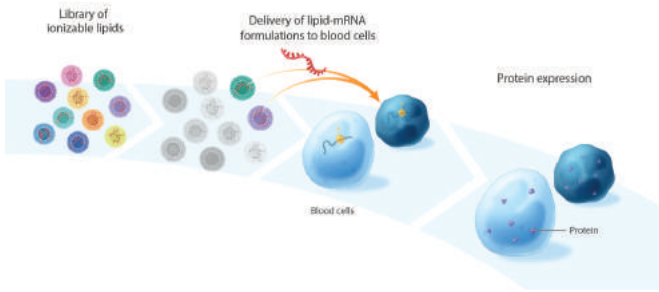
payloading using a quantifiable internal fluorescent protein. We provide two viable protocols for internal labelling with distinct advantages and a potential model to continue exploration of novel approaches.

563 Rational Design of Multivalent Ionizable Lipid Delivery Systems for mRNA Delivery to Blood Cells

Elizabeth Belcher[1], Joseph Pisano[2], Ariadna Lubinus[2], Kyle M. Garland[1], Christopher B. Rohde[2], Matthew Angel[1,2]

[1]Eterna Therapeutics Inc., Cambridge, MA,[2]Factor Bioscience Inc., Cambridge, MA

In recent years, lipid-based mRNA delivery has become the gold standard method for inducing exogenous protein production *in vivo* as evidenced by the success of the COVID-19 mRNA vaccines. While intramuscular injections are ideal for vaccine applications, intravenous injections are generally more suitable for achieving broad internal distribution of therapeutic payloads. Following systemic administration, blood cells are the first cells encountered by lipid nanoparticles (LNPs) and therefore serve as high interest targets for *in situ* protein production. With the goal of identifying a lipid formulation capable of efficiently transfecting blood cells, we synthesized and screened a library of 16 multivalent ionizable lipids with variations in headgroup and lipid tail. Headgroup variations included spermine (a naturally occurring biomolecule), dihydroxyspermine, 2-hydroxypropylamine, and ethanolamine (the headgroup of SM-102, the ionizable lipid component of Spikevax). The lipid tails varied in degree of unsaturation, carbon chain length, and head-to-tail spacer length. Lipids were characterized as lipoplexes and as solid LNPs, using mRNA encoding green fluorescent protein (GFP) as representative nucleic acid cargo. Nanoparticle size, surface charge, mRNA encapsulation, transfection efficiency, and cellular toxicity were evaluated. Lipoplexes were formulated at various weight ratios of lipid/mRNA, and mRNA-loading efficiency was determined via gel electrophoresis. The lowest lipid/mRNA weight ratio that displayed complete complexation for each lipid was used for the corresponding lipids in subsequent *in vitro* analyses. Notably, the greatest transfection efficiency in the lipoplex form was induced by FB3-54, a lipid comprised of a spermine headgroup and bis hexyl 2-hexyldecanoate tails. FB3-54 lipoplexes enabled efficient transfection of GFP mRNA in the THP-1 human monocyte cell line and exhibited a half-maximal effective concentration (EC_{50}) of 147 ng RNA per 50,000 cells, which was lower than that of Lipofectamine 3000 (242 ng RNA per 50,000 cells). The measured diameter of the FB3-54 lipoplexes was 359 nm. FB3-54 also functioned effectively as a solid LNP when using a molar ratio of 50:38.5:10:1.5 (ionizable lipid/cholesterol/DSPC/DMG-PEG_{2000}) and a 0.12 weight ratio of mRNA to ionizable lipid. FB3-54 LNPs were 170 nm in diameter, possessed a surface charge of +3.6 mV (at a pH of 7.0), demonstrated near complete encapsulation efficiency, and exhibited greater *in vitro* transfection efficiency than the clinically used Dlin-MC3-DMA LNPs. The ability to efficiently target blood cells using lipid delivery systems opens the door to a variety of applications, including potent *in vivo* mRNA delivery and cell reprogramming.



564 siRNA Treatment for Hereditary Tyrosinemia Type I (HT1)

Mercedes Barzi[1], Tong Chen[1], Madeline Hemmingsen[1], Gordon He[1], Mark Keibler[2], Azadeh Sichani[2], Benny Garfinkel[2], Karl-Dimiter Bissig[1]

[1]Duke University, Durham, NC,[2]Alnylam Pharmaceuticals, Cambridge, MA

Hereditary Tyrosinemia Type I (HT1) is an autosomalrecessive disorder caused by mutations of fumarylacetoacetate hydrolase (*FAH*),the last enzyme of the tyrosine catabolism pathway. HT1 is inherited in anautosomal recessive manner affecting 1 in 100,000 newborns. Absence of FAHcauses the accumulation of toxic metabolites (such as succinylacetone, maleylacetoacetateand fumarylacetoacetate) that can damage the liver and the kidneys leading to acuteliver failure, renal disfunction and death, if untreated. HT1 management consistsof minimizing the built up of toxic metabolites by a very restrictive low tyrosine/lowphenylalanine diet in combination with nitisinone (NTBC), a small molecule drug that blocks4-hydroxyphenylpyruvate dioxygenase (HPD), an upstream enzyme in the catabolic pathway. Kidney damage and hepatocarcinoma (HCC) development are the most common long-termcomplications of this disorder when patients are not fully compliant, arecurrent problem in other metabolic disorders that require such a strictlifetime regimen. In recent years, liver-targetedsmall interfering RNA (siRNA)-baseddrugs have been approved for monogenetic disorders such as Hereditary ATTR(hATTR) Amyloidosis, Hypercholesterolemia, Hepatic Porphyria (AHP) and Primary HyperoxaluriaType I (PH1). HPD is a great target candidate for HT1 siRNA therapy since ithas been clinically demonstrated that its inhibition can prevent the diseasephenotype. We have previously shown that the deletion of the HPD genespecifically in the liver with CRISPR/Cas9 editing technology can rescue themetabolic phenotype of HT1 mice. In this study, we investigate theefficacy of HPD siRNA therapy in preventing FAH knockout mice from developingHT1 in the absence of nitisinone. All mice injected with HPD-siRNAs showlong-term survival, have low levels of succinylacetone and present no signs ofkidney toxicity.

565 Use of Low-Intensity Transcranial Focused Ultrasound for Targeted Delivery of Exosomes to the Brain

Jacqueline Lara[1], Jon Haroon[2], Linda Flores[1], Marisa McDonald[1], Kennedy Mahdavi[2], Victoria Venkatraman[2], Hoi Wa Ngai[1], Samantha Schafer[3], Mark Schafer[3], Mohamed Hammad[1], Isaac Nardi[4], Taylor Kuhn[5,6], Duncan Ross[4,6], Sheldon Jordan[2,5], Karen S. Aboody[1,6]

[1]Beckman Research Institute of the City of Hope, Duarte, CA,[2]The Regenesis Project, Santa Monica, CA,[3]Drexel Univeristy, Philadelphia, PA,[4]Kimera Labs Inc., Miramar, FL,[5]University of California Los Angeles, Los Angeles, CA,[6]Neurosomes Bio, Miramar, FL

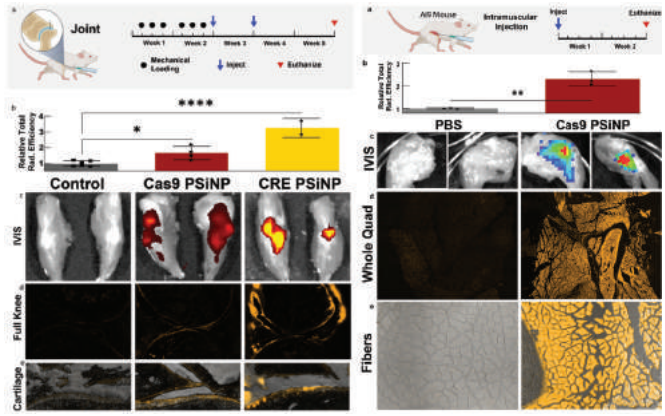
The blood-brain barrier (BBB) presents a significant challenge for targeted drug delivery. In the present study, low-intensity focused ultrasound (LIfUS) was assessed for its ability to influence brain vessel endothelium, as well as its ability to increase the localization of small molecules when injected intravenously. Ultrasound is a well-established clinical technique for neurological diagnosis; however, LIfUS has recently been explored for its potential as a safe and controlled non-invasive, non-pharmacological technique for selective delivery of molecules up to 150 kDA to the brain that normally cannot bypass the BBB. A wide range of potential treatments are made possible by LIfUS, including directing exosomes to specified brain regions. When compared to stem cells, exosomes have high anti-inflammatory and regenerative properties, and low immunogenicity. Specifically, stem cell-derived exosomes have been shown to have multiple anti-inflammatory and neuro-restorative roles across multiple CNS indications including stroke, traumatic brain injury, Alzheimer's disease, and Parkinson's disease. This novel combination of applying pre-treatment with targeted LIfUS to directly localize intravenously delivered exosomes to specific region of the brain has high impact therapeutic potential to be deployed in a cost-effective manner in a clinical setting. In this study, LIfUS was applied in a targeted fashion to the right side of the rat brain to enhance the localization of intravenously administered labeled exosomes to the hippocampus. Our first set of results looking at the effect of LIfUS insonation on BBB integrity showed increased adhesion and transcytosis spread of dextran tracer in the endothelium. Further study results demonstrated a significantly increased concentration of exosomes in the right hippocampus when compared to the untreated contralateral (left) hippocampus, and when compared to the control group (brain untreated with LIfUS). Additionally, this study showed no evidence of pathological changes, edema, or hemorrhage. Further studies with larger sample sizes are warranted to support these results, with the goal of translation to patient trials.

566 Porous Silicon Nanoparticles Deliver Cas9 Ribonucleoprotein *In Vitro* and *In Vivo*

Brock Fletcher[1], Juan Colazo[1], Larry Stokes[1], Morgan Struthers[1], Fang Yu[1], Jonathan Brunger[2], Craig L. Duvall[3]

[1]Vanderbilt, Nashville, TN,[2]Vanderbilt, Franklin, TN,[3]Vanderbilt University, Nashville, TN

Background: Ex-vivo cell engineering has positively impacted medicine, yet has costly practical drawbacks well known to the field. Engineering cells in situ thus has serious clinical promise but remains an unsolved challenge due to limitations of viral manufacturing, safety, and non-viral material science. Porous Silicon Nanoparticles (PSiNPs) are a unique nanoscale material with interesting characteristics making them interesting as a gene delivery vehicle—specifically, they have been shown to load cargoes as diverse as DNA, RNA, PNA, proteins, and small-molecule drugs. PSiNPs are also fully biodegradable and well-tolerated. Prior work in our group has demonstrated that coating PNA-loaded PSiNPs in a polymer, PEG-DB, serves to stabilize the particles and facilitate endosomal escape into the cytosol. **Approach:** In this work, we optimized PegDB-PSiNP nanoparticles in Vitro for delivery of gene-editing proteins and demonstrated their In Vivo effectiveness after intraarticular, intramuscular, or intravenous administration. Additionally, we have begun optimizing for delivery of DNA for plasmid or donor-DNA applications. **Methods:** PSiNPs were verified by TGA and DLS. Loading of proteins was screening in vitro and verified by BCA assay and SDS-PAGE densitometry. In Vitro uptake and endosomal escape were verified by timecourse confocal microscopy. Gene-editing in vitro was screened using mTmG fluorescent reporter cassette in NIH-3T3 mouse fibroblasts and compared to Lipofectamine CRISPRMAX. In Vivo experiments were performed in Ai9 reporter (tdTomato inducible) mice and editing was verified by IVIS and cryohistology. **Results:** Optimizing the formulation in vitro resulted in endosomal escape ~10x, and DNA editing levels ~2x, that of Lipofectamine CRISPRMAX. Intraarticular administration resulted in DNA-editing in both the cartilage and synovium. Intramuscular administration resulted in nearly 100% positive muscle fibers at the administration site. Systemically administered Cas9-PSiNPs target to and edit in injured muscle at least as well as a commercial standard for mRNA—Polyplus in vivo jetRNA.



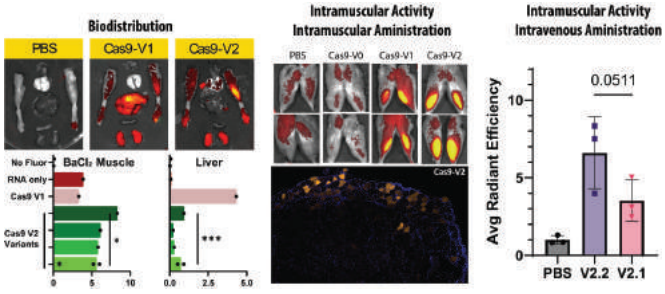
567 Intravenously Administered Carrier-Free Engineered Cas9 Ribonucleoproteins Target-To and Edit Inflamed Muscle

Brock Fletcher, Isabel Vallecillo-Viejo, Stokes Larry, Fang Yu, Craig L. Duvall

Vanderbilt University, Nashville, TN

Background: Gene editing proteins are commonly regarded as incompatible with directly delivery, needing to be encapsulated and/or delivered in encoded (e.g., mRNA or AAV) form. However, this creates carrier-associated risks—be it AAV immunogenicity or cationic lipid toxicity. These issues motivate our pursue of a strategy

for "carrier-free" delivery. Carrier-free ribonucleoprotein (RNP) delivery for gene editing has been demonstrated for applications where the cargo is direct-injected intratumorally or intracranially. Systemic diseases, like Duchenne's Muscular Dystrophy (DMD), are not amenable to treatment with local injections. We seek to develop a carrier free RNP for systemic delivery to edit skeletal muscle, toward a therapy for DMD, a genetic disease characterized by muscle injury, inflammation, and degeneration. **Approach:** We hypothesized that, by targeting Cas9 RNP to sites of inflammation and avoiding liver accumulation, we could achieve gene-editing in inflamed muscle after intravenous administration. **Methods:** Engineered Chimeric Cas9 proteins were predicted using Alphafold, and then expressed in E. Coli and purified. Enzymatic activity was verified in vitro to explore structure-function relationships and narrow candidates for in vivo exploration. To explore biodistribution, guide RNA and/or Cas9 protein was fluorescently labeled and administered intravenously. To explore editing, Cas9 RNPs were formed to target Ai9 reporter (tdTomato inducible) mice. To explore local editing, Cas9 RNPs were administered intramuscularly to healthy muscle of Ai9 mice. To explore systemic editing, muscle inflammation was induced 2 days before RNP treatment by intramuscular administration of Barium Chloride. On day zero, Cas9 RNPs were administered systemically via tail vein. Ai9 mice were sacrificed after 1 week and analyzed via IVIS imaging. **Results**: Engineered Cas9 Variants were enzymatically active. Preliminary IVIS results suggest that after intravenous injection, engineered Cas9 Variants (Cas9-V2) experienced an ~80% decrease in liver accumulation and an ~100% increase in injured muscle accumulation relative Cas9 engineered only to enhance delivery (Cas9-V1). Directly injected into muscle, a Cas9 engineered only to enhance delivery (Cas9-V1) had >6-times the editing signal of a un-engineered Cas9 (Cas9-V0). Cas9 engineered to both enhance delivery and targeting (Cas9-V2) had >20 times the editing of standard Cas9. After intravenous administration, an engineered Cas9 variant had significantly increased IVIS editing signal over baseline. Further work is ongoing thanks to the sponsorship of Sarepta Therapeutics, Inc.



568 Efficient Delivery of Nucleic Acids by Lipid Nanoparticles to the Liver, Spleen, and Brain

Rohit Sharma, Bernardus Edgar William, Kenneth Loi, Niren Murthy

Bioengineering, University of California Berkeley, Berkeley, CA

The delivery of genetic drugs such as mRNA or plasmid DNA has remained elusive yet critical for the development of gene-editing therapeutics. Viral delivery methods that have been traditionally used present the risk of uncontrolled expression of the delivered genes. Thus, non-viral delivery methods that can enable transient gene expression are desired. mRNA delivery via lipid nanoparticles (LNPs) has been successfully used in clinics marking a milestone for mRNA therapeutics. In this study, we generated and tested four different LNP formulations composed of the multivalent cationic and neutral lipid headgroups. We screened these formulations by delivering various mRNA in vitro and in vivo. For in vitro studies, we tested the efficacy of these formulations by delivering chemically modified sgRNA and Cas9 mRNA on neuronal primary cells and Cre mRNA on brain organoids. Furthermore, we successfully delivered luciferase mRNA in vivo by intravenous, intramuscular, intraperitoneal, and subcutaneous injections. Across in vitro and in vivo studies, our formulation showed better transfection efficiency compared to the standard FDA-approved D-Lin formulation. Of the four formulations, the multivalent cationic LNP demonstrated efficient mRNA and plasmid DNA co-delivery in vitro. Our results show these formulations can efficiently deliver nucleic acids to various organs, offering a promising platform for treating or curing muscle, skin, liver, spleen, and brain diseases.

569 Exploring Avenues Beyond the Liver: Optimization of Fusogenix Proteolipid Vehicles for Safe and Effective Delivery of Nucleic Acid

Arun Raturi[1], Douglas Brown[2], Ping Wee[1], Amirali Bukhari[2], Prakash Bhandari[1], Hector Vega[1], Liliya Grin[2], Maryam Hejazi[2], Jitendra Kumar[1], Paola Solis[2], Natasha Govindasamy[2], Fahed Elian[2], Ivana Machado[2], Natasha Rana[2], Bijal Rawal[2], Brendan Todd[1], Oliver Zhang[1], Chandra McAllister[2], Rodrigo Quevedo[2], Roy Duncan[3], John D. Lewis[1]

[1]Entos Pharmaceuticals, San Diego, CA,[2]Entos Pharmaceuticals, Edmonton, AB, Canada,[3]Dalhousie University, Halifax, NS, Canada

Despite the promise of genetic medicines to treat various diseases, their success has been limited by challenges in delivering nucleic acids effectively and tolerably. Lipid nanoparticle (LNP) delivery platforms have undergone incremental improvements leading to commercial success, but still face issues with cellular toxicity and a biodistribution profile which is limited to the liver. To address these concerns, we developed a proteolipid vehicle (PLV) made from a chimeric fusion-associated small transmembrane (FAST) protein and a well-tolerated lipid formulation. We investigated whether extra-hepatic delivery could be achieved without the need for external targeting ligands by examining the effect of modifying the biophysical properties of FAST-PLVs on biodistribution. PLVs were manufactured using different parameters such as helper lipid composition and ratios, N/P charge ratio, PEGylation, and microfluidic flow rate, and we were able to achieve dramatic changes in size and physicochemical properties, irrespective of the encapsulated cargo (DNA, mRNA, siRNA). Modulating these parameters altered the affinity of FAST-PLVs to a variety of extra-hepatic tissues, such as muscle, lungs, and kidneys, and improved the efficacy of gene expression (DNA/mRNA) or knockdown (siRNA) in target tissues. We then set out to compare the performance of FAST-PLVs to three clinical LNP formulations (MC3-LNPs, Pfizer-LNPs, and Moderna-LNPs) via different routes of administration (ROA), such as intramuscular, intrathecal lumbar, intracerebroventricular, and intravitreal injections. The injection of FAST-PLVs through these routes of administration (ROA) resulted

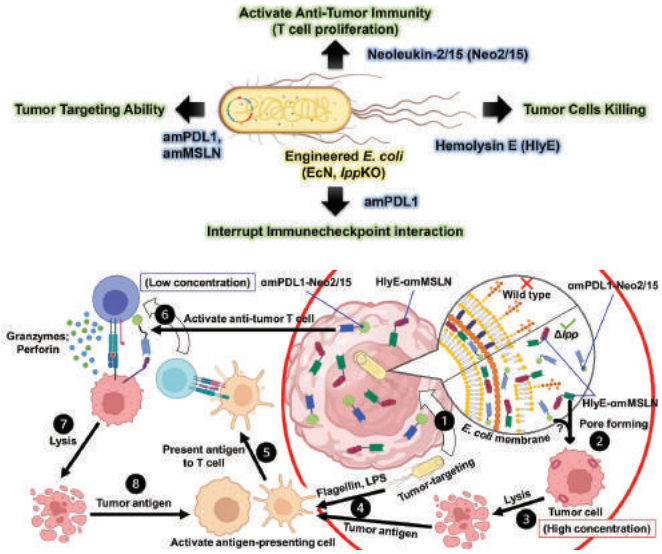
in robust localized expression of FLuc in the expected organ. For example, intrathecally administered FAST-PLVs were effectively distributed throughout the central nervous system and achieved high FLuc expression in multiple brain regions. However, all three conventional LNP formulations showed considerable liver-tropism, resulting in significant FLuc expression in the liver, regardless of the ROA. In contrast, FAST-PLVs did not show any off-target FLuc expression irrespective of the ROA. This was associated by a favorable safety profile, as mice administered with FAST-PLVs had significantly lower circulating cytokine levels and showed no signs of pathology in histological analysis. Taken together, we show that extra-hepatic delivery of nucleic acids can be achieved by FAST-PLVs, and that they lack off-target effect, making them a safe and promising platform for the clinical development of genetic medicines.

570 Development of Multi-Functional Anti-Tumor E. coli for Cancer Therapy

Cheng-Hao Liu[1,2], Yi-Chung Pan[1], Wan-Ju Lien[1,3], Yun Mou[1]

[1]Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan,[2]Taiwan International Graduate Program in Molecular Medicine, Taipei, Taiwan,[3]Institute of Clinical Medicine National Yang Ming Chiao Tung University, Taipei, Taiwan

Non-pathogenic *Escherichia coli* (*E. coli*) is one of the microbes that has shown promising efficacy in cancer therapy. Benefiting from the immunosuppressive environment, *E. coli* can target and colonize primary and metastatic tumors in mouse models and compete with cancer cells for resources. However, bacterial therapy using wild-type *E. coli* can only moderately inhibit tumor growth without complete eradication. We plan to design interleukin-2 (IL2) variants secreted from *E. coli* and evaluate their anti-tumor ability. The recombinant IL2, which stimulates the proliferation of lymphocytes, was the first FDA-approved cytokine for cancer therapy, including malignant melanoma and renal cell carcinoma. Unfortunately, IL2 also activates the regulatory T (Treg) cells and inhibits the tumoricidal function of cytotoxic T lymphocytes (CTLs). Neoleukin-2/15 (Neo2/15) and superkine-2 (Sk2) are artificial IL2 variants that show better CTL proliferation over Treg in mouse models. Our mouse experiments indicated that the intratumoral injection of Neo2/15-secreting *E. coli* significantly suppressed the tumor growth. Further characterizations revealed that the number of TILs significantly increased after treating with the Neo2/15-secreting *E. coli*. We also found that the cured mice had induced immunological memory, as the re-challenges of the cancer cells did not develop any tumors. To further strengthen the anti-tumor ability of *E. coli* especially through the intravenous administration, we developed a multifunctional anti-tumor *E. coli* (MATE). MATE integrates the functions of tumor targeting, tumor killing, and immune activation by expressing multiple therapeutic proteins, including Neo2/15, anti-PDL1, and hemolysin E (HlyE). We demonstrated *in vitro* that MATE can efficiently kill the cancer cells as well as stimulate the T-cell proliferation. More importantly, MATE also exerted excellent anti-tumor activity via the intravenous injection in the mouse model. This work provides an early successful example of integrating multiple anti-tumor strategies into one bacterial entity for cancer therapy.



571 Lipid Nanoparticle Composition Shapes Immune Response to mRNA Vaccine and Potency of Anticancer Immunity

Yining Zhu

Biomedical Engineering, Johns Hopkins University, Baltimore, MD

Introduction: Lipid nanoparticles (LNPs) have been successfully designed as immunostimulatory delivery platforms for antigen-encoding mRNA, as exemplified by the LNP-based COVID-19 vaccines. However, there is a lack of systematic investigation into the effect of LNP composition on properties and efficacy of the immune responses elicited by mRNA LNP vaccines. Here, we developed a multi-step screening method to optimize the type of helper lipid and component ratios in an LNP formulation to efficiently deliver antigen-encoding mRNA to antigen presenting cells for vaccine-based cancer immunotherapy. By screening *in vitro* transfection activity, dendritic cell (DC) maturation and antigen presentation, and *in vivo* for immune activation and suppression of tumor growth, LNP formulations with potent antitumor efficacy are investigated as delivery systems for anti-cancer mRNA vaccines.**Methods:** To generate a 1,080 formulation LNP library, we used DLin-MC3-DMA as the ionizable lipid, cholesterol, DMG-PEG2000, and one of six helper phospholipids (DOTAP, DDAB, DOPE, DSPC, 14PA, and 18PG) that were previously used in FDA-approved or experimental LNP formulations. By varying the following parameters: (1) combined molar percentage of DLin-MC3-DMA and helper lipid; (2) weight ratio of cholesterol to DMG-PEG2000; (3) weight ratio of DLin-MC3-DMA to helper lipid; and (4) the molar ratio of chargeable groups in ionizable lipid to phosphate groups in pDNA (N/P ratio), a series of LNP formulations were generated using mRNA to screen *in vitro* for transfection efficiency in DCs. Selected LNP formulations were then loaded with ovalbumin (OVA) mRNA to assess the ability of antigen presentation, and induction of co-stimulatory molecule expression by DCs. LNPs with the highest DC transfection, antigen presentation, and maturation were further tested *in vivo* for transport to the draining lymph nodes (dLNs) via subcutaneous (s.c.) injection. LNPs showing effective transfection in dLN cells were administered s.c. into C57BL/6J mice to evaluate the immune responses

and anticancer efficacy in prophylactic and therapeutic treatment models of melanoma.**Results:** Based on the initial library screening, top-performing LNP formulations exhibited higher *in vitro* transfection efficiency in DC2.4 cells were tested in freshly isolated bone marrow-derived DCs (BMDCs) for antigen presentation and maturation analyses (Fig. 1A). The antigen presentation and maturation levels of APCs in dLNs were examined after s.c. injection of selected LNPs (C10, D6, and F5) (Fig. 1B). These three LNPs showed higher SIINFEKL-H-2Kb+ DC levels in dLNs and were tested for their vaccination efficiency. A significantly higher numbers of Th1 cells (CD4+IFN-γ+) were observed for all three formulations (Fig. 1C), though C10-treated group also showed the highest Th2 response along with a high OVA-specific IgG titer (Figure 1D-E). All three formulations are then tested on B16-OVA model and showed strong tumor growth inhibition efficacy with a prolonged overall survival time (Figure 1F). Furthermore, compared to D6 and F5, which generated strong Th1 response only, C10 LNPs, triggering both Th1 and Th2 responses, yielded a markedly improved protection effect.**Conclusion:**This LNP screening platform allows for identification of the best-performing mRNA LNPs for APC-specific gene expression, and tuning Th1/Th2 skewed immune response. Among the top candidates, C10 elicits potent Th1 and Th2 responses and mediates most potent antitumor efficacy compared to formulations with only Th1-skewed response.

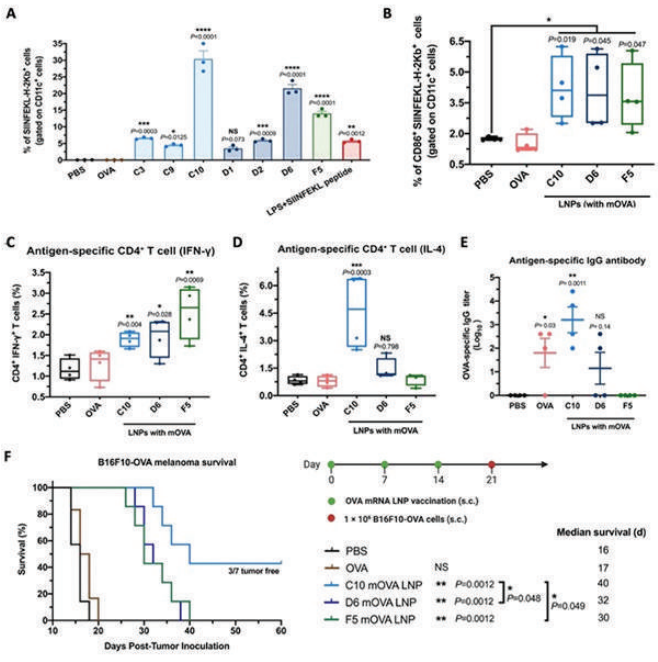


Figure 1. (A-B) SIINFEKL-MHC-I presentation by DCs treated with OVA mRNA LNPs *in vitro* (A) or *in vivo* (B). (C-E) Intracellular staining for IFN-γ (C) and IL-4 (D) in CD4+ T cells, and OVA antibody (E) after vaccinated with OVA mRNA LNPs. (F) Mouse survival following a prophylactic vaccination model for OVA-B16-F10 melanoma in C57BL/6 mice (n = 7; 10 μg mOVA per injection).

572 A PSMA Neovasculature-Inducible CA9 CAR Resistant to FASL and TGFB Mediated Suppression for the Treatment of ccRCC

Jenessa B. Smith, Angela Boroughs, Irene Scarfo, Nickolas Attanasio, Thomas Gardner, Jennifer McDevitt, Laura Lim, Nishant Mehta, Suchismita Mohanty, James Zhang, Eric Cui, Vibhavari Sail, Amanda Fearon, Samuel Williams, Stephen Santoro, W. Nicholas Haining, Levi Gray-Rupp

Arsenal Biosciences, South San Francisco, CA

Clinically effective CAR-T cell therapy for solid tumors , will require substantial T cell engineering to increase their specificity and potency. We have developed an Integrated Circuit T cell (ICT) that encodes multiple synthetic "modules" in order to overcome diverse barriers to efficacy in clear cell renal cell carcinoma (ccRCC) ICT cells are generated via CRISPR-mediated, targeted knock-in of a single large transgene into a newly identified safe-harbor locus (GS94). Both primary and metastatic sites of ccRCC are highly vascularized, with the majority of tumor cells expressing elevated levels of carbonic anhydrase IX (CA9), suggesting CA9 may be an excellent CAR target. However, CA9 is also expressed in healthy bile ducts and stomach tissue which has led to on-target, off-tumor toxicities in patients treated with constitutive CA9 CAR T cells. To improve the therapeutic index of CA9 CAR T cells, we developed an "AND" logic gated ICT cell that requires the presence of two antigens to trigger tumor cell killing, thereby enhancing tumor specificity. Induction of the CA9 CAR is gated on the expression of prostate specific membrane antigen (PSMA) found on the tumor neovasculature of ccRCC. Importantly, PSMA and CA9 are not co-expressed in normal tissues. When the anti-PSMA priming receptor (PrimeRTM) binds PSMA, PrimeR engagement triggers proteolytic release of a chimeric, fully human transcription factor that induces expression of a CA9 CAR. We confirmed the feasibility of vascular priming using a transwell assay where ICTs were primed by a PSMA-expressing endothelial cell line and then migrated across the transwell membrane to kill CA9 expressing RCC cells. In addition, a dual flank xenograft model was used to show logic gated circuits selectively kill tumors that express both CA9 and PSMA, and not tumors that express CA9 alone. Transforming growth factor beta (TGFb) is an immunosuppressive cytokine known to be highly expressed in ccRCC. To further increase the potency and persistence of the ICT cells, an shRNA cassette was developed targeting both FAS and TGFBR2, a receptor required for TGFB signaling in T cells. Addition of FAS/TGFBR2 shRNA enhanced antitumor activity of PSMA x CA9 logic gate expressing T cells during in vitro chronic stimulation assays conducted in the presence of exogenous TGFb. Furthermore, FAS/TGFBR shRNA containing ICTs demonstrated enhanced anti-tumor activity in multiple xenograft RCC models. Collectively, these results demonstrate that PSMA x CA9 ICT cells can (i) selectively target antigens that cannot be safely targeted by conventional CARs and (ii) overcome multiple suppressive mechanisms in the tumor microenvironment.

573 An Oral Cancer Vaccine Using a *Bifidobactrerium* Vector Displaying a WT1 Antigen Protein for the Treatment of Urothelial Carcinoma

Toshiro Shirakawa[1], Koichi Kitagawa[1], Hideto Ueki[2], Takuto Hara[2], Junya Furukawa[2], Jovelle Fernandez[1], Nobuyuki Hinata[3], Hideaki Miyake[4], Masato Fujisawa[2]

[1]Kobe University Graduate School of Science, Technology and Innovation, Kobe, Japan,[2]Kobe University Graduate School of Medicine, Kobe, Japan,[3]Hiroshima University Graduate School of Medicine, Hiroshima, Japan,[4]Hamamatsu University School of Medicine, Hamamats, Japan

Cancer immunotherapy with immune-checkpoint inhibitors (ICIs) including PD-1/PD-L1 inhibitors has been well established for various types of cancer including urothelial carcinoma (UC). However, monotherapy with ICIs can only achieve a durable response in a subset of patients. There is a great unmet need for ICI-resistant tumors and combining ICIs with cancer vaccines which forcibly induce an antitumor T cell response is a reasonable strategy. Previously, we generated a *Bifidobacterium* (*B.*) *longum* displaying a WT1 tumor associated antigen as an oral cancer vaccine. In our pre-clinical study, we explored the feasibility of this oral vaccine in a C3H/He mouse UC model (*Molecular Therapy: Oncolytics*, Vol. 22, 593-, 2021). A recombinant *B. longum* 420 displaying a partial murine-WT1 protein and an MBT-2 mouse UC cell line endogenously expressing WT1 protein were used in the study. Results reveal that a combination of oral administration of 1.0×10^9 colony-forming units (cfu) of *B. longum* 420, 5 times a week for 5 weeks, and intraperitoneal injections of 200μg of anti-PD-1 antibody twice a week for 2 weeks, completely suppressed the MBT-2 tumor growth and cured all mice tested, while all mice treated with anti-PD-1 antibody alone died. Furthermore, CD4 and CD8 positive T cells significantly increased in the tumor-infiltrating lymphocytes (TILs) of combination treatment group. Tumors which continuously grew despite the initial anti-PD-1 treatment were selected as anti-PD-1 antibody-resistant tumors. In the anti-PD-1 antibody-resistant tumor model, this vaccine alone significantly inhibited the tumor growth, while combination with continuous anti-PD-1 antibody did not demonstrate significant tumor growth inhibition. Interestingly, the number of regulatory T cells in TILs of the vaccine alone group was significantly lower than the combination treatment group. These results suggest that this oral cancer vaccine alone or as an adjunct to anti-PD-1 antibody could provide a novel treatment option for patients with advanced UC. From January 2023 at Kobe University Hospital, we started a Phase I clinical study (jRCT registered# 2051220143) of B440 (a lyophilized recombinant *B. longum* 440 displaying a partial human WT1 protein) monotherapy in patients with advanced UC resistant to PD-1/PD-L1 inhibitors. A total of 12 patients will be enrolled in this study and they will receive oral administration of B440 800mg or 1600mg, 5 times a week for 4 weeks. B440 is encapsulated in acid-resistant hard capsule, and one capsule contains 200mg of B440 equivalent to 2×10^{10} cfu of *B. longum* 440. In this Phase I study, safety (dose limiting toxicity) and efficacy (response rate, progression free survival) will be evaluated along with immunological parameters and bacterial compositions of the intestinal flora of participants. In this presentation, we will present a progress report of the Phase I study as well as the results of preclinical studies.

574 CAR-NK Cells Can Mediate Inflammatory Toxicities *In Vitro*

Supreet Khanal, Nirjal Bhattarai

FDA, Silver Spring, MD

Chimeric antigen receptor expressing NK (CAR-NK) cells are increasingly being developed to treat wide variety of human diseases. Unlike CAR-T cells, which are known to cause inflammatory toxicities such as cytokine release syndrome (CRS) and neurotoxicity, CAR-NK cells are thought to be safer based on limited published clinical data. For example, in a small clinical study (N=11), following administration of HLA-matched CD19 CAR-NK cells, none of the patients developed CRS or neurotoxicity. However, another study found CAR-NK cell therapy can cause inflammatory toxicities in some patients. Thus, it is unclear if CAR-NK cells are universally less inflammatory or its potential to cause inflammatory toxicities is dependent upon manufacturing factors such as NK cell source material, manufacturing process, or patient-specific factors such as disease type, tumor burden etc. Here we studied NK and T cells from same individuals (N=6) to assess if NK cells are less inflammatory than T cells, and to identify any factor(s) that may contribute towards inflammatory toxicities during CAR-NK cell therapy. We found that following activation, NK cells secrete significantly less inflammatory cytokines (IFN-γ and GM-CSF) compared to T cells from the same individual. Next, we compared NK and T cells for their ability to activate myeloid cells (MCs) *in vitro* as a measure to cause inflammatory toxicities. MCs treated with activated NK cell supernatant produced significantly less pro-inflammatory cytokines (IL-6 and IL-1β) compared to T cells. However, we did find that NK cells can activate MCs *in vitro*. Next, we sought to identify factors released by NK cells that activate MCs. Activated NK cell supernatant was subjected to size exclusion columns, and various fractions of different sizes were obtained. Each fraction was tested for MC activation. MC activation was significantly greater in the higher molecular weight (MW) fractions (>100kDa) compared to the lower MW fractions (<100kDa). Next, each of these fractions were subjected to the cytokine array to identify cytokines present within these fractions. Using data from multiple independent cytokine arrays, and published literature, we identified 13 candidate proteins that may contribute towards MC activation. From extensive antibody-based neutralization studies, we identified four candidate proteins as primary mediators of MC activation *in vitro* and neutralization of these four proteins resulted in over 50% reduction in MC activation. Furthermore, neutralization of these four proteins did not significantly impact NK cell cytotoxic functions. Current studies are underway to further validate these findings and rationally engineer CAR-NK cells by knocking out these inflammatory proteins using CRISPR/Cas with goals to improve safety and efficacy of CAR-NK cell therapy. Our data suggest that although NK cells are less inflammatory than T cells, NK cells can cause MC activation and can contribute towards inflammatory toxicities.

575 Human Plasma Cells Engineered to Produce Bi-Specific T Cell Engagers Show *In Vivo* Anti-Tumor Efficacy

Tyler Hill[1], Parnal Narvekar[1], Gregory Asher[1], Nathan Camp[1], Kerri Thomas[1], Sarah Tasian[2,3], David J. Rawlings[4,5], Richard James[4,6]

[1]Seattle Children's Research Institute - Seattle, Washington, Seattle, WA,[2]Department of Pediatrics, Children's Hospital of Philadelphia, Philadelphia, PA,[3]Department of Pediatrics, University of Pennsylvannia Perelman School of Medicine, Philadelphia, PA,[4]Seattle Children's Research Institute, Seattle, WA,[5]Departments of Pediatrics and Immunology, University of Washington, Seattle, WA,[6]Departments of Pediatrics and Pharmacology, University of Washington, Seattle, WA

Bispecific T cell Engagers (BiTEs) have emerged as an important tool for the management and treatment of human hematological malignancies. However, BiTEs suffer from problems that hamper more general use including short serum half-life and on-target toxicity in non-tumor sites. Advances in genome-engineering have enabled the generation of human plasma cells that secrete large quantities of therapeutic proteins and that are capable of long-term in vivo engraftment in humanized mouse models. As a next step towards clinical translation in cancer therapy, here we describe the development and testing of a CRISPR Cas9 genome engineering strategy to generate ex vivo genome-engineered human plasma cells that express high levels of either an anti-CD19 (blinatumomab) or anti-CD33 (AMG 330) BiTE. We show that human plasma cells engineered to express BiTEs are capable of meditating T cell activation and direct T cell killing of target cancer cell lines, as well as primary human cells expressing the targets *in vitro*. Furthermore, BiTE-expressing plasma cells are capable of eliciting tumor eradication *in vivo* following local delivery to implanted tumor cells. Finally, immunocompromised mice engrafted with anti-CD19-BiTE secreting plasma cells were resistant to expansion of $CD19^+$ patient derived leukemia, a model that mimics the use of the anti-CD19 BiTE blinatumomab as a bridge to hematopoietic stem cell transplant or potential long-term therapy. These findings support further research into genome engineered human plasma cells for use as a local delivery system of BiTEs for the treatment of leukemias, lymphomas, and possibly other cancers.

576 Single-Cell RNA-Sequencing Uncovers a Neuron-Like Macrophage Subset Associated with Cancer Pain

Philip Chiu-Tsun Tang, Max Kam-Kwan Chan, Zoey Zeyuan Ji, Xiaohua Jiang, Ka-Fai To, Patrick Ming Kuen Tang

Chinese University of Hong Kong, Hong Kong, Hong Kong

Pain is a common complication of advanced cancer with yet defined mechanism (Ji et al, Science 2016). Better understanding the immunodynamics of tumor microenvironment may identify effective therapeutic target for cancer pain (Tang et al, Advanced Science 2022). Here, we discovered a direct mechanism of tumor-associated macrophage (TAM) for promoting de novo neurogenesis via a subset showing neuronal phenotypes and pain receptors expression associated with cancer-driven nocifensive behaviors. This subset is rich in lung adenocarcinoma associated with poorer prognosis. By elucidating the transcriptome dynamics of TAM with single-cell RNA-sequencing analysis, we discovered a novel phenomenon "Macrophage to Neuron-like cell Transition" (MNT) as a direct mechanism for promoting tumoral neurogenesis, evidencing by macrophage depletion and fate-mapping study in syngeneic lung carcinoma mouse models. Encouragingly, we detected neuronal phenotypes and activities of the MNT cells in vitro. Adoptive transfer of the MNT cells into NOD/SCID mice markedly enhanced their cancer-associated nocifensive behaviors. Importantly, we identified macrophage-specific Tcf3 as a pivotal regulator for promoting MNT at genomic level, its disruption effectively blocked the tumor innervation and cancer-dependent nocifensive behaviors in vivo. Thus, MNT may represent a novel therapeutic target for cancer pain. AcknowledgementThis study was supported by the Research Grants Council of Hong Kong (RGC 14106518, 14111019, 14111720); RGC Postdoctoral Fellowship Scheme (PDFS2122-4S06); The Chinese University of Hong Kong's Faculty Innovation Award (4620528), Direct Grant for Research (4054510 and 4054668), and Postdoctoral Fellowship Scheme 2021-22 (NL/LT/PDFS2022/0360/22lt).

577 Genome-Wide CRISPR Screen Identifies Factors Influencing Natural Killer (NK) Cell Activity Against NK-Resistant Tumor Models

Louise Rethacker[1], Hugo Romero[1], Simon Nicoletti[1], Vincent Guitard[1], Marie-Eve Lalonde[2], Christine Gadoury[2], Marc Sasseville[2], Richard Marcotte[2], Kathie Beland[1], Elie Haddad[1]

[1]CHU Sainte-Justine, Montréal, QC, Canada,[2]Conseil National de Recherches du Canada, Montréal, QC, Canada

Natural killer (NK) cells are innate lymphocytes that demonstrate cytotoxic activity towards stressed-self and/or modified-self cells (i.e. cancer cells). NK cells demonstrate strong anti-leukemic activity and bone marrow infiltration by NK cells is associated with a good prognosis in Acute Lymphocytic Leukemia (ALL) patients. However, NK cell activity is decreased in some patients because of the development of resistance mechanisms and NK cell exhaustion. To develop new therapies or improve existing ones, we need to fully understand how NK cells respond and kill ALL cells and what are the genes and pathways involved in this response. In order to identify key genes regulating sensitivity or resistance to NK cell cytotoxicity, we performed a whole-genome CRISPR screen in 697 B-ALL cell line. Using the Yusa CRISPR library, we induced mutations resulting in the knock out (KO) of 18,010 genes in 697 cells. Then, we co-cultured those cells with primary activated NK cells, derived from the NK-cell Activation and Expansion System (NKAES), until we reached more than 80% of target cell death. In previous cytotoxic assays, we showed that 697 cells are resistant to NK cell lysis after 4h of co-culture but become more sensitive after 24h of co-culture. Considering these results and to reach 80% of cytotoxicity, we did two rounds of 24h of co-culture at a ratio 4:1 (effector : target). First, the MAGeCK Robust Rank Analysis in surviving cells identified the death receptor pathway as the major mechanism involved in the NK cell mediated lysis of 697 cells. In fact, sgRNA targeting *FADD*, *CASP8*, *FAS* and *TNFRSF10A* were enriched in resistant tumor cells. We generated the 697 cell line KO for *FADD* and confirmed with a cytotoxicity assay that loss of FADD decreased NK cell-mediated killing. Furthermore, as expected

the analysis of the depleted sgRNA in surviving 697 cells showed that loss of *HLA-E, HLA-C* and *B2M* increase their sensitivity to NK cells. HLA molecules are known ligands of NK cell inhibitory receptors, HLA-E is a ligand of NKG2A and HLA-C is recognized by the killer cell immunoglobulin receptors (KIRs). In summary, the preliminary results of our study suggest that in resistant B-ALL, induction of the death receptor pathway or blocking NKG2A and/or KIR receptors might be a solution to enhance the efficacy of NK cell based immunotherapy.

578 Harnessing CRISPR/Cas9 Mutagenesis Screening for Rational Design of Next-Generation CAR-NKT Therapy Against Neuroblastoma

Gengwen Tian[1], Xavier Rios[1], Gabriel Barragan[1], Janice Drabek[1], Claudia Amador[1], Chunchao Zhang[1], Leonid S. Metelitsa[2]

[1]Pediatric, Baylor College of Medicine, Houston, TX,[2]Baylor College of Medicine, Sugar Land, TX

Background and aims: Natural killer T cells (NKTs) possess innate antitumor properties that provide advantages over conventional T cells for use in cancer immunotherapy. We found that NKTs expressing a chimeric antigen receptor (CAR) specific for neuroblastoma antigen GD2 showed better tumor infiltration and ability to modify the tumor microenvironment than GD2-CAR T cells. Genes that regulate NKT cell persistence, functional fitness, and central memory differentiation remain largely unknown. To address this gap, we have developed a CRISPR/Cas9 screening system to identify genes that regulate the persistence and antitumor activity of NKTs and GD2-CAR NKTs for therapeutic targeting. **Methods:** We have developed the first CRISPR/Cas9 screening system for use in human NKTs and GD2-CAR NKTs to identify genes that regulate survival and proliferation of these cells during *in vitro* serial tumor challenge. As part of this system, we generated a library of guide (g)RNAs (five per gene) specific for a panel of 1,117 immune-related and 48 non-targeting gRNA controls. We have developed methods for graded lentiviral transduction of NKTs/CAR-NKTs followed by multiplexed functional testing and next generation sequencing of gRNA-transduced cells. We also established a system to validate candidate genes that includes *in vitro* and *in vivo* functional assays. **Results:** Our first screening round in human NKTs yielded nine candidate genes of interest, out of which we have found that PRDM-1 knockout improved NKT persistence during *in vitro* serial tumor challenge and increased expression of CD62L, a marker of central memory differentiation that has been shown to correlate with improved anti-tumor activity of GD2.CAR-NKT cells in an ongoing phase 1 clinical trial in neuroblastoma patients (NCT03294954). **Conclusions:** A CRISPR/Cas9-based screening system is feasible for use in human NKTs/CAR-NKTs to identify novel genes that regulate persistence and antitumor potential of NKTs in an unbiased manner. Results obtained from this study will ultimately help to enhance the antitumor efficacy of NKT cell-based cancer immunotherapy.

579 An *Ex Vivo* 3D Tumor Microenvironment-Mimicry Culture to Study TAM Modulation of Cancer Immunotherapy

Yanruide Li

University of California, Los Angeles, Los Angeles, CA

Tumor-associated macrophages (TAMs) accumulate in the solid tumor microenvironment (TME) and have been shown to promote tumor growth and dampen antitumor immune responses. TAM-mediated suppression of T-cell antitumor reactivity is considered to be a major obstacle for many immunotherapies, including immune checkpoint blockade and adoptive T/CAR-T-cell therapies. An ex vivo culture system closely mimicking the TME can greatly facilitate the study of cancer immunotherapies. Here, we report the development of a 3D TME-mimicry culture that is comprised of the three major components of a human TME, including human tumor cells, TAMs, and tumor antigen-specific T cells. This TME-mimicry culture can readout the TAM-mediated suppression of T-cell antitumor reactivity, and therefore can be used to study TAM modulation of T-cell-based cancer immunotherapy. As a proof-of-principle, the studies of a PD-1/PD-L1 blockade therapy and a MAO-A blockade therapy were performed and validated.

580 Tumor-Localized Administration of α-GalCer to Recruit Invariant Natural Killer T Cells and Enhance Their Antitumor Activity Against Solid Tumors

Yanruide Li

University of California, Los Angeles, Los Angeles, CA

Invariant natural killer T (iNKT) cells have the capacity to mount potent anti-tumor reactivity and have therefore become a focus in the development of cell-based immunotherapy. iNKT cells attack tumor cells using multiple mechanisms with a high efficacy; however, their clinical application has been limited because of their low numbers in cancer patients and difficulties in infiltrating solid tumors. In this study, we aimed to overcome these critical limitations by using α-GalCer, a synthetic glycolipid ligand specifically activating iNKT cells, to recruit iNKT to solid tumors. By adoptively transferring human iNKT cells into tumor-bearing humanized NSG mice and administering a single dose of tumor-localized α-GalCer, we demonstrated the rapid recruitment of human iNKT cells into solid tumors in as little as one day and a significantly enhanced tumor killing ability. Using firefly luciferase-labeled iNKT cells, we monitored the tissue biodistribution and pharmacokinetics/pharmacodynamics (PK/PD) of human iNKT cells in tumor-bearing NSG mice. Collectively, these preclinical studies demonstrate the promise of an αGC-driven iNKT cell-based immunotherapy to target solid tumors with higher efficacy and precision.

581 Targeting WNT Signaling for Improved Glioma Immunotherapy

Margarita Gutova[1], Jonathan Hibbard[2], Eric MA[2], Alex Levy[3], Runxiang Qiu[1], Cu Nguyen[4], Elizabeth Melendez[4], Brenda Aguilar[2], Renate Starr[2], Yin Holly[4], Nyam-Osor Chimge[4], Russell Rockne[3], Masaya Ono[5], Christine Brown[2], Michael Kahn[4]

[1]Department of Stem Cell Biology and Regenerative Medicine, City of Hope, Duarte, CA,[2]Department of Hematology and Hematopoietic Cell Transplantation, T Cell Laboratory, City of Hope, Duarte, CA,[3]Department of Computational and Quantitative Medicine, City of Hope, Duarte, CA,[4]Department of Cancer Biology and Molecular Medicine, City of Hope, Duarte, CA,[5]Department of Clinical Proteomics, National Cancer Center Research Institute, Tokyo, Japan

Impressive results in a subset of cancers have been obtained using checkpoint immunotherapies including anti-CTLA4, anti-PD-1, and anti-PD-L1 or CAR-T therapies . However, the heterogeneity of tumors, low mutational burden, single antigen targeting, and associated antigen escape often contribute to non-responsiveness and potential tumor recurrence despite these therapeutic efforts. An important common mechanism of resistance observed in immunologically "cold tumors", including gliomas, involves aberrant activation of the Wnt/β-catenin signaling pathway. Enhanced tumor-intrinsic Wnt/β-catenin signaling appears to be a common mechanism mediating cancer immune evasion and is associated with the presence of an immunosuppressive cell subset as well as the prevention of effective dendritic cell presentation and T-effector cell recruitment and function. Increased expression of β-catenin inversely correlates with the presence of $CD8^+$ T cells and dendritic cells in multiple tumor types including glioma. Furthermore, Wnt pathway activation is correlated with tumor stemness and poor treatment outcome. The hostile tumor microenvironment (TME) is associated with decreased tumor antigen presentation, and greatly reduced or even lost efficacy of various therapies, including adoptive T cell immunotherapy. Therefore, targeted downregulation of Wnt/β-catenin signaling--thereby enhancing the response to immunotherapy in patients with relapsed and refractory tumors--is an attractive therapeutic approach. In the current study, we determined the effects of the small molecule, highly specific Wnt/CBP/β-catenin antagonist ICG-001 on glioma tumor cells and the TME--including immune cell infiltration, blood vessel decompression and metabolic changes. Differentiation of glioma cells and loss of glioma stem cells should enhance the antitumor immune response. We demonstrated *in vitro* cytostatic effects and a switch from proliferation to differentiation after treatment with ICG-001 using multiple patient-derived (PDX) glioma cell lines and murine tumors (GL261, K-Luc). We further demonstrated in these glioma cell lines that ICG-001 downregulated the CBP/β-catenin target gene, *survivin/BIRC5*--a hallmark of selective inhibition of Wnt/CBP/β-catenin signaling. Utilizing NanoString and proteomic analysis, we investigated the effects of ICG-001 *in vitro* on the patient derived glioma cell lines PBT030 and PBT147, and metabolic pathways regulated by Wnt signaling. Furthermore, we found that in a syngeneic mouse model of glioma (K-luc), ICG-001 treatment enhances tumor infiltration by $CD3^+$ and $CD8^+$ cells with increased expression of the vascular endothelial marker CD31 (PECAM-1) on days 7, 14 and 21 post tumor engraftment. We conclude that reprogramming the glioma tumor microenvironment by means of differentiation of glioma stem cells, modulation of the stroma and immune cell activation and recruitment, utilizing the pleiotropic effects of biochemically specific Wnt/CBP/β-catenin antagonists, may enhance immunotherapy in glioma patients.

582 Refining Chimeric Antigen Receptors via Barcoded Protein Domain Combination Pooled Screening

Xavier Rios[1], Osmay Pardias[1], Marc Morales[1], Pradyot Bhattacharya[1], Chunchao N. Zhang[1], Erica J. Di Pierro[1], Gengwen Tian[1], Gabriel A. Barragan[1], Pavel Sumazin[1], Leonid S. Metelitsa[2]

[1]Baylor College of Medicine, Houston, TX,[2]Baylor College of Medicine, Sugar Land, TX

Chimeric antigen receptor (CAR)-T cells are a rapidly emerging form of cancer immunotherapy, but the process for developing new CAR constructs is time-consuming and inefficient. To address this challenge, we developed a cloning strategy in which individual CAR domains are serially assembled and each domain includes a unique DNA barcode, allowing simultaneous quantification of CAR frequencies in pooled populations by next-generation sequencing. Using this method, we generated 360 CAR constructs that target clinically validated tumor antigens CD19 and GD2. We transduced T cells with these libraries and exposed the cells to CD19+ Raji or GD2+ CHLA255 tumor cells, then screened for constructs mediating superior proliferation and expansion by quantifying changes in barcode frequencies. In the process of evaluating individual domain contributions, we unexpectedly found that the effects of the hinge domain varied significantly between CD19- and GD2-based CARs. When comparing costimulatory domains, we observed that 4-1BB occurred more frequently than CD28 in the top-performing CARs. Importantly, the screen identified clinically validated CD19- and GD2-CAR constructs with either CD28 or 4-1BB domains among the top constructs. We did not detect significant differences between second- and third-generation CAR architectures, but top-performing third-generation CARs contained 4-1BB in the proximal position. Further characterization revealed that the dilute retroviral supernatant used for screening enhanced the anti-tumor functionality of CAR-T cells retrovirally transduced with a GD2/4-1BB construct both *in vitro* and *in vivo* mouse tumor models. Therefore, using our novel combinatorial method to assess the functionality of CAR constructs, we demonstrated the importance of structural domains including the hinge alone and in relation to the single-chain variable fragment, co-stimulatory elements and their position within the CAR, and transgene copy number in CAR-T cells for optimal CAR activity. This screening approach is readily scalable and has the potential to greatly accelerate the development of CAR-based cancer immunotherapies.

583 Transactivator-Free, Doxycycline-Inducible CAR-T Cells (iTRUCKs) for Improved Antitumor Efficacy

Pedro Justicia-Lirio[1], Noelia Maldonado-Perez[1], Carmen Barbero-Jimenez[1], Carmen Griñán-Lisón[2], Saul Navarro-Marchal[2], Maria Castella[3], Marina Cortijo-Gutierrez[1], Manel Juan[4], Pilar Muñoz[1], Juan Antonio Marchal[1,5], Maria Tristán-Manzano[1], Francisco Martin[1,6]

[1]Genomic Medicina / Immunology, GENYO / University of Granada, Granada, Spain,[2]Department of Human Anatomy and Embryology, University of Granada, Granada, Spain,[3]6Department of Hematology, ICMHO, Hospital Clínic de Barcelona, Barcelona, Spain,[4]Hospital Clínic de Barcelona, Barcelona, Spain,[5]Department of Human Anatomy and Embryology, Granada University, Granada, Spain,[6]Departamento de Bioquimica y Biologia Molecular III e Inmunologia, Granada University, Granada, Spain

Solid tumors treatment with Chimeric Antigen Receptor (CAR)-redirected T cells remains a challenge due to inhibitory tumor microenvironment (TME), poor tumor infiltration and poor CAR-T cells persistence. Arming CAR-T cells with immunomodulatory molecules (4th generation CAR-T cells or TRUCKs) could overcome these limitations but, at the same time, it will increase CAR-T toxicities. It is therefore crucial to develop inducible systems that can control the activity of these TRUCKs. We have previously developed an all-in-one transactivator-free doxycycline (Dox)-inducible, lentiviral vector (LVs) (Lent-On-Plus or LOP). Using these platform, we have generated the *first-in-class,* 4th generation anti-CD19-CAR-T cells engineered to release IL-18 only in presence of Dox and in the absence of transactivators (iTRUCK-1918). Antitumor potency of iTRUCK-1918 can be controlled with low Dox concentrations, improving antitumor potency against lymphoma and a CD19+ pancreatic cancer model, both *in vitro* and *in vivo*. Dox addition to iTRUCK-1918, increased T stem cell memory/T central memory phenotypes, reduced exhaustion markers and polarize M2 (pro-tumor) to M1 (anti-tumor) macrophages in a co-culture system. These results showed that LOP LVs can generate iTRUCKs that can be controlled with Dox *in vitro* and *in vivo*, constituting a promising tool for improving CAR-T cell potency, while controlling side effects.

584 Combination Treatment of Temozolomide + PARP Inhibitor Sensitize Ovarian Cancer Cells for Gamma Delta T Cell Killing through NKG2DL Expression

Lei Ding[1], Gabrielle Siegers[1], Yanjie Li[1], Mariska ter Haak[1], Amber Jones[2], Trishna Goswami[1], Anita Hjelmeland[2], Lawrence S. Lamb[1]

[1]IN8bio, Birmingham, AL,[2]University of Alabama at Birmingham, Birmingham, AL

With a five-year survival rate of less than 50%, ovarian cancer (OVCA) is the deadliest cancer impacting women. The most common and devastating histological subtype is high-grade serous ovarian cancer (HGSOC), comprising ~70-80% of deaths. While first-line surgery and platinum chemotherapy are initially effective, most cases recur. Over the last decade, poly ADP-ribose polymerase inhibitors (PARPi) have revolutionized HGSOC therapy and improved patient outcomes; however, recurrence remains a significant obstacle, with the emergence of cross-resistance to both platinum and PARPi. As such, new approaches are needed to tackle this unmet need. Alkylating agents such as temozolomide (TMZ) increase NKG2D-ligand (NKG2DL) expression on cancer cells through the DNA damage response (DDR) pathway, enhancing gamma-delta (γδ) T cell cytotoxicity. We hypothesized that the combination of PARPi + TMZ would synergize to further potentiate γδ T cell targeting in the context of HGSOC. We first determined the effect of TMZ monotherapy or in combination with the PARPi niraparib on the growth and viability of various OVCA cell lines. TMZ monotherapy did not show significant cytotoxicity in concentrations up to 300μM for the OVCA cells tested. OVCA cells are far more sensitive to niraparib monotherapy with LD30 ranging from 1.5 μM (OVCAR-8) to 9.63 μM (KURAMOCHI). In addition, the combined treatment of TMZ (100uM) and various concentration of niraparib showed enhanced cytotoxicity to the OVCA cells over that of single-agent treatment. We then examined 3 OVCA cell lines (OVCAR-3, OVSAHO, and KURAMOCHI) for DDR-induced upregulation of NKG2DL. NKG2DL expression was determined by flow cytometry for cells treated for 24h with vehicle, TMZ (200 μM), niraparib (5 μM) or the combination of TMZ and niraparib and expressed as % increase of median fluorescence intensity (MFI). Single-agent treatment with TMZ or niraparib upregulated NKG2DL expression (MIC-A, MIC-B, ULBP-1, and ULBP-2,5,6) between 8% and 60%. Interestingly, combination treatment of TMZ + niraparib resulted in a much greater increase (53% to 210%) of NKG2DL expression suggesting a synergistic effect. We cocultured the OVCA cell lines with activated and expanded Vδ2+ γδ T cells at increasing effector to target (E: T) ratios for 36 hours. γδ T cells demonstrated cytotoxicity against all three OVCA cell lines in a linear dose response manner. At E:T ratio 20:1, γδ T cells killed 63.4%±5.2%, 26.4%±6.0%, and 57.7%±3.8% of OVCAR-3, OVSAHO, and KURAMOCHI cells, respectively. These findings indicate that OVCA is a potential candidate extracranial tumor for concurrent infusion of chemo-protected DeltEx DRI γδ T cells + TMZ, currently in Phase I trials for glioblastoma (NCT04165941), along with adjuvant PARPi.

585 bbT369, a Clinical-Stage Dual-Targeted and CBLB Gene Edited Autologous CAR T Product for Non-Hodgkin Lymphoma, Shows Edit Driven Enhanced Activity in Preclinical *In Vitro* and *In Vivo* Models

Mike Certo[1], Sema Kurtulus[1], John Evans[2], Maria L. Cabral[1], Nicholas Rouillard[3], Vinh Khang Nguyen[1], Mai Fujiwara[1], Sharlene Adams[3], James B. Rottman[3], Daniel Zak[1], Emily Thompson[3], Molly R. Perkins[4], Philip D. Gregory[1]

[1]2Seventy Bio, Cambridge, MA,[2]2seventybio.com, Cambridge, MA,[3]Bluebird Bio, Cambridge, MA,[4]Bluebird Bio, Boston, MA

Anti-CD19 CAR T cell therapies have improved outcomes for non-Hodgkin lymphoma (NHL) patients. However, only about 30-40% of patients treated with commercially available CAR T cell therapies achieve long term remission, highlighting the need for more

efficacious and durable treatments. Emerging clinical data suggest several failure modes for CD19 CAR T cell therapies including: loss or downregulation of CD19 antigen, loss of co-stimulation pathways on tumor cells, exhaustion of CAR T cells, and immunosuppressive microenvironments. To overcome these hurdles, we devised the next-generation autologous CAR T cell therapy bbT369, currently in first-in-human Phase 1/2 trial (CRC-403 NCT05169489). bbT369 is a dual targeted (CD79a/CD20) CAR T cell therapy that uses an OR gate design to limit antigen escape, has split 41BB and CD28 co-stimulatory domain architecture to augment T cell activation, and contains a knock-out of the *CBLB* gene to enhance potency and reduce T cell exhaustion. Here we highlight aspects of our product design and performance, including demonstrating enhancement of CAR T activity derived from the CBLB edit in a variety of in vitro assays. We show that CD79a and CD20 expression is B cell lineage restricted in normal human tissue and confirm that these proteins are co-expressed in diffuse large B cell samples. To target these antigens, we developed a split dual-targeting CAR configuration and demonstrate it provides superior activity for bbT369-directed tumor cell killing of dual and single antigen positive tumor cells compared with traditional dual-CAR designs. To determine the importance of the CBLB edit on different aspects of CAR T cell function, we performed a suite of assays designed to model distinct challenges to maximal CAR T cell activity within the tumor, specifically: 1.) Chronic activation via a serial stimulation assay, 2.) Antigen downregulation via sub-optimal bead-based activation, 3.) Immunosuppression via T cell stimulation in the presence of recombinant TGFβ or plate-bound PD-L1, and 4.) Loss of costimulatory signaling via co-culture of T cells with CD58KO target cell lines. These data demonstrate that the CBLB gene edit directly contributes to enhancing the activity of the bbT369 CAR T cells across each of these *in vitro* model systems vs unedited controls. In addition, we show that bbT369 T cells drive greater T cell expansion and durable tumor control compared with unedited controls *in vivo* using a xenograft NSG mouse model. Collectively, the data support the potential for bbT369 to provide deeper and more durable responses in NHL patients including those with more challenging disease characteristics.

586 Effective Combination Immunotherapy Using onCARlytics and Artemis® CD19 T Cells Against Hepatocellular Carcinoma (HCC)

Anthony K. Park[1], Isabel Monroy[1], Guangyan Xiong[2], Yuwei Ren[1], Colin Cook[1], Seonah Kang[3], vivien Chan[2], Cheng Liu[2], Leslie M. O. Chong[4], Monil Shah[4], Sharon Yavrom[4], Melissa Polasek[4], Yuman Fong[1], Saul Priceman[1]

[1]City of Hope, Duarte, CA,[2]Eureka, Emeryville, CA,[3]City of Hope National Medical Center, Duarte, CA,[4]Imugene, New South Wales, Australia

Hepatocellular carcinoma (HCC) is the most common type of primary liver cancer and the sixth most common cancer worldwide. Currently, there are six systemic therapies available for patients with advanced disease including atezolizumab in combination with bevacizumab, lenvatinib, regorafenib, cabozantinib and ramucirumab while curative treatments include ablation, surgical resection, and liver transplantation. CD19 targeting chimeric antigen receptor (CAR) T cell therapy has demonstrated impressive clinical outcomes but translating this therapy to solid cancer has been met with various challenges, including the immunosuppressive microenvironment, on-target off-tumor toxicity, and antigen heterogeneity. To date, CAR T cell therapies against HCC targeting antigens such as alpha-fetoprotein and glypican-3 have shown nominal efficacy in clinical trials. Therefore, development of novel and innovative therapeutic approaches against HCC are desperately needed to overcome the challenges and improve clinical outcomes. Oncolytic viruses (OV) are a novel and attractive form of immunotherapy due to the ability to target tumor cells selectively, even in the absence of tumor specific antigens, and deliver genes of interest for therapeutic intervention. We have harnessed this capability of OV and developed a chimeric vaccinia-based OV called CF33-CD19t (onCARlytics) that delivers a non-signaling, truncated CD19 (CD19t) antigen to solid tumors allowing CD19-specific T cells to target them. In order to target CD19t expressed on the surface of solid tumor cells, we combined onCARlytics with CD19 ARTEMIS® T cells, a CD19-targeting adoptively engineered T cell powered by the ARTEMIS® antibody-T cell receptor (AbTCR) platform. The ARTEMIS® AbTCR distinguishes itself from traditional CAR by its recruitment of endogenous CD3 complex and utilizing the same activation and regulatory signaling pathways used by natural TCRs. Tumors infected with onCARlytics induced robust CD19t surface-antigen expression prior to virus-induced tumor lysis. Co-cultured CD19 ARTEMIS® T cells secreted cytokines and elicited potent cytolytic activity against infected HCC tumor cells. In addition, this combination approach demonstrated impressive *in vivo* anti-tumor responses in a human xenograft HepG2 tumor model. By using this combination OV and CAR T cell strategy, we have now broadened the utility of CD19 ARTEMIS® T cells to otherwise target-less tumors such as HCC, which we anticipate can be applied to a wide array of solid cancers as an effective immunotherapy approach.

587 Targeting TIM-3 for Metabolic Natural Killer Cell Activation Against Glioblastoma

Ngoc Tram Dao, Sandro Matosevic

Industrial and Physical Pharmacy, Purdue University College of Pharmacy, West Lafayette, IN

Background: Natural killer (NK) cells hold potential as one of the next generation adoptive cell therapy candidates due to their allogenecity, capability to lyse target without prior sensitization, and low risk of host-versus-graft disease. Thus, being able to utilize NK receptors to drive their cytotoxicity remains crucial. Additionally, for treatments of solid tumors, NK cells need to retain their viability against the suppressive microenvironment. One method is to leverage the surface receptor TIM-3, which lies at the intersection of NK cytotoxic functions and metabolism - the mTOR-associated pathways. **Methods:** Human NK cells were isolated from healthy adult peripheral blood, and expanded in K562-based feeder media. Flow cytometry was used to phenotype TIM-3 surface expression and phosphorylation of mTOR, Akt, and ribosomal protein S6 (rpS6). TIM-3 *knock-out* (TIM-3 KO) NK cells were generated by electroporating CRISPR/Cas9 ribonucleoprotein complexes, and subsequently cultured in 24-well G-Rex plates. Function and immune activation of TIM-3 *wild-type* and TIM-3 *KO* NK cell variants, in the presence or absence of mTOR inhibitors against patient-derived GBM43 were evaluated through target lysis, degranulation, and cytokine secretion. 3D tumor spheroids were

generated with GBM43 and 40 μg/mL collagen in 96-well ultra-low attachment plates, and NK cells were co-incubated for 4 days to test for long-term cytotoxicity. **Results:** We found that TIM-3 expression on *ex vivo*-expanded NK cells responded to inhibition of both mTOR complexes by torin-1 but not to single mTOR complex inhibition by either rapamycin or JR-AB2-011. Specifically, TIM-3 expression increased in response to torin-1, but did not change upon the addition of rapamycin or JR-AB2-011. To investigate this association, we challenged NK cells exposed to torin-1 against GBM43 *in vitro*, and observed that NK cells and torin-1 have co-operative toxicity against GBM43. We also noticed that TIM-3 *KO* NK cells did not exhibit similar co-operative effects, suggesting that the increase in target lysis could be attributed to the upregulation of TIM-3 expression. We also report changes in phosphorylation of different mTOR-associated proteins between TIM-3 *WT* and TIM-3 *KO* NK cells, which could contribute to changes in NK cell metabolism, ultimately leading to differences in cytotoxicity and cytokine production against 2D glioblastoma monolayer and 3D tumor spheroids. **Conclusions:** We determined that on *ex* vivo human NK cells, TIM-3 responds to mTOR activation as a possible means to protect NK cell metabolism, cytotoxicity and cytokine production in settings of metabolic inhibition. This protection of NK cells against mTOR inhibition, combined with our previously published data that TIM-3 upregulation increased production of FN-γ production, a cytokine that sensitize glioblastoma to NK-mediated lysis, afford an opportunity to increase the efficacy of NK cell therapy against glioblastoma by the addition of mTOR inhibitors without compromising any of NK cell functions.

588 Optimization of CAR T Cells Against the C Domain of Tenascin C for Pediatric Brain and Solid Tumor Immunotherapy

Elizabeth Wickman[1], Jessica Wagner[2], Timothy Shaw[2], Liqing Tian[2], Jorge Andres Ibanez[2], Heather Sheppard[2], Jason Chiang[2], Matthew R. Bell[2], Giedre Krenciute[2], Jinghui Zhang[2], Stephen Gottschalk[2]

[1]St. Jude Graduate School, Memphis, TN,[2]St. Jude Children's Research Hospital, Memphis, TN

Identifying safe, targetable antigens is a critical roadblock for the success of pediatric solid and brain tumor chimeric antigen receptor (CAR) T cells. To overcome this limitation, we developed a pipeline to identify exons upregulated in tumors when compared to normal tissues. A top candidate from our screen is the C exon from the long isoform of Tenascin C (C.TNC), an extracellular membrane (ECM) protein with high expression in pediatric osteosarcomas and gliomas. We verified C.TNC expression in diffuse intrinsic pontine glioma (DIPG), high-grade glioma (HGG), and pediatric sarcoma cell lines through RT-qPCR and IHC. Indeed, all evaluated cell lines express the splice variant, and in IHC images of primary tumors, there is a marked stromal deposition of C.TNC. We then generated a second-generation C.TNC-CAR with an scFv specific for C.TNC and a CD28z signaling domain. Using retroviral transduction of primary T cells, we achieve an average transduction efficiency of 66%. C.TNC-CAR T cells killed in an antigen and CAR-dependent manner in *in vitro* cytotoxicity assays. Upon antigen stimulation, C.TNC-CAR T cells produce significant amounts of cytokines and can eradicate tumor cells *in vitro*. With these data, we tested the C.TNC-CAR T cell effector function against established *in vivo* models of sarcomas and DIPGs. C.TNC-CAR T cells expanded transiently at tumor sites, resulting in limited antitumor activity. In an attempt to improve C.TNC-CAR T cell effector function, we first explored canonical changes to the linker, hinge, and transmembrane domains of the C.TNC-CAR. While several CAR constructs improved the effector function of CAR T cells *in vitro* as judged by IFNg production and cytolytic activity, this did not translate into improved antitumor activity *in vivo*. Therefore, we are currently investigating if providing cytokine support through the expression of leucine zipper-based constitutively active cytokine receptors (ZipRs) can improve the effector function of C.TNC-CAR T cells. *In vitro*, expression of ZipRs in C.TNC-CAR T cells enhances their ability to recursively kill tumor cells, and *in vivo* studies are underway. In summary, CAR T cells can target ECM proteins such as C.TNC and elicit an antitumor response. Our initial studies with C.TNC-CAR T cells warrant their further development for the immunotherapy of pediatric brain and solid tumors.

589 Monitoring FAP CAR T Cell Therapy with PET Imaging

Estela Noguera-Ortega[1], Iris K. Lee[2], Zebin Xiao[3], Leslie Todd[3], Liousia Maria[1], Kexiang Xu[2], Kimberly J. Edwards[4], Katheryn Lohith[4], Michael D. Farwell[4], John Scholler[5], Carl H. June[1], Steven M. Albelda[1], Ellen Puré[3], Mark A. Sellmyer[4]

[1]Center for Cellular Immunotherapies, University of Pennsylvania, Philadelphia, PA,[2]Department of Bioengineering, University of Pennsylvania, Philadelphia, PA,[3]Department of Biomedical Sciences, University of Pennsylvania, Philadelphia, PA,[4]Department of Radiology, University of Pennsylvania, Philadelphia, PA,[5]Center for Cellular Immunotherapies, University of Pennsylvannia, Philadelphia, PA

Two of the major obstacles that adoptive cell transfer immunotherapy needs to overcome to be successful in solid tumors are 1) the immunosuppressive tumor microenvironment (TME) and 2) the lack of robust biomarkers that allow for the identification of patients that would benefit from the therapy and for monitoring of the treatment response. Here we paired a CAR T cell therapy with a companion Positron Emission Tomography (PET) imaging approach that allows for serial, non-invasive, whole-body visualization of a biological target of interest -in this specific case, Fibroblast Activating Protein (FAP). FAP is a cell surface serine protease that is highly expressed by cancer associated fibroblasts in the TME that participate in the generation of the immunosuppressive stromagenic response in solid tumors. We designed a novel FAP CAR construct based on the scFv of the 4G5 antibody developed, in house, against canine FAP that cross-reacts against mouse and human FAP. In this study, we utilized the ^{18}F-radiolabeled FAP inhibitor (FAPI), [^{18}F]AlF-FAPI-74, to image FAP in two different mouse tumor models. First, the probe specificity was evaluated in the I45 human mesothelioma tumor model (a line which does not induce FAP^{+} fibroblasts). I45 WT and I45 cells transduced with human FAP were injected s.c. into the opposite flanks of a mouse and imaged following 2 weeks of tumor growth. We observed a 7.5-fold higher uptake of [^{18}F]AlF-FAPI-74 in the I45 huFAP tumor compared to the WT, demonstrating the high specificity of the probe for FAP. Next, we used a more clinically-relevant A549 model where the tumor cells do not express FAP but induce a stromagenic response and drive the

recruitment of FAP$^+$ stromal cells in the TME. [^{18}F]AlF-FAPI-74 PET/CT following 3 weeks of tumor growth showed a 6.5-fold increased radiotracer uptake in the tumor relative to the muscle at the baseline scan. Using this model, we evaluated the potential of our new CAR T cells to reduce tumor burden, as well as evaluating the potential of the [^{18}F]AlF-FAPI-74 tracer as a tool to monitor the clearance of FAP-expressing cells in response to FAP CAR T cell therapy. Immediately after the baseline scan, we injected 5x10^6 FAP CAR T cells iv. At day 14 post-T cell injection, mice treated with FAP CAR T cells had significantly smaller tumors relative to the control group, which were treated with T cells that do not express the CAR, highlighting the therapeutic efficacy of the FAP CAR T cell therapy. Moreover, [^{18}F]AlF-FAPI-74 PET/CT imaging showed no detectable tracer uptake in the tumors treated with FAP targeted CAR T. These findings were confirmed by immunofluorescence, indicating successful clearance of the FAP$^+$ stroma by the injected FAP CAR T cells. In conclusion, the new 4G5 FAP CAR shows specific targeting toward mouse stroma infiltrating lung adenocarcinoma xenografts. PET imaging is a powerful tool that can have may applications. PET imaging of FAP could be a highly useful approach to stratify patients prior to FAP CAR T therapy, as well as to monitor the pharmacodynamic response for FAP-targeted therapies.

590 CRTE7A2-01: A HPV-16 E7$_{11-19}$ Specific TCR Targeting HPV-Related Cancers

Xingwang Xie

Beijing Corregene Biotechnology Co.Ltd, Beijing, China

Most cervical and anal cancers and over 25% of head and neck cancers is caused by infection with high-risk human papillomavirus (HPV). HPV16 is the most common high-risk HPV that induces cancers. HPV E7 oncoprotein is essential for HPV-induced carcinogenic transformation and is homogenously expressed in HPV-related cancer cells, these aspects make HPV E7 oncoprotein an ideal target for TCR-engineered T cell therapy. In a recent Phase I trial at the National Cancer Institute (NCI), an E7 TCR-T therapy (NCI-E7-TCR) showed a 50% objective response rate in heavily treated metastatic HPV-related cancers. By tetramer staining of expanded tumor infiltrating lymphocytes (TILs) form cervical cancer patients and CIN2 patients carrying the HLA-A*02:01 allele, we sorted T cells specifically recognized the HLA-A*02:01-restricted HPV16 E7$_{11-19}$ epitope with FASC single cell sorting. TCRα and β chains were obtained for each sorted single T cell by Corregene's Single T cell TCR Cloning platform. For each TCR candidate, the affinity, cytotoxicity, IFN-γ release, T cell proliferation and specificity were evaluated deeply by in vitro assays. We obtained a high-affinity TCR sequence that specifically recognized the HLA-A*02:01-restricted HPV16 E7$_{11-19}$ epitope: CRTE7A2-01. CRTE7A2-01 showed comparable affinity but better expression intensity and stability on T cells relative to the NCI TCR. Consequently, TCR-T engineered with CRTE7A2-01 outperformed T cells engineered with NCI-E7-TCR in all vitro assays. Moreover, CRTE7A2-01 displayed great specificity: no allo-reactivity evaluation against over 70 HLAs, no reactivity to a panel of over 30 HPV16-negative cell lines, and no off-target hits in extensive alanine scan(X-SCAN).In vivo experiments showed that CRTE7A2-01 TCR-T could significantly inhibit the growth of subcutaneous Hela tumors (overexpressing HLA-A*02:01 and HPV16 E7) in nude mice, greatly infiltrate into tumor tissues and persistently proliferated in peripheral blood. Furthermore, CRTE7A2 shows excellent safety in vivo. We are now conducting a single center, open, single arm dose escalation phase I study to evaluate the safety, tolerability, and efficacy of CRTE7A2-01 TCR-T cell for HPV16 positive advanced cervical, anal, or head and neck cancers. The study will determine MTD of CRTE7A2-01 TCR-T cell injection, as well as investigate RP2D (NCT05122221).

591 The Safety and Efficacy of Systemic Delivery of a New Liver-De-Targeted TGFβ Signaling Inhibiting Adenovirus in an Immunocompetent Triple Negative Mouse Mammary Tumor Model

Soon Cheon Shin[1], Renee Vickman[2], Beniamin Filimon[1], Yuefeng Yang[3], Zebin Hu[4], Kathy A Mangold[5], Megan Sullivan[5], Karen Kaul[5], Bellur S Prabhakar[6], Hans Schreiber[7], Weidong Xu[1]

[1]Department of Medicine, NorthShore University HealthSystem, Evanston, IL,[2]Center for Personalized Cancer Care, NorthShore University HealthSystem, Evanston, IL,[3]Department of Experimental Medical Science, Key Laboratory of Diagnosis and Treatment of Digestive System Tumors of Zhejiang Province, Ningbo, Zhejiang, China,[4]National Institutes for Food and Drug Control, Beijing, China,[5]Department of Pathology and Laboratory Medicine, NorthShore University HealthSystem, Evanston, IL,[6]Department of Microbiology and Immunology, University of Illinois College of Medicine, Chicago, IL,[7]Department of Pathology, The University of Chicago, Chicago, IL

Aberrant TGFβ signaling has been shown to be negatively associated with disease-free survival (DFS) and overall survival (OS) of metastatic triple negative breast cancer (mTNBC), and positively linked to metastasis and tumor immune escape. Previously, we have found that oncolytic adenoviruses expressing a TGFβ signaling inhibitory protein (sTGFβRIIFc) inhibited bone metastasis in a human TNBC cell line (MDA-MB-231) immunodeficient intracardiac mouse model with systemic administration, and induced immune activation in a mouse TNBC cell line (4T1) immunocompetent subcutaneous model with intratumoral injection. Systemic administration of adenoviruses is predicted as the best route to treat mTNBC but faces the challenges of increased toxicity and viral clearance. To overcome these challenges, we have created a liver-de-targeted sTGFβRIIFc- and Lyp-1 peptide-expressing adenovirus (mHAdLyp.sT) with enhanced breast cancer cell tropism. We profiled its safety and immune response features on day 14 and day 25 of tumor cell inoculation in the 4T1 model. Our data showed that the systemic administration of mHAdLyp.sT resulted in reduced hepatic and systemic toxicity as indicated by serum ALT, LDH and pro-inflammatory cytokine levels when compared with the regular sTGFβRIIFc-expressing adenovirus (Ad.sT). sTGFβRIIFc expression and inhibition of TGFβ-1 were confirmed in serum and/or tumor tissues by ELISA and qRT-PCR, respectively. Our flow analysis revealed that mHAdLyp.sT is effective in increasing anti-tumor CD8$^+$ cells, monocytes/monocytic MDSCs (CD11b$^+$Ly-6C^{hi}Ly-6G$^-$), and M1 macrophages (F4/80$^+$CD11c$^+$) in blood, tumor, or spleen on day 14. We further tested the therapeutic effects of mHAdLyp.sT alone and in combination with immune checkpoint inhibitors (ICIs) in this

model. Although mHAdLyp.sT alone didn't elicit significant changes in primary tumor progression by tumor volume and in tumor weight, histological lung analysis at the endpoint showed significant inhibition of lung metastasis by mHAdLyp.sT ($p<0.0001$ compared to the buffer group). When mHAdLyp.sT was combined with both anti-PD-1 and anti-CTLA-4 antibodies (triple treatment) primary 4T1 tumor growth was significantly inhibited too ($p<0.001$ on day 23). Furthermore, the flow analysis showed that the triple treatment still had a significant increase of $CD8^+$ T cells in blood and spleen at the end of the experiment. Both $CD8^+$ and $CD4^+$ effector or effector memory (TE/EM) subsets ($CD44^+CD62L^-$) in blood were also significantly increased by the triple treatment, suggesting tumor immune stimulation by the triple treatment is sustained for a long time period. Currently, we are further testing optimal doses of mHAdLyp.sT for preclinical studies and exploring more molecular mechanisms behind its interaction with ICIs. We are confident in advancing this new treatment option for mTNBC.

592 Replication Competent Adenovirus-Mediated Cytotoxic and Interleukin-12 Gene Therapy in Prostate Cancer: 36-month Follow-Up Data from a Phase I Clinical Trial

Shyam Nyati[1], Hans Stricker[2], Kenneth N. Barton[3], Pin Li[2], Mohamed Elshaikh[1], Haythem Ali[2], Stephen L. Brown[2], Clara Hwang[2], James Peabody[2], Svend O. Freytag[2], Benjamin Movsas[1], Farzan Siddiqui[1]

[1]Radiation Oncology, Henry Ford Health System, Detroit, MI,[2]Henry Ford Health System, Detroit, MI,[3]Henry Ford Health System, Troy, MI

Introduction: Men with locally recurrent prostate cancer, after definitive radiotherapy, have few therapeutic options. Oncolytic adenovirus-mediated cytotoxic gene therapy is an investigational cancer therapy. Delivery of the suicide gene to the tumor is by direct intratumoral or systemic injection of a viral vector containing the suicide gene. Our approach incorporates yeast cytosine deaminase (yCD) and herpes simplex virus thymidine kinase (HSV-1 TK), to confer sensitivity to 5-fluorocytosine (5-FC) and Valganciclovir (vGCV), respectively. The pro-drugs are converted into active drugs that inhibit DNA damage repair. Here we report the safety of oncolytic adenovirus-mediated suicide gene therapy that incorporates an interleukin-12 (IL12) gene for treatment of recurrent prostate cancer. **Methods:** In this phase I study, a replication-competent adenovirus (Ad5-yCD/*mut*TK_{SR39}rep-hIL-12) expressing yCD/mutTK_{SR39} (yeast cytidine deaminase/mutant S39R HSV-1 thymidine kinase) and human IL-12 (IL12) was injected into tumors of 15 subjects with recurrent prostate cancer (T1c-T2) at escalating doses (1×10^{10}, 3×10^{10}, 1×10^{11}, 3×10^{11}, or 1×10^{12} viral particles). Subjects received 5-FC and vGCV for 7 days. The study endpoint was toxicity through day 30. Experimental endpoints included measurements of serum IL12, interferon gamma (IFNγ), and CXCL10 to assess immune system activation. Peripheral blood mononuclear cells (PBMC) and proliferation markers were analyzed by flow cytometry. **Results and conclusions:** Fifteen patients received Ad5-yCD/*mut*TK_{SR39}rep-hIL-12 and oral 5-FC and vGCV. Approximately 92% of the 115 adverse events observed were grade 1/2 requiring no medical intervention. Ad5-yCD/*mut*TK_{SR39}rep-hIL-12 DNA was detected in the blood of only two patients. Elevated serum IL12, IFNγ, and CXCL10 levels were detected in 57%, 93%, and 79% of subjects, respectively. Serum cytokines demonstrated viral dose dependency, especially apparent in the highest-dose cohorts. Analysis of immune cell populations indicated activation after Ad5-yCD/*mut*TK_{SR39}rep-hIL-12 administration in cohort 5. The study did not detect a significant difference in the PSA doubling time (PSADT) between pre and post treatment by paired Wilcoxon rank test ($p=0.17$). There was no correlation between adenoviral dose and PSADT in each cohort separately or pooled (cohorts1-3 and cohorts 4-5). The study maximum tolerated dose (MTD) was not reached indicating 10^{12} viral particles was safe. This trial confirmed that replication-competent Ad5-IL-12 adenovirus (Ad5-yCD/*mut*TK_{SR39}*rep*-hIL-12) was well tolerated when administered locally to prostate tumors.

593 Targeting Breast Cancer Stem Cells with Mammalian Orthoreovirus (MRV)

Natasha Ivelisse Roman[1], Julia Davydova[2], Pranav Danthi[3], Julie Ostrander[4]

[1]Department of Pharmacology, UMN, Minneapolis, MN,[2]Department of Surgery, UMN, Minneapolis, MN,[3]Department of Biology, Indiana University, Blomington, IN,[4]Department of Medicine, UMN, Minneapolis, MN

Breast cancer is the second leading cause of cancer deaths among women in the United States. Estrogen receptor positive [ER+] breast cancer has a more favorable prognosis; however, patients can experience recurrence for many years after initial diagnosis. Breast cancer stem cells (BCSC), which are dormant and exist as a minority sub-population (0-5%), drive recurrence, metastasis and resistance to therapies that primarily target rapidly proliferating tumor cells. Current treatments are insufficient to cure metastatic ER+ breast cancer and there are no FDA approved therapeutics that target BCSC. Mammalian orthoreovirus (MRV) is an oncolytic virotherapy tested in clinical trials for many cancer types including metastatic breast cancer. MRV was found to be safe, but efficacy limited as a monotherapy. In our studies we compared several laboratory MRV strains (T1L, R2) to the strain most similar to Reolysin, which is being tested in clinical trials (i.e. T3D). Our studies suggest that T3D is less effective in killing ER+ breast cancer cells and BCSCs. We aimed to generate novel MRV strains with enhanced BCSC-targeting capacity by serially passaging T1L and R2 MRV strains in BCSC enriched 3D tumorsphere cultures. Our preliminary data have shown that serially passaged (SP) MRV strains (T1L SP, R2 SP) are more effective in decreasing MCF-7 paclitaxel resistant (TaxR) cell viability and inhibiting tumorsphere formation compared to the parental (P) strains (T1L P, R2 P). MRV induces cell death by different mechanisms (apoptosis, necroptosis) depending on the cell type. The mechanisms of MRV-induced cell death in BCSC and non-BCSC populations are unknown. We aim to define the effects of MRV-induced death comparing parental vs MRV serially passaged strains on BCSC and non- BCSC cell populations using flow cytometry, and cell death assays. We anticipate these studies will lead to an improved MRV oncolytic virotherapy that will be combined with clinically relevant inhibitors, such as CDK4/6 inhibitors and anti-estrogens, to prevent and treat therapy-resistant ER+ breast cancer.

595 Toca 511/5-FC Treatment Has the Potential to Increase the Therapeutic Efficacy of Anti-PD-1 Antibody in an Immunocompetent Murine Pancreatic Cancer Model

Hiroki Niwa[1,2], Toru Nakamura[1], Hiroki Kushiya[1], Tomohiro Suzuki[1], Kazuho Inoko[1], Kei Hiraoka[1,2], Akihito Inagaki[3], Takahiro Tsuchikawa[1], Toshiaki Shichinohe[1], Kasahara Noriyuki[3,4], Satoshi Hirano[1]

[1]Department of Gastroenterological Surgery II, Hokkaido University Graduate School of Medicine, Sapporo, Japan,[2]Department of Clinical Research, National Hospital Organization (NHO) Hakodate National Hospital, Hakodate, Japan,[3]Department of Neurological Surgery, University of California, San Francisco, CA,[4]Department of Radiation Oncology, University of California, CA

Pancreatic ductal adenocarcinoma (PDAC) is one of the most lethal cancers and its clinical outcome remains poor, necessitating the development of novel therapeutic strategies. Prodrug activator gene therapy with Toca 511, a tumor-selective retroviral replicating vector encoding an optimized yeast cytosine deaminase (yCD) gene, has demonstrated therapeutic efficacy in a variety of preclinical cancer models and has shown some promise in clinical trials for recurrent high-grade glioma. Toca 511 exerts direct anti-tumor effects through yCD-mediated intratumoral conversion of the prodrug 5-fluorocytosine (5-FC) to the active drug 5-fluorouracil (5-FU). In addition, previous results suggest Toca 511/5-FC suicide gene therapy can also induce anti-tumor immunity. In recent years, immune checkpoint inhibitors (ICIs) were considered as a novel therapy in various cancers, but the therapeutic efficacy of single-agent ICI in clinical trials of advanced PDAC patients was poor. Therefore, various combination therapy with chemotherapy or radiotherapy for PDAC have been investigated to increase sensitivity to ICIs. Here, we first conducted CTL assay and immunohistochemical analysis and investigated the anti-tumor immunity induced by Toca 511/5-FC treatment in an immunocompetent murine bilateral subcutaneous PDAC tumor model. Furthermore, we evaluated the therapeutic effects achieved in combination with anti-programmed cell death protein 1 (PD-1) antibody. Bilateral subcutaneous tumor models were established in C57BL/6J mice by inoculation of the syngeneic murine PDAC cell line Pan02 into both flanks, and ipsilateral flank tumors were initially transduced with Toca 511, while contralateral flank tumors served as untransduced controls. In CTL assays, the 5-FC treatment group demonstrated significantly higher $CD8^+$ T effector cell-mediated cytotoxicity against Pan02 target cells than did the PBS control group. In immunohistochemical analysis, the 5-FC treatment group showed significantly higher T cell infiltration than did the PBS control group. Combination therapy with Toca 511/5-FC treatment and anti-PD-1 antibody achieved significantly stronger tumor growth inhibition against untransduced tumors than Toca 511/5-FC treatment alone. Furthermore, $CD8^+$ or $CD4^+$ T-cell depletion completely eliminated the therapeutic effects of combination therapy. These data showed that $CD8^+$ or $CD4^+$ T-cell-dependent anti-tumor immune responses were important for the therapeutic efficacy of Toca 511/5-FC treatment and combination therapy. These results indicate that Toca 511/5-FC treatment has the potential to increase the therapeutic efficacy of immune checkpoint inhibitors and the combination therapy may be a promising clinical treatment strategy for PDAC.

596 Exploring Novel Viro-Immunotherapies Using "Armed" Oncolytic Adenoviruses and Adoptive T-cell Therapy to Target Pancreatic Ductal Adenocarcinoma

Brett L. Roach[1], Masato Yamamoto[2]

[1]Department of Surgery, University of Minnesota, Twin Cities, Minneapolis, MN,[2]Department of Surgery, University of Minnesota, Minneapolis, MN

Introduction: Pancreatic ductal adenocarcinoma (PDAC) is the third leading cause of cancer-related mortalities and is projected to become second by 2030. There is an urgent need for the development of more efficient therapeutics targeting PDAC. Two primary features make PDAC refractory to conventional therapeutics. First, the highly immunosuppressive tumor microenvironment (TME) plays a crucial role in impeding the innate and effector arms of the immune system to prevent anti-tumor responses. Second, desmoplasia causes formation of fibrotic tissue within and around tumor tissue, which creates a physical barrier for infiltration of anti-tumor immune cells and therapeutics. The goal of this project is to develop viro-immunotherapies against PDAC that target the immunosuppressive TME and desmoplasia by utilizing "armed" oncolytic adenoviruses (OAds) and adoptive T-cell therapy (ATCT). I have selected three transgenes to "arm" my OAd constructs: i.) TGF-beta blocker, ii.) interleukin-7 (IL-7), and iii.) interferon gamma (IFN-gamma). Methods: "Armed" replication-deficient adenovirus (Ad) constructs were first generated to isolate transgene function from oncolytic activity. Each transgene was individually cloned into the E1 region of Ad-5 (WT). Viral particles were amplified in 293 cells and purified via ultracentrifugation using a CsCl gradient. Anti-tumor effects were measured using a syngeneic mouse model. C57BL/6 mice were subcutaneously injected with KPC cells (mouse PDAC cell line), and tumors were treated intratumorally with Ad constructs. To measure systemic (abscopal) effects of virus treatment, bilateral tumors were established, and only one side was treated. For IHC staining, tumors were harvested at various time points, fixed in 10% neutral-buffered formalin, sectioned, and stained for immune cell infiltration and fibrosis. Results: Tumor growth was significantly inhibited after treatment with each "armed" Ad construct (Figure 1A). Furthermore, significant tumor infiltration of anti-tumor immune cells was induced upon treatment (Figure 1B) as well as a decrease in fibrosis. Abscopal effects were observed on non-injected tumors after injection of ipsilateral tumors as well as an increase in tumor infiltration of anti-tumor immune cells in untreated tumors (Figure 1C-D). Conclusions: All three "armed" Ad constructs exerted significant anti-tumor effects, and constructs armed with either IFN-gamma or TGF-beta blocker induced significant abscopal effects. These findings have broad implications in the field of pancreatic cancer by shedding light on how the TME can be manipulated to enhance anti-tumor effects to aid in the development of more efficient therapeutics against PDAC. Moreover, therapeutics inducing abscopal effects should be highly valued because most PDAC patients die from metastasis. Future Directions: To obtain a mechanistic understanding of the anti-tumor effects, depletion of immune cells in mice (CD4+ and CD8+ T-cells and NK cells) will be performed prior to virus treatment to see how the absence of these cells affect tumor growth. "Armed" replication-competent constructs will be generated to see how the added effects of oncolysis with transgene activity may enhance anti-

tumor responses. Finally, OAd constructs will be combined with mesothelin-targeted chimeric antigen receptor (CAR) T-cells using xenograft models in SCID mice.

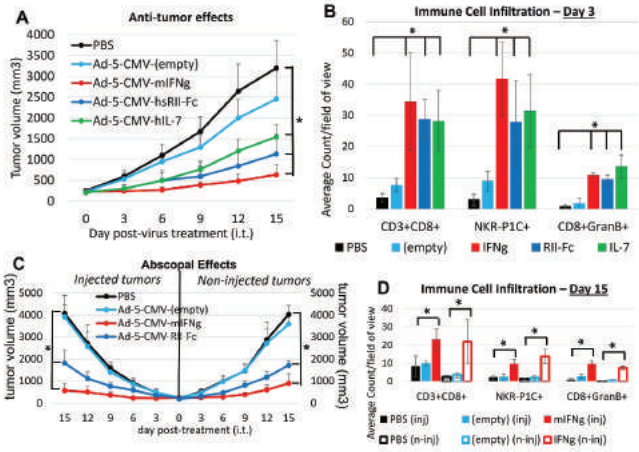

Figure 1.) Anti-tumor effects of "armed" Ad constructs. **A.)** C57BL/6 mice bearing subcutaneous KPC tumors were treated intratumorally with virus constructs at days 0 and 6, and tumor volume was tracked every 3 days. **B.)** Tumors harvested on day 3 were stained for CD3+CD8+ T-cells, NK cells (NKR-P1C+), and activated T-cells (CD8+GranB+). **C.)** Abscopal effects were measured using bilateral subcutaneous tumors and injecting with virus on only one side (day 0 and 6). **D.)** Injected and non-injected tumors were harvested on day 15 and stained as described in **B**. *$P < 0.05$*

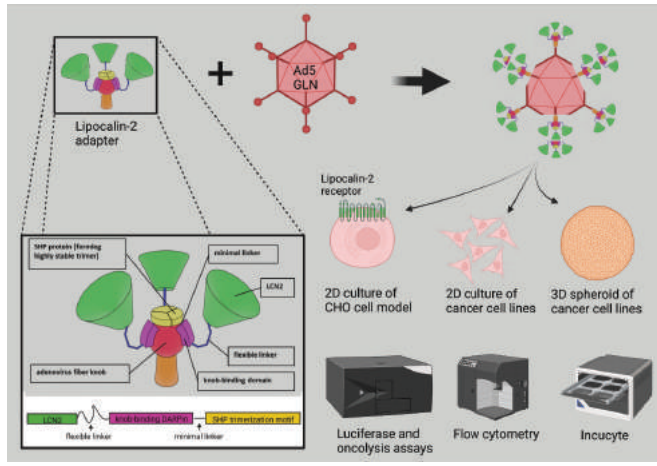
597 Targeting Oncolytic Adenoviruses to Cancer Cells Using a Designed Ankyrin Repeat Protein (DARPin) Lipocalin-2 (LCN2) Fusion Protein

Sebastian Schellhorn[1], Dominik Brücher[2], Natascha A. Wolff[3], Katrin Schröer[1], Erwan Sallard[1], Kemal Mese[1], Wenli Zhang[1], Eric Ehrke-Schulz[1], Frank Thévenod[3], Andreas Plückthun[4], Anja Ehrhardt[1]

[1]Human Medicine, Virology and Microbiology, Center for Biomedical Education and Research (ZBAF), Witten/Herdecke University, Witten, Germany,[2]Vector Biopharma, Basel, Switzerland,[3]Human Medicine, Institute of Physiology, Center for Biomedical Education and Research (ZBAF), Witten/Herdecke University, Witten, Germany,[4]Department of Biochemistry, University of Zurich, Zurich, Switzerland

Oncolytic viruses are a promising technology to attack cancer cells and to recruit immune cells to the tumor site. Since the Lipocalin-2 receptor (LCN2R) is expressed on most cancer cells, we used its ligand lipocalin-2 (LCN2) to target oncolytic adenoviruses (Ads) to cancer cells. Therefore, we fused a designed ankyrin repeat protein (DARPin) adapter binding the knob of Ad type 5 (knob5) to LCN2 to retarget the virus towards LCN2R with the aim of analyzing the basic characteristics of this novel targeting approach. The adapter was tested *in vitro* with Chinese Hamster Ovary (CHO) cells stably expressing the LCN2R and on 20 cancer cell lines (CCLs) using an Ad5 vector encoding luciferase and green fluorescent protein (GFP). Luciferase assays with the LCN2 adapter (LA) showed 10-fold higher infection compared to blocking adapter (BA) in CHO cells expressing LCN2R, but also in cells not expressing the LCN2R. Most CCLs showed an increased viral uptake of LA-bound virus compared to BA-bound virus and for five CCLs viral uptake was comparable to unmodified Ad5. Flow cytometry and hexon immunostainings also revealed increased uptake of LA-bound Ads compared with BA-bound Ads in most tested CCLs. Virus spread was studied in 3D cell culture models and nine CCLs showed increased and earlier fluorescence signals for LA-bound virus compared to BA-bound virus. Mechanistically we show that the LCN2 adapter increases viral uptake only in the absence of its ligand Enterobactin (Ent) and independently of iron. Together, we characterized a novel DARPin-based system resulting in enhanced uptake demonstrating potential for future oncolytic virotherapy. A graphical abstract of the applied retargeting strategy is displayed below (Created with BioRender.com).



598 Oncolytic Adenovirus Expressing NIS for the Therapy of Chemoresistant Breast Cancer Stem Cells

Sacha Robert[1], Natasha I. Roman[2], Kari Jacobsen[1], Margarita V. Romanenko[1], Kazuho Inoko[1], Stacey Wilber[1], Daniel Lyadov[1], Christopher J. LaRocca[1], Julie Ostrander[3], Julia Davydova[1]

[1]Department of Surgery, University of Minnesota, Minneapolis, MN,[2]Department of Pharmacology, University of Minnesota, Minneapolis, MN,[3]Department of Medicine, University of Minnesota, Minneapolis, MN

Recurrence of metastatic breast cancer arising from acquired endocrine and chemotherapy resistance remains a health burden for women with luminal estrogen-receptor positive (ER+) breast cancer. Disseminated ER+ tumor cells can remain viable but quiescent for years to decades. A crucial factor contributing to metastatic spread include the maintenance and expansion of breast cancer stem cells (BCSCs). Since BCSCs exhibit enhanced resistance to chemo and endocrine therapies, there is a need for more efficient treatment options. We aim to use Oncolytic adenoviruses (OAd) to target BCSCs. OAd are engineered to selectively replicate in cancer cells leading to the destruction of targeted cancer tissue. Our laboratory has engineered OAd encoding the sodium/iodide symporter (NIS), a protein that mediates uptake of iodine for radiotherapy and imaging. In this OAd, the NIS gene was inserted into the E3 region to allow continual gene expression as the virus replicates under control of the COX2 promoter. To improve infectivity, we have equipped virus with the Ad5/Ad3-modified fiber which allows to CD46 and hDSG2 receptors attachment. We hypothesized that OAd-NIS can target and lyse breast CSCs, resulting in the decrease of local recurrences risk by treating preexisting, clinically undetectable micrometastatic deposits. We demonstrated that our OAd-NIS has enhanced binding and

exhibits superior oncolysis in human breast cancer cells from all breast cancer subtypes, including ER+ luminal cells. We also found OAd-NIS to be selective for breast cancer cells as the virus exhibited minimum oncolytic activity and NIS expression in normal human mammary epithelial cells. The deletion of the Adenovirus Death Protein (ADP) greatly improved the expression of NIS in breast cancer cells, most likely due to greater NIS membrane localization. To confirm the potential of OAd-NIS to target BCSCs population, we employed ER+ paclitaxel-resistant (TaxR) cells and 3D models which have been shown to exhibit stem cell markers (e.g. ALDH+ or $CD44^{hi}/CD24^{lo}$). We have previously shown that TaxR cells generate more tumorspheres compared to the parental, chemosensitive MCF-7 cells, a feature of CSCs to form colonies in serum-free suspension culture. Importantly, the killing effect of OAd-NIS in TaxR cells was improved compared to that in control MCF-7 cells. This correlated well with the increased NIS gene and protein expression in TaxR cells, as shown by qPCR and immunofluorescence staining, respectively. More importantly, in contrast to MCF-7 control, when TaxR cells were co-treated with virus and paclitaxel, we found that OAd-NIS reversed chemoresistance, sensitizing TaxR cells to paclitaxel upon virus infection. Finally, in a tumorsphere assay, we found that OAd-NIS inhibits the formation of tumorspheres in TaxR and MCF-7 3D cultures, and successfully destroys already formed tumorspheres upon infection. This study confirmed the potential of OAd-NIS to target and effectively destroy BCSCs population. Our next steps include evaluation of the stem cell markers in TaxR cells upon OAd-NIS infection and in vivo potential of OAd-NIS to facilitate radioiodine-based imaging and therapy. Our studies also suggest that OAd-NIS could be used as an adjuvant therapy in combination with paclitaxel to treat ER+ breast cancer patients with recurrent metastatic disease. We plan to test this hypothesis using the mouse mammary intraductal injection model, which closely recapitulated human breast cancer progression and will form distant metastasis from ER+ breast cancer cells.

599 Retroviral Replicating Vector-Mediated Prodrug-Activator Gene Therapy Achieved Highly Efficient Tumor Transduction and Antitumor Efficacy in Experimental Human Gastric Cancer

Shuji Kubo[1], Hiroaki Fujino[1], Noriyuki Kasahara[2], Emiko Sonoda[1]

[1]Laboratory of Molecular and Genetic Therapeutics, Institute for Advanced Medical Sciences, Hyogo Medical University, Nishinomiya, Japan,[2]University of California, San Francisco, San Francisco, CA

Retroviral replicating vectors (RRVs) can selectively replicate within tumor cells. RRV can mediate efficient tumor-specific delivery of prodrug activator genes into tumor cells, and subsequent prodrug administration leads to synchronized cell killing of infected tumor cells. Here we evaluated two different RRV derived from amphotropic murine leukemia virus (AMLV) and gibbon ape leukemia virus (GALV), which utilize different cellular receptors (PiT-2 and PiT-1, respectively) for viral entry, in human gastric cancer cells. Quantitative RT-PCR showed that expression levels of PiT-2 were higher than PiT-1 in all gastric cancer cell lines tested. Consequently, AMLV encoding the green fluorescent protein gene infected and replicated more efficiently than GALV in most gastric cancer cell lines. In contrast, neither RRV showed efficient infection of normal human fibroblasts. Next, AMLV encoding yeast cytosine deaminase (CD), which converts the prodrug 5-fluorocytosine (5-FC) to the active drug 5-fluorouracil, showed efficient killing of most gastric cancer cells in the presence of 5-FC prodrug compared to GALV. This differential cytotoxicity between AMLV vs. GALV correlated with viral PiT-2 vs. PiT-1 receptor expression level and virus spread efficiency in gastric cancer cells. Moreover, in MKN-74 subcutaneous xenograft models of gastric cancer, AMLV-CD showed significant antitumor effects compared to GALV-CD. Furthermore, in the MKN-74 recurrent tumor model in which 5-FC was discontinued, resumption of 5-FC reduced tumor volume without further administration of RRV. These findings indicate that AMLV-mediated prodrug-activator gene therapy may be beneficial for treating human gastric cancer. Furthermore, custom utilization of alternative RRV strains according to differential expression levels of viral receptors may enable more personalized and effective cancer virotherapy in future studies.

600 Inhibition of c-MYC in Hepatocellular Carcinoma via AAV8 Mediated Gene Transfer

Isaiah L. Reeves, Stephen M. Winston, Yunyu Spence, Christopher Morton, Andrew M. Davidoff

Department of Surgery, St. Jude Children's Research Hospital, Memphis, TN

Inhibiting the key transcription factor MYC has long been a goal due to its central role in human cancers; although, it has yet to be accomplished clinically. Hepatocellular carcinoma (HCC) is the most common liver malignancy in adults and the second most common liver tumor in children and is often associated with MYC deregulation. The mini protein Omomyc has been shown to induce tumor regression in a variety of cancer types by preventing the heterodimerization of c-MYC and it obligate binding partner MAX, thus preventing its transcriptional activation. but questions about in vivo peptide toxicity and efficacy remain. Due to the natural high liver tropism of AAV8, we hypothesized that targeted delivery of Omomyc using the AAV platform will be much more efficacious and limit off target toxicity as opposed to other delivery methodologies. Expression of Omomyc in HCC cell lines *in vitro* by transient transfection and doxycycline induced expression induces an 8-20 fold inhibition of proliferation depending on cell type, including G2 cell cycle arrest (about 50%) in the high c-MYC expressing cell line Hep3B. We have also demonstrated a 2-fold induction of autophagy, measured via mCherry-GFP-LC3 levels in HCC cell lines with a direct correlation to the amount of c-MYC expressed in these cell lines. When combined with conventional therapeutics like the multi-kinase inhibitor sorafenib, Omomyc induces autophagy another 20%. Additionally, Omomyc results in significant levels of cell death (20-60%), in direct correlation with the level of c-MYC protein expression. Our preliminary data suggests that this could be due to induction of autophagic cell death, with mitigation of the effect seen when treated with Bafilomycin A1 or Chloroquine. Treatment of HCC with recombinant AAV8 with vector genomes encoding Omomyc results in a profound cytostatic effect (2-7 fold lower proliferation rate), and very strong cytotoxicity when combined with sorafenib, leading to high levels of cell death in Hep3B cells. We have also demonstrated a potential synergistic effect of combining autophagy inducing compounds like sorafenib and mTOR inhibitors being able

to increase transduction efficiency by approximately 50-60% in our HCC cells lines. Taken together, our data suggest that our novel AAV8 delivery of Omomyc has the ability to inhibit cellular proliferation, induce autophagy, and induce cell death in HCC which may prove to be a novel therapeutic approach for the treatment of HCC, especially when combined with conventional therapeutics.

601 TRAIL Gene Transfection Using Innovative Lipid Vector in Association with Chemotherapy Efficiently Kills Cisplatin-Resistant Ovarian Cancer Cells

Quoc Manh Nguyen[1], Pierre-François Dupré[1,2], Mathieu Berchel[3], Frédérique d'Arbonneau[1,4], Tristan Montier[1,5]

[1]Univ Brest, Inserm, UMR 1078, GGB-GTCA Team, "Gene Transfer and Combined Therapeutic Approaches", Brest, France,[2]CHU Brest, Gynecological Surgery Department, Brest, France,[3]Univ Brest, CNRS, CEMCA UMR 6521, 6 Avenue Victor Le Gorgeu, Brest, France,[4]CHU Brest, Dentistry Service, Odontology Department, Univ Brest, Brest, France,[5]CHU Brest, Medical Genetics and Reproductive Biology Cepartment, Center of Reference for Rare Diseases "Neuromuscular Diseases", Brest, France

Introduction: Ovarian cancer (OC) is the most lethal gynecologic cancer among women in developed countries. Most of the patients will experience recurrence and succumb to the chemo-resistant disease. Overcoming the resistance to platinum salts represents a major unmet need. Tumor necrosis factor (TNF)-related apoptosis-inducing ligand (TRAIL) is capable of inducing apoptosis primarily in tumor cells upon ligation with its death receptors (DR). Its pro-apoptotic effect has been well investigated. However, the application of recombinant forms of TRAIL and agonistic antibodies of its receptors have provided disappointing results in clinical trials due to short half-life *in vivo*, potential hepatotoxicity and poor cancer-targeting ability. Thus, TRAIL gene therapy has been developed to overcome these limitations. Here we described the killing effect of TRAIL gene, transfected by our innovative bioinsprired lipid vector BSV163/DOPE (**Figure 1**), in association with cisplatin to treat ovarian cancer cell lines and its cisplatin-resistant analogs. **Methods:** Caov3 and OVCAR3 cell lines were selected to represent high-grade serous ovarian cancer. Cisplatin-resistant Caov3 (CR-Caov3) cells were achieved by culturing Caov3 cells in the presence of cisplatin over 6 months. Luciferase-encoding plasmid (pGM144, 3759 bp) was used as a transfection control plasmid for TRAIL-encoding plasmid (pVAX2-TRAIL, 3771 bp). The lipid vector BSV163/DOPE was formulated and used to encapsulate and transfect various plasmids. Transfection properties were determined by the luciferase assay and RT-qPCR. Cell viability following different treatments was evaluated with MTT assay. Mechanistic studies were also carried out. **Results:** The cisplatin sensitivity of various cell lines was evaluated by MTT assay. CR-Caov3 cells were more resistant to the killing effect of cisplatin than the parental line at various concentrations after 48 or 72 hours incubation. Luciferase activity was determined after cellular transfection using pGM144 complexed by BSV163/DOPE at different charge ratios (CR 2-4) and CR4 was considered the most effective. Using CR4, we transfected both cisplatin-sensitive and -resistant ovarian cancer cells with BSV163/DOPE/pVAX2-TRAIL and verified the expression of TRAIL mRNA. The apoptosis rate in cells treated with the combinatory treatment (TRAIL transfection + cisplatin) was higher in comparison with each treatment separated. In CR-Caov3 cells, the apoptosis rate induced by the combined treatment, TRAIL transfection, or cisplatin were 40%, 20% and 10% respectively. These results demonstrated a substantial interest in using BSV163/DOPE as a gene delivery system in ovarian cancer gene therapy and encourage the use of TRAIL transgene to fight cisplatin resistance.

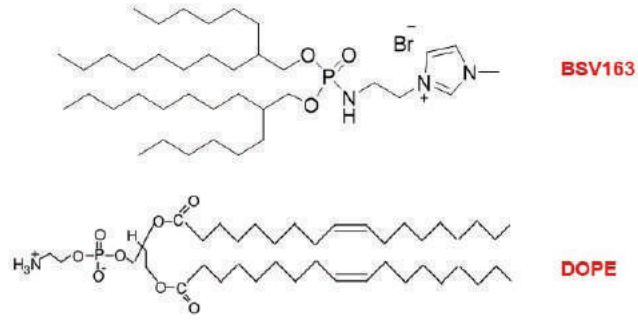


Figure 1. The structure of cationic lipid vector BSV163 and neutral helper lipid DOPE

602 An All-Prime Editing One-Step Approach for Non-Viral Generation of a Multiplex-Edited Allogeneic CAR-T Cell Product

Emily J. Pomeroy, Andrew V. Anzalone, Christopher J. Podracky, Noah B. Bloch, David P. Waterman, Reyna Chang, Arika A. Dwivedi, Kanut Laoharawee, Justin G. Tedeschi, Elizabeth R. Macari, Jennifer L. Gori, Jeremy S. Duffield

Prime Medicine, Cambridge, MA

Despite the success of CAR-T cell therapy in the treatment of a subset of hematological malignancies, the autologous nature of commercially available CAR-T products and limited clinical efficacy against solid tumors have delayed broad application of this therapy. In particular, manufacturing autologous CAR-T therapies is costly and time-consuming, and the rate of manufacturing failure is high. To overcome these limitations, targeted nucleases have been used to disrupt genes involved in alloreactivity and T cell regulation, with the goal of creating an allogeneic 'off the shelf' CAR-T cell product with enhanced function. The use of nucleases such as CRISPR-Cas9 to generate a multiplex edited allogeneic CAR-T cell product may be limited due to the risk of chromosomal rearrangements and genotoxicity that can occur when double-strand breaks (DSBs) are induced at multiple loci simultaneously. Alternatively, base editors have been used for targeted gene disruption without the induction of DSBs via single nucleotide conversion to disrupt a splice site or introduce a single premature stop (pmSTOP) codon. However, this approach is limited to transition mutations and cannot be used to integrate large genetic cargo, which is required to generate CAR-T cells. Prime Editing (PE) can be used for precise and programmable gene disruption via multiple strategies, including introduction of multiple pmSTOP codons, splice site disruption, frameshift mutations, or deletion of large segments of regulatory or coding sequence. Further, Prime-Assisted Site-Specific Integrase Gene

Editing (PASSIGE) can be used to precisely and flexibly integrate large genetic cargo at a specific locus. Together, PE-mediated gene knock out and PASSIGE can be tailored to generate a more broadly applicable, potentially safer, and more effective CAR-T cell product. To evaluate the efficacy of an all-PE non-viral approach to CAR-T cell generation, PASSIGE and PE mediated gene knockout were used to generate CD19-CAR-T cells. PE precisely knocked out the endogenous T cell receptor alpha constant (*TRAC*) locus in up to >90% of human T cells. Disruption of the endogenous TCR is required to prevent graft-versus-host disease (GvHD) in the context of an allogeneic T cell product. Co-delivery of a non-viral DNA donor template with PASSIGE editing components resulted in targeted integration of a 3.5 kb CD19-CAR transgene expression cassette at the *TRAC* locus in >60% of the T cells, with no observed impact on T cell viability, phenotype, or functionality. CD19 CAR-T cells generated using PASSIGE show potent anti-tumor activity and cytokine production in response to $CD19^+$ tumor cell lines. Further experiments demonstrated efficient multiplex PE at up to three target sites simultaneously and PASSIGE mediated integration of the CD19-CAR at the *TRAC* locus. These results show that a PE platform can be used to generate multiplex edited CAR-T cells without the need for viral vectors and without causing DSBs. This modular, one-step, nonviral delivery Prime Editing platform expands the applicability of T cell therapies for the treatment of tumors and immune diseases.

603 Safety-Switch Engineered Anti-CD117 CAR T Cells Eradicate Human Acute Myeloid Leukemia and Hematopoietic Stem Cells

Chiara F. Magnani[1], Renier Myburgh[1], Silvan Brunn[1], Morgane Chambovey[1], Marianna Ponzo[2], Laura Volta[1], Christian Pellegrino[1], Steve Pascolo[3], Csaba Miskey[4], Zoltan Ivics[4], Judith Shizuru[5], Dario Neri[6], Markus G. Manz[1]

[1]Department of Medical Oncology and Haematology Clinic, University Hospital Zurich, University of Zurich, Comprehensive Cancer Center Zurich (CCCZ), Zurich, Switzerland,[2]Tettamanti Research Center, University of Milano-Bicocca, Monza, Italy,[3]Departement of Dermatology, Universitätsspital Zurich, University of Zurich, Zurich, Switzerland,[4]Division of Medical Biotechnology, Paul-Ehrlich-Institut, Langen, Germany,[5]Division of Stem Cell Transplantation and Regenerative Medicine, Department of Pediatrics, Stanford University School of Medicine, Stanford, CA,[6]Department of Chemistry and Applied Biosciences, Institute of Pharmaceutical Sciences, ETH Zurich, Comprehensive Cancer Center Zurich (CCCZ), Zurich, Switzerland

Acute Myeloid Leukemia (AML) derives from the acquisition of mutations in hematopoietic stem and progenitor cells (HSPCs), which gives rise to a rare population of malignant leukemia-initiating cells (LIC). As AML-LICs are a source of disease relapse after treatment, their eradication is essential for the cure of AML. A main issue in the field is the sharing of cell-of-origin surface antigens between HSPCs and AML-LICs, baring the consequence of healthy HSPC depletion and subsequent severe myeloablation. Depletion of CD117+ cells can nevertheless facilitate bone marrow niche clearance and subsequent allogeneic HSC transplantation (HSCT) in absence of non-genotoxic preconditioning. However, this concept implies early termination of chimeric antigen receptor (CAR) T-cell activity to prevent subsequent graft rejection. In the current study, we therefore exploit several non-viral technologies for the generation of engineered T cells expressing anti-CD117 CAR molecules as well as safety-switches to pre-clinically test their efficacy and termination. We showed that electroporation of an IVT mRNA encoding an anti-CD117 CAR is feasible to generate functional T cells that temporarily express CD117 CAR molecules, exhibit transient cytotoxicity, and *in vivo* activity against CD117+ cells when infused in at least two high doses into mice. Alternatively, stable expression of anti-CD117 CAR and the iC9 suicide gene in T cells by using an integrating sleeping beauty (SB) vector allowed for fit CAR T-cell products associated with high proportion of T memory stem cells and low levels of exhaustion markers. SB anti-CD117 CAR T cells showed potent cytotoxic activity *in vitro* and underwent apoptosis when iC9 transgenes were activated. Anti-CD117 CAR T cells engineered with the SB vector also showed anti-leukemic activity in a human tumor xenograft model and completely depleted healthy HSPC in immunodeficient mice reconstituted with a human hematopoiesis. Our data indicate that CAR T cells have to persist two weeks for achieving complete HSPC depletion, which may also lead to durable leukemia remission. Furthermore, CAR T cells were terminated *in vivo* by combining activation of iC9 and Antithymocyte Globulin (ATG) administration, which would allow for CAR T-cell depletion before allo-HSCT. Notably, we observed no difference in activity when CAR T cells produced by a non-viral approach with the SB vector were compared with cells engineered with LV vectors. Taken together, our results indicate that non-viral engineering with SB can produce functional CAR T cells even with complex vectors that include safety switch delivery. Anti-CD117 CAR T cells can lead to potent anti-tumor activity and complete eradication of HSPCs, envisioning its application prior to allo-HSCT in early clinical trials of patients with high-risk AML or Myelodysplastic Syndrome.

604 Expanding the Scope of Multiplex Engineering for Superior Generation of Efficient CAR T-cells

Jordan Skinner[1], Emilie Dessez[2], Sandra Rozlan[2], Maria Feola[1], Diane Tkach[1], Alex Boyne[1], Piril Erler[1], Alexandre Juillerat[3], David Sourdive[2], Philippe Duchateau[2], Laurent Poirot[2], Beatriz Aranda-Orgilles[1]

[1]Cellectis Inc, New York, NY,[2]Cellectis, Paris, France,[3]Cellectis, New York, NY

CAR T-cell therapies have revolutionized the way we can treat hematological malignancies. In the meanwhile, the presence of additional physiological and biological barriers imposed by the microenvironment has limited the ability to target solid tumors. In recent years, advances in genomic-based cellular engineering are bringing us a step closer to conquer solid tumors. This glimpse of success also demonstrated that we need to be able to creatively modify and equip CAR T-cells to target these tumors. A caveat to this is that increasing the number of genetic modifications at the cellular level could compromise the level of editing efficiency as well as lead to genomic toxicities. Here, we show that we can use our state-of-the-art TALEN® technology to precisely edit up to four loci simultaneously while delivering several additional payloads to increase the efficacy and persistence of CAR T-cells. We take it a step further and use a curated combination of genome engineering technologies including

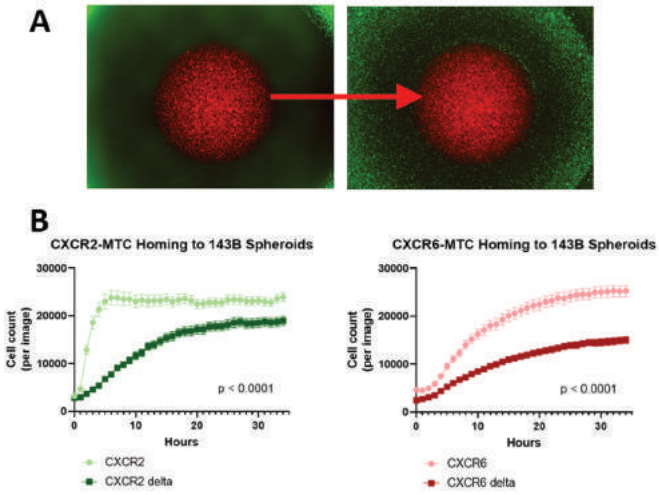
TALE base editors to increase the efficiency of multiplexed gene editing while protecting genomic integrity. By carefully choosing a range of gene and cell engineering approaches, we can develop CAR T-cells focused on unmet medical needs with a high level of efficiency for gene editing and targeted-integration. We also show that this high efficiency in TALEN®-mediated gene-edition does not lead to increased gene integrations at undesired loci. Moreover, we show that multiplexed engineering does not compromise CAR T-cell function, which in turn can be enhanced and display improved anti-tumor activity. Thus, multiplexed engineering at superior efficiency rates while preserving genomic integrity has the potential to generate highly functional CAR T-cells to advance in the fight against solid tumors.

605 Patient Based Selection of Receptors Driving Chemokine-Mediated Homing Enhances B7H3.CAR T Cell Efficacy Against Pediatric Osteosarcoma

Lindsay J. Talbot[1], Ashley Chabot[1], Aaron Ross[2], Alexandra Beckett[3], Phuong Nguyen[3], Andrew Fleming[1], Peter Chockley[3], Heather Sheppard[4], Stephen Gottschalk[3], Christopher DeRenzo[3]

[1]Surgery, St. Jude Children's Research Hospital, Memphis, TN,[2]Pediatrics, Texas Children's Hospital, Houston, TX,[3]BMTCT, St. Jude Children's Research Hospital, Memphis, TN,[4]Pathology, St. Jude Children's Research Hospital, Memphis, TN

Background: Despite significant preclinical promise, clinical efficacy of CAR T cells against osteosarcoma (OS) has been limited. One strategy to improve their efficacy may be to drive chemokine-mediated homing of CAR T cells to tumor sites. We sought to determine the primary chemokines secreted by OS and evaluate efficacy of CAR T cells expressing the cognate receptors. **Methods/Results**: We developed a patient-based pipeline to identify chemokines secreted by pediatric solid tumors. RNA-seq data for 50 known chemokines was obtained from 456 tumor samples in the CSTN network. Simultaneously, chemokine secretion was quantified in media in which surgical specimens post resection are transported at our institution (n = 8). We identified 7 chemokines produced by OS (IL8, CXCL10, CXCL12, CXCL16, RANTES, CCL18, CCL21) and assessed cognate receptors for expression on donor T cells (n = 5). CXCR2 (0.34%) and CXCR6 (3.3%), cognate receptors for IL8 and CXCL16, had minimal endogenous expression. We produced lentiviral vectors expressing CXCR2, CXCR6, or a control receptor and transduced donor T cells to assess quality and chemotaxis (n = 5). CXCR2- and CXCR6-T cells had similar phenotypes to controls. In transwell assays, CXCR2- and CXCR6-T cells exhibited dose-dependent migration towards rhIL8 ($p < 0.0001$) and rhCXCL16 ($p < 0.0001$). In a novel 3D spheroid homing assay, CXCR2- and CXCR6-T cells demonstrated improved homing towards 143B OS spheroids compared to controls ($p < 0.001$), with CXCR2-T cells having faster homing kinetics than CXCR6-T cells and controls, but similar plateau (**Fig 1**). To assess *in vivo* homing, 143B tumors were surgically implanted in the right tibia of NSG mice, and IV injected ffluc-(+) CXCR-T cells were tracked by bioluminescence. CXCR6-T cells exhibited enhanced homing to tumors compared to CXCR2-T cells and controls ($p < 0.0001$, n = 5/group). We next evaluated chemotactic and antitumor activity of CXCR2- and CXCR6.B7-H3.CAR T cells. CXCR2 or CXCR6 expression in B7-H3.CAR T cells did not change their phenotype, but increased IFNγ production (n = 6; $p < 0.01$) in 143B coculture assays with no effect on IL2 production. Homing of CXCR.B7-H3.CAR T cells in 3D spheroid assays mirrored that seen with CXCR-T cells, which was enhanced compared to B7-H3.CAR T cells (n = 5, $p < 0.001$). CXCR2.B7-H3.CAR T cells also demonstrated faster killing in 3D spheroid culture compared to CXCR6.B7-H3.CAR and B7-H3.CAR T cells ($p < 0.001$). *In vivo,* CXCR2- and CXCR6.B7-H3.CAR T cells demonstrated earlier tumor-specific homing and expansion (n = 5/group; $p < 0.05$ at days 9, 10, 17 - 27) with less non-specific expansion compared to B7-H3.CAR T cells. Finally, 143B tumor-bearing mice injected IV with CXCR2- or CXCR6.B7-H3.CAR T cells survived longer than mice treated with B7-H3.CAR T cells (n = 5-10/group; $p < 0.001$). **Conclusions**: Patient-based determination of chemokines secreted by pediatric OS identifies robust targets for chemokine receptor modification of CAR T cells. CXCR2 and CXCR6 both enhance homing of B7-H3.CAR T cells, with improved antitumor activity and evidence of reduced non-specific expansion *in vivo*. Optimization of these receptors with additional CARs active in OS is warranted.



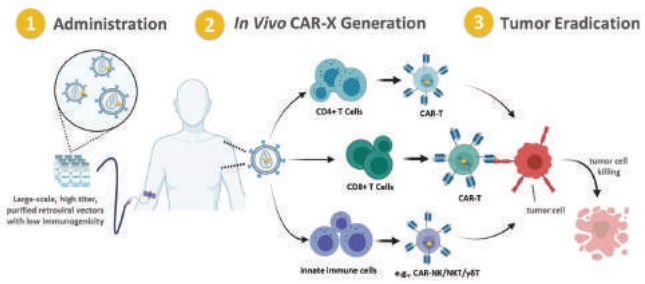
606 *In Vivo* Genetic Medicine Designed to Simultaneously Engineer Innate and Adaptive Immune Cells to Express Chimeric Antigen Receptors and Generate Durable, Anti-Cancer Immune Responses

Traci Ostertag[1], Carlos Ibañez[1], Nicholas A. Boyle[1], Douglas J. Jolly[2], Derek Ostertag[1]

[1]AbintusBio, San Diego, CA,[2]Abintus Bio Inc., San Diego, CA

The gene therapy field has advanced tremendously since the first gene therapy patient was functionally cured in 1990 with a T cell therapy modified with a gammaretroviral vector (gRV). The safety and tolerability of gRV is supported by clinical trials involving direct in vivo administration in over 600 patients and in trials involving ex vivo use in 1,000's of patients without a single incident of integration-related toxicity spanning more than 2 decades. These advances include the market-leading CAR-T product, axicabtagene ciloleucel, which is made using gRV vectors to achieve stable CAR expression. Despite durable clinical efficacy in about 40% of patients with relapsed or refractory

lymphoma, issues related to safety and costs have hampered patient access in the community setting where most lymphoma patients are treated. Meanwhile, in vivo engineering of circulating immune cells was seen in several clinical trials involving intravenous administration of gRV manufactured with high titer, high purity, and low immunogenicity at commercial GMP scale and at a comparatively low cost. Preferential gene delivery to circulating immune cells was attributed to a short half-life and requirement for dividing cells. Building on these advances we are developing an in vivo CAR product candidate, ABIN-19, which simultaneously engineers innate and adaptive immune cells and may overcome the challenges with autologous and allogeneic ex vivo cell therapies (see figure below).



We report on the preclinical development of ABIN-19, which is designed to engineer circulating innate and adaptive immune cell subsets to express CAR. High titer, high purity gRV encoding a CD19-CAR was intravenously delivered to CD19+ syngeneic lymphoma or humanized-NSG rodent models. In the syngeneic models, after intravenous delivery of vector encoding CD19 CAR, we saw simultaneous engineering of circulating innate and adaptive immune cells including natural killer (NK) cells, alpha/beta T cells (primarily effector and central memory subsets), monocytes, and natural killer T cells. Corresponding with antitumor effects, NK cells showed markers of activation including upregulation of CD69 and KLRG1. Further, alpha/beta T cells upregulated CD25, an activation marker, and expansion of central memory subsets was observed. Corresponding with T cell activation was emigration of innate and adaptive immune cells out of the periphery to sites of lymphoma. In non-tumor bearing humanized NSG models, injection of vector encoding CD19 CAR resulted in T cell activation and subsequent CD19+ B cell aplasia, a phenomenon also reported in ex vivo CAR T models. In vivo CAR products, such as ABIN-19, that engineer innate and adaptive immune cells in situ, have the potential to achieve a differentiated efficacy and safety profile and warrant clinical investigation.

607 Innovative 4th Generation Lentiviral Vectors to Enable *In Vivo* CAR T-cell Generation

Tiziana Coradin[1], Alun Barnard[1], Amy Keating[1], Anurag Kulkarni[1], John O'Driscoll[1], Lynsey Whilding[1], Diana Pombal[1], Elisa Monzon-Casanova[1], Zara Hannoun[2], Jack Lewis[1], Oliver Pearson[1], Robert Powles[2], Mathew Veal[1], Daniel Beck[1], Deirdre O'Connor[1], Sara Ferluga[1], Ben Alberts[1], Jordan Wright[1], Dan C. Farley[1], Andre Raposo[1], Kyri Mitrophanous[1], Nicholas Clarkson[1], Rachael A. Nimmo[1], Yatish Lad[1]

[1]Oxford Biomedica, Oxford, United Kingdom,[2]Oxford Biomedica (UK) Limited, Oxford, United Kingdom

CAR T-cell therapy is an important and exciting treatment modality with several approved products. While significant clinical benefit has been observed in patients there are several challenges with autologous *ex vivo* CAR T therapies: cell processing is complex, can take time and is expensive. Furthermore, the limited availability of appropriate GMP manufacturing facilities and clinical sites, restricts both the number of patients that can be treated and the geographical locations in which treatment can be offered. In addition, CAR T-cell fitness is impacted during manufacture which can impair clinical success. Generation of CAR T-cells within the patient themselves (*in vivo*) would bypass the need for *ex vivo* cell manufacture leading to substantial cost reduction, avoid cell manufacturing failures and delays and therefore treatment would be more widely accessible. Here, we present findings on several technical developments and innovations in our lentiviral vector platform that have the potential to improve the safety and efficiency of *in vivo* CAR T-cell generation. Firstly, we utilise a transgene repression system in the producer cell which prevents CAR incorporation into the vector particle which therefore avoids the unwanted transduction of tumour cells, which would otherwise lead to masking of the antigen and loss of tumour control. In addition, this approach could reduce possible immune reactions either to CAR on viral particles or on transduced cells. During *ex vivo* CAR T-cell generation, viral envelope proteins with a broad cellular tropism, such as VSVG, are routinely used. However, the safety and efficacy of *in vivo* CAR therapy will require a toolkit of vectors that target specific immune cell subsets. We therefore investigated modifications to viral envelope proteins that would alter the cellular tropism and re-target vectors to specifically transduce T-cells. We have demonstrated *in vitro* that molecular retargeting of lentiviral vectors can drive highly selective transduction of T cells and generate functional CAR T-cells. Finally, we combined several of these innovations and tested systemic injection of CAR lentiviral vectors in mice with a humanised immune system. We show the vectors are well tolerated, drive the generation and expansion of CAR immune cells in the blood, and can also lead to the expected B cell aplasia. In conclusion, *in vivo* generation of CAR cells by the systemic injection of a lentiviral vector has the potential to dramatically widen the availability and accessibility of treatment. We report a number of technical developments and innovations that address key challenges to developing a safe and effective *in vivo* CAR cell therapy which, together with Oxford Biomedica's ability to produce high quantities and high quality of commercial grade vector, will form the basis for new *in vivo* CAR-T products with which to treat patients for oncology and autoimmune indications.

608 RESET: A Novel TCR Coupled Antigen Receptor Displaying Superior Targeting Sensitivity and Pharmacologically Controlled Anti-Tumor Activity

Jardin A. Leleux, Olmo Sonzogni, Jill Rosenberg, Jack McGinty, Anita Venkitaraman, Jordan Jarjour
2seventy bio, Cambridge, MA

Chimeric antigen receptor (CAR) T cells are effective therapies for hematological malignancies, where target antigens are exclusively yet robustly expressed on the tumor and cells with low toxicity risks (e.g., B cells). For other tumors, available target antigens often lack ideal expression, necessitating improvements in targeting sensitivity, potency, control, and/or exhaustion mitigation to achieve robust anti-tumor efficacy. Endogenous T cell receptor (TCR) activation is acutely sensitive to low target abundance and naturally propagates effector and long-term memory functions, suggesting that mimicking TCR activation may provide a solution. Here, we describe a novel receptor architecture called RESET (rapamycin-enabled, switchable endogenous TCR) that combines: (i) the antibody-based targeting of CARs; (ii) the drug-regulated activity of the DARIC technology (a "drug on" CAR T system); and (iii) the natural signaling proficiency and inherent sensitivity of TCRs. The RESET receptor comprises two functional units that enable toggling of RESET T cells between inert and activated states through rapamycin-induced dimerization. Specifically, RESET appends the FKBP-rapamycin binding protein (FRB) to CD3ε, which naturally integrates into the endogenous TCR-CD3 complex. A second unit is expressed on the T cell surface that includes a tumor targeting antibody linked to FK506-binding protein (FKBP). Dimerization of FRB and FKBP occurs with the addition of rapamycin, linking tumor targeting to the endogenous TCR and driving T cell activation in an antigen-dependent and rapamycin-regulated manner. Complete dependence of RESET function on TCR integration was confirmed by transducing RESET into T cells edited to eliminate TCRα expression. Surface trafficking of the FRB-CD3e polypeptide was lost in the absence of the TCR, concomitantly ablating RESET T cell function.Next, we explored the antigen-dependent behavior of RESET T cells. Despite requiring rapamycin for full activation, standard and drug-regulated CAR T cells can display tonic signaling (e.g., cytokine release) that prevents them from achieving a fully inert state when rapamycin and/or antigen are absent. In contrast, TCR coupled RESET T cells do not induce tonic signaling, indicating that the "off" state of this architecture is more complete. CD33-targeted RESET T cells (RESET33) are also more potently reactive to CD33+ tumor cells after rapamycin dimerization *in vitro*, secreting ~3x more cytokine than CD33-targeted regulated CAR T cells when challenged with low antigen density tumor cells. This enhancement was also observed in preclinical NSG mouse models *in vivo*, where RESET33 T cells more deeply controlled systemic CD33+ AML tumor models, providing a significant survival benefit in comparison to DARIC33 T cells. Our data suggest that RESET T cells outperform standard drug-regulated, second-generation CAR T cells and show hallmarks of TCR activation that suggest targeting fidelity comparable to native T cell responses. Pharmacological control serves to broaden the scope of targetable antigens and may mitigate T cell exhaustion caused by continuous antigen exposure. The convergence of drug regulated antigen targeting and natural immune receptor signaling may better replicate the kinetics and physiology of T cell responses, resulting in more successful immunotherapies. Taken together, these data support the clinical evaluation of RESET in a target indication such as AML, where "drug-on" targeting with TCR signaling sensitivity may enable more robust anti-tumor activity, while the more complete "drug-off" state allows for myeloid reconstitution and provides relief from T cell exhaustion.

609 Cell and Molecular Optimization Overcome Barriers to Enable CRISPRa-Driven Genome-Wide Gain-of-Function Screens in Primary CAR T Cells

Benjamin Curtis[1], Cailyn Spurrell[1], Tiffanie Chai[1], Natalie Murren[1], Lindsay Flint[1], Aalton Lande[1], Marissa Leonardi[1], Michael C. Jensen[2]
[1]Seattle Children's Therapeutics, Seattle Children's Research Institute, Seattle, WA,[2]Seattle Children's Research Institute, Seattle, WA

Chimeric Antigen Receptor (CAR) T cell therapy has revolutionized the treatment of B cell malignancies and translating this success to other cancers remains an ongoing clinical objective. Next-generation T cell products in development today aim to genetically modulate many facets of cell behavior, and gene-nominating platforms have provided a useful framework for prioritization. Among competing screening approaches, CRISPR activation (CRISPRa) technology permits gain-of-function (GoF) gene surveys at genome-wide scale, but routine implementation in primary T cells has been stymied by high cell requirements (~10^8) and poor dCas9 expression. Here, we describe a novel cell manufacturing schema using an all-in-one transposon-based gene delivery system coupled with CAR-restricted cell expansion to generate yields of primary T cells bearing CAR and CRISPRa transgenes, well above the threshold needed for genome-scale screening. Long-term GoF potency is achieved via vector optimization to prevent CRISPRa gene silencing (>90%$^+$); library representation is preserved by delaying guide RNA transfer until late in primary manufacturing, thus preventing bottlenecking and premature candidate pruning. CRISPRa-CAR T cells manufactured via this pipeline retain potent on-target gene-overexpression (>85% target$^+$) across varied cell subsets (e.g. Tim-3$^+$/Lag3$^+$) and timescales (>14 days). When deployed to survival-based genome-wide selection landscapes, CRISPRa-CAR pools can successfully nominate endogenous genes capable of enhancing both CAR T persistence and cytokine-free survival. This system will have broad utility for therapy-enhancing gene discovery.

610 Effective Targeting of Gastric Cancer Peritoneal Metastases with Cytokine-Endowed TAG72-Directed CAR T Cells

Isabel Monroy[1], Anthony K. Park[2], Annie Yang[1], Yuwei Ren[1], John Murad[1], Stephen J. Forman[1], Saul Priceman[1], Yanghee Woo[3], Eric H. G. Lee[4]
[1]City of Hope, Duarte, CA,[2]City of Hope, CA,[3]City of Hope Medical Center, Duarte, CA,[4]Georgia Institute of Technology, Atlanta, GA

Gastric cancer (GC) with peritoneal metastases (PM) is fatal within 8 months of diagnosis. Molecular heterogeneity of GC and poor immunogenicity of peritoneal immune tumor microenvironment

(TME) limit the benefits of existing immunotherapeutic strategies that include trastuzumab (anti-HER2), ramucirumab (anti-VEGF), pembrolizumab, and nivolumab (anti-PD-1). To address the immunosuppressive and immunologically "cold" nature of the peritoneal TME, we investigated a novel chimeric antigen tumor-associated glycoprotein 72 (TAG72) and interleukin-12 (IL-12) combination in GCPM. From 28 patients, surgically resected primary gastric tumors identified to have positive TAG72 expression in >90% of the specimens stained with anti-TAG72 antibody. Encouragingly, 45% showed "strong" TAG72 expression supporting TAG72-CAR T cells as an attractive therapeutic target in GC. A TAG72-CAR T cell (currently in a phase 1 trial for patients with ovarian cancer) cocultured with malignant ascites obtained from GC patients with PM effectively target TAG72+ peritoneal GC cells. We further studied this phenomenon using SNU-16, a human gastric cancer cell-line derived from ascites with strong TAG72 expression. With this model, we show that TAG72-CAR T cells can effectively and consistently target SNU-16 leading to reduced tumor burden and prolonged survival in NSG mice. Additionally, our newly engineered TAG72-CAR T cells with a membrane-bound version of the IL-12 (mbIL12) cytokine significantly enhanced anti-tumor efficacy of TAG72-CAR T cells leading to more durable *in vivo* therapeutic responses. A novel immunotherapeutic combination using autologous mbIL12-engineered TAG72-CAR T cell therapy is a promising strategy to help overcome the therapeutic failures in GCPM patients.

611 Identifying Anti-Tumor Lymphocytes by Immune Fingerprinting Solid Tumors

Goran Marinkovic, Ilse Wolters, Irene Chan, Ellen van den Munckhof, Wilco Knetsch, Maurits de Koning, Dirk van Alewijk

Viroclinics-DDL, a Cebra Research Company, Rijskwijk, Netherlands

Background: Tumor infiltrating lymphocytes (TILs) are all lymphocytic $CD3^+$ cells that have interacted with and invaded the tumor tissue. These cells might display a cytotoxic antitumor activity and therefore be crucial for promoting anti-tumor response or on the other hand dampened it. Regardless of the roll they play, overall assessment of TILs profile and immune status of the tumor microenvironment has its practical value when assessing tumor mutational burden, effectiveness anti-tumor therapy or when designing and monitor T-cell based therapy. Large numbers of formalin-fixed paraffin embedded tumor tissues Worldwide are valuable source of material for TILs analysis. However, time during which tissue was fixed and stored in this way has a detrimental effect on the quality of the obtained RNA material and it is a limiting factor in obtaining TILs repertoire. **Methods:** We performed an immune repertoire profiling analysis of four different solid tumor types, namely: ovary, colon, lung, and breast, all being formalin fixed, paraffin embedded and stored for different periods of time (ranging from 15 months up to 8 years). All samples were stored at room temperature. In brief, histological tumor samples were examined for the presence of T cell. Following, consecutive sections of 10um in diameter were made and RNA was isolated. Assessment of the RNA quality was determined based on DV200 parameter. Following, the presence of T cell RNA material was determined by quantifying the expression of CD247. To assess immune status of the tumor, we performed whole-tissue RNA sequencing. **Results:** Pathological tissue assessment in these four tumors was varying between 20 and 100%, having the smallest portion in the breast carcinoma and largest in the ovary adenocarcinoma. No fibrosis and no necrosis were noticed in any of the samples. T-cell infiltrations were approximately occupying from 3% to 15% of the tumor tissue. Isolated RNA material was of the sufficient quality for the immune repertoire profiling as the DV200 value in all sample was higher than 50%. TCR repertoire profile was successfully obtained from ovary and colon adenocarcinoma. Clonal analysis was performed utilizing TCR beta reads and particular clones were determined using sequence of the CDR3 domain. Prolonged storage increased singletons and unmapped reads. Furthermore, RNA sequencing was successfully performed in all tumor samples regardless of the storing time providing a full immune profile of the tumor microenvironment. **Conclusion:** Our results indicate that duration of the storage significantly affect robustness of the obtained TILs repertoires.

612 A Novel TGFβ Switch Receptor Drives Robust MAGE-A4 TCR Anti-Tumor Activity with a Favorable Safety Profile

Esteban Carrizosa, Margherita Norelli, Sonia Das Yekkirala, Martina Canestraro, Benjamin Boyerinas, Roy Dornbrook, Andreya Gatling, Adrianna Graziano, Thomas Haas, Ryan Hannon, Abigail Hanson, Collin Walter, Jingyu Peng, Jordan Jarjour

2seventy bio, Cambridge, MA

Adoptive T cell therapies have transformed clinical practice in advanced B cell cancers but have yet to achieve similar responses in other hematological or solid tumors. Two dominant factors limit robust efficacy in these settings: the rarity of antigens with tumor specific, high density, homogenous expression; and the immunosuppressive milieu within solid tumors. Thus, we sought to develop a T cell therapy targeted to a tumor antigen with demonstrated clinical efficacy and safety and further layered with technology that not only mitigates but exploits immunosuppression to enhance anti-tumor responses. MAGE-A4 is a cancer/testis antigen with robust intracellular expression in several solid tumors yet is undetectable in healthy tissues. Here we describe a TCR targeting an HLA-A*02:01 presented MAGE-A4 peptide engineered to achieve obligate TCR α-chain and β-chain heterodimerization, improving transgenic MAGE-A4 TCR expression and minimizing mispairing with endogenous TCR chains. In vitro safety studies confirmed the specificity of this TCR, revealing a limited set of off-target peptides which were derisked in overexpression studies, and no reactivity to a panel of normal cells. Solid tumors frequently secrete TGFβ, a pleiotropic cytokine that suppresses T cell responses. Pharmacological inhibition of TGFβ is challenging due to the existence of multiple isoforms with distinct functions, toxicity due to TGFβ function in healthy tissues, and the complexities of inactive TGFβ secretion and activation. Instead, we aimed to counteract the immunosuppressive effects of TGFβ within engineered T cells. We developed a two-component, bifunctional chimeric TGFβ-IL12 switch receptor (CTBR12) whose polypeptides: (i) pair with the endogenous TGFβ receptor chains and, upon TGFβ binding, block downstream suppressive signaling in a dominant negative manner; and (ii) when paired together, convert TGFβ binding into pro-inflammatory signaling events that enhance anti-tumor function. T cells transduced with a

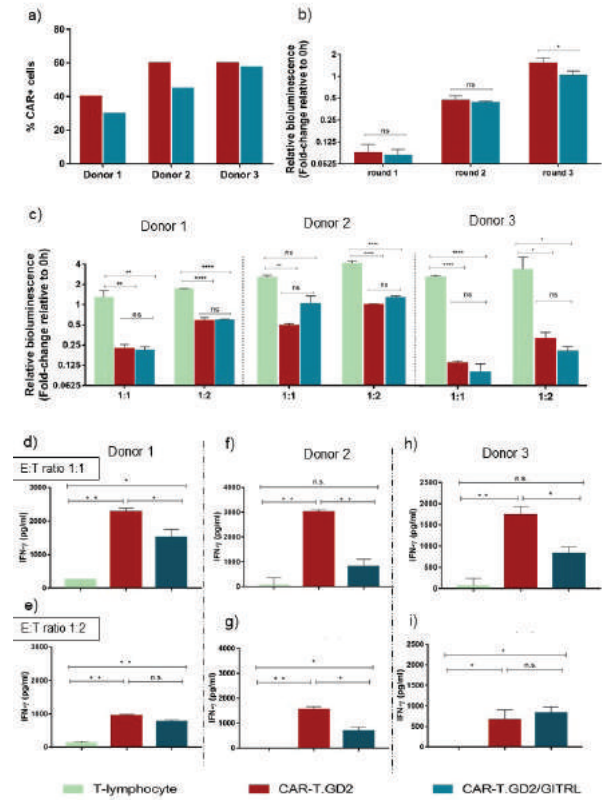
multi-cistronic lentiviral vector co-expressing the pairing-enhanced MAGE-A4 TCR and CTBR12 demonstrated robust antigen-dependent responses that were significantly enhanced upon exposure to TGFβ, whereas MAGE-A4 TCR controls lacking CTBR12 were substantially suppressed. We observed biochemical signatures and functional hallmarks of concurrent TGFβ receptor inactivation and IL12 receptor pathway activation, which were also fully dependent on the presence of TGFβ. CTBR12 co-expression did not alter the safety profile of the MAGE-A4 TCR. In two murine xenograft tumor models with abundant TGFβ, T cells co-expressing the MAGE-A4 TCR and CTBR12 both controlled tumors at T cell doses that elicited only minimal responses without CTBR12 co-expression and exhibited superior durability of response overall. Pharmacokinetic analysis demonstrated 1.5-2-fold enhanced peak T cell expansion in the MAGE-A4 + CTBR12 cohort relative to MAGE-A4 TCR alone, and importantly both cohorts showed similar longitudinal contraction of T cells, demonstrating that the physiological regulation of T cell dynamics is not grossly disturbed by CTBR12. Taken together, the combination of a highly active TCR with a strong specificity profile and a synthetic receptor that leverages an immunosuppressive cytokine to deliver a pro-inflammatory signal has the potential to safely enhance T cell potency in otherwise intractable solid tumors. Our data support an upcoming clinical trial to evaluate the safety and efficacy of autologous T cells co-expressing the pairing enhanced MAGE-A4 TCR with CTBR12 in solid tumors.

613 A New Anti GD2 CAR T Cell Construction Containing GITRL Coestimulatory Molecule Combines Persistent Lysing Capacity and IFNy Secretion Against Glioblastoma Cells

Izadora Peter Furtado[1], Heloisa Brand[2], Roberta Silveira[1], Rafaela Rossetti[1], Daianne Fantacini[2], Lev Tsyrenov[3], Hiroshi Shiku[4], Lucas Eduardo Souza[1], Dimas Tadeu Covas[5]

[1]Center for Cell-Based Therapy, University of Sao Paulo, Ribeirão Preto, Brazil,[2]Butantan Institute, Ribeirão Preto, Brazil,[3]Mie University, Tsu, Japan,[4]Mie University, Tsu, Mie, Japan,[5]Center for Cell-Based Therapy, University of Sao Paulo; Butantan Institute, Ribeirão Preto, Brazil

The adoptive transfer of T cells expressing chimeric antigen receptors (CAR) has resulted in the complete B-cell malignancies remission rates. However, the therapeutic efficacy of CAR-T cells is still low or non-existent against solid tumors, which constitute the vast majority of neoplasms. One of the main reasons for this failure is the presence of ligands and immunosuppressive cells in the tumor microenvironment. Also, full activation of T cells requires the engagement of costimulatory molecules whose expression is temporally segregated and whose nature of biochemical signals are complementary. This is the case of CD28, expressed constitutively, and GITR, expressed right after the initial activation of T cells. Therefore, our hypothesis is that the combined expression of a CAR containing the costimulatory domain CD28 and the GITR ligand (GITRL) will potentiate the antineoplastic action of CAR-T cells and suppress the action of regulatory T cells in the tumor microenvironment, thus possibly reducing local immunosuppression. Then, the aim of this study was to evaluate in vitro the therapeutic efficiency of anti-GD2 CAR-T cells coexpressing GITRL using as a model a CAR against the ganglioside GD2, which is highly immunogenic and expressed in glioblastoma. To test our hypothesis, we generated two lentiviral vectors to express CAR anti-GD2 (CAR.GD2) and another one coexpressing CAR anti-GD2 and GITRL (CAR.GD2/GITRL). Next, we used these lentiviral particles to transduce human T cells isolated from PBMC samples of three different donors, and we achieved CAR positive cells frequency in 40-60% of the cells transduced with CAR.GD2 vector and 30-58% for CAR.GD2/GITRL vector. To verify the functional activity of these CAR-T cells, we performed a coculture against luciferase-expressing GD2+ T98G glioblastoma cells and GD2- HCT-166 colon carcinoma cells. We tested two effector:target ratios (E:T). After coculture, we observed a potent cytotoxic activity for both CAR vectors, with around 90% of T98G cell lysis, while sparing HCT-116 cancer cells, demonstrating GD2-restricted cytotoxic activity. After that, we asked whether these CAR-T cells could keep their lysis capacity after additional rechallenges of coculture. Indeed, the cytotoxic effect was persistent after two additional coculture rounds and the CAR-T.GD2/GITRL was able to retract the tumor cell proliferation during the third round better than CAR.GD2 cells. Additionally, we detected high levels of IFNy in the coculture supernantants samples of both CAR-T cells demonstrating that tumor cell killing was associated with secretion of IFNy. Therefore, the potential results of this project will foster the development of a new advanced cellular immunotherapy strategy for the treatment of solid GD2+ neoplasms. Figure subtitle: a) CAR+ cells frequency between T cells of three donors transduced with vectors CAR.GD2 and CAR.GD2/GITRL; b) three rounds of coculture to demonstrate the persistent lysis capacity; c) coculture assay to evaluate the cytotoxic effect against glioblastoma cells in two E:T ratios; d-i) IFNy secretion in coculture supernantants.



614 Antigen Binding Domain Influences CD47-CAR T Cell Function in Both Constitutively Active and Inducible Systems

Alexandra Beckett[1,2], Stephen Gottschalk[1], Chris DeRenzo[1]

[1]Bone Marrow Transplantation and Cellular Therapy, St. Jude Children's Research Hospital, Memphis, TN,[2]St. Jude Graduate School of Biomedical Sciences, Memphis, TN

Chimeric antigen receptor (CAR) T cell therapy has shown considerable success against hematological malignancies but has yet to exhibit the same success against solid tumors. Several roadblocks must be overcome to yield successful CAR T cell therapies for solid tumors, including limited T cell persistence, the immunosuppressive tumor microenvironment (TME), and tumor heterogeneity/antigen escape. One way to target solid tumors and potentially overcome some immune suppression within the TME is by targeting CD47. CD47 is a 'macrophage don't eat me' signal that is highly expressed by multiple solid tumors to evade immune-mediated elimination. As CD47 is expressed at lower levels on normal tissues, inducible CD47-CAR T cells activated only within the TME may achieve antitumor activity with limited 'on-target, off-cancer' toxicity. We previously demonstrated that high-affinity SIRPα receptor variant based CD47-CAR (CV1-CAR) T cells downregulate CD47 on their cell surface to evade fratricide and enable antitumor activity in vitro. However, loss of surface CD47 prevents CAR T cell persistence in vivo due to macrophage-mediated elimination. Here we sought to 1) evaluate an scFv based CD47-CAR T cell product with a lower affinity antigen-binding domain (B6H12) and 2) generate inducible CD47-CAR T cells for functional characterization. As CV1 has a high affinity for CD47 (K_D ~11pM), we developed a second CD47-CAR based on the B6H12 ScFv (K_D ~5.27nM). Similar to CV1-CAR T cells, B6H12-CAR T cells downregulate CD47 surface expression and eliminate non-transduced T cells post-transduction resulting in a ~100% B6H12-CAR positive population. We previously found robust expansion of CV1-CAR T cells preceded by an initial lag in expansion post transduction, however B6H12-CAR T cells had significantly impaired expansion that did not recover at any time post transduction. Despite limited expansion, B6H12-CAR T cells exert antitumor activity in vitro and, consistent with CV1-CAR T cells, lack antitumor activity in vivo likely due to macrophage mediated elimination. Given that multiple constitutively active CD47-CAR T cell products downregulate CD47 and fail to function in vivo, we generated CD47-CARs under control of a doxycycline inducible (Tet-On) promoter that constitutively express ZsGreen (ZsG) as a detection marker (indB6H12- and indCV1-CAR). In the absence of doxycycline, indB6H12- and indCV1-CAR CAR T cells have no impaired expansion. Upon treatment with doxycycline ind.B6H12-CAR T cells had high CAR expression, decreased surface CD47 expression, and are capable of killing CD47 positive targets in vitro. Interestingly, when indCV1-CAR T cells were treated with doxycycline, no CAR was detected on the cell surface despite expressing ZsG, which confirms successful transduction. This suggested the indCV1-CAR may be expressed, albeit sequestered within T cells by binding intracellular CD47. We therefore asked if indCV1-CARs are expressed in CD47 negative cells (OV10). Indeed, upon treatment with doxycycline the indCV1-CAR was expressed on the surface of OV10 cells. Overall, these results demonstrate the CAR binding domain influences CD47-CAR T cell functional characteristics in both constitutive and inducible systems. While studies are ongoing, we demonstrate that 1) similar to CV1-CAR T cells, B6H12-CAR T cells downregulate CD47 surface expression and lack antitumor activity in vivo and 2) CD47-CAR binding domain determines CAR surface expression upon activation in an inducible system. We speculate that CAR affinity or binding site on CD47 is responsible for differing CD47-CAR T cell functional phenotypes and studies are underway to elucidate mechanisms of these findings.

615 Dissecting Gene Networks in LV-Targeted Phagocytic Cell Populations

Chiara Bresesti[1,2], Thomas Kerzel[1], Marco Notaro[1,2], Giovanna Giacca[1,2], Ivan Merelli[1], Stefano Beretta[1], Luigi M. Naldini[1,2], Mario Leonardo Squadrito[1,2]

[1]SR-TIGET, Milan, Italy,[2]Università Vita-Salute San Raffaele, Milan, Italy

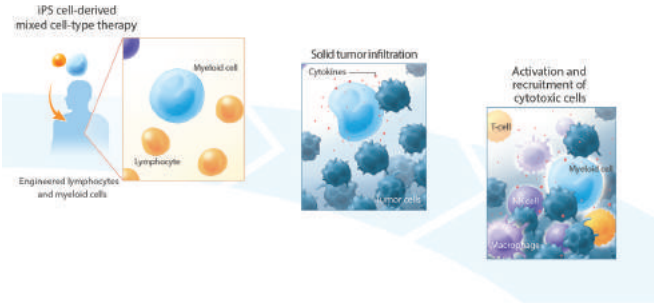
Viral vectors are versatile and efficient tools for genetic engineering of eukaryotic cells. Among these, VSV-G-pseudotyped lentiviral vectors (LVs) have been extensively investigated for their capacity to stably transduce non-proliferating cells. Upon intravenous injection in non-human primates and mice, LVs efficiently transduce numerous cell populations in the liver and to a lesser extent in the spleen. Thus, LVs can be efficiently employed to drive transgene expression in well-defined hepatic or splenic cell populations. Albeit *in vivo* LV-transduced cell populations and the transcriptional networks active in said cell types have been described, an in-depth molecular characterization is only partially known. Understanding LV biodistribution and dissecting the molecular circuits that govern the genetic functions of LV-transduced cells, may be of key relevance to exploit systemically delivered LVs in distinct pathological conditions. We delivered GFP-encoding LVs to adult mice through tail vein injection and observed transgene expression by flow cytometric and immunofluorescence analyses. We identified several distinct splenic and hepatic cell populations that were transduced by LVs. The genetic programs of these cells in healthy tissue and in the presence of liver metastases were characterized by employing total and small RNA sequencing analyses. We identified key microRNAs (miRNAs) that may regulate important biological functions in liver resident macrophages, Kupffer cells. By measuring miRNA activity at single cell level, we found that miR-342-3p was downregulated in Kupffer cells in the presence of liver metastases, suggesting an anti-tumor function of this miRNA. Building on this observation, we enforced miR-342-3p expression in Kupffer cells in mice bearing liver metastases by employing systemically delivered LVs. We found delayed liver metastasis growth and immune activation, suggesting that restoring miR-342-3p expression level may reprogram Kupffer cell functions from protumoral to antitumoral. Moreover, we identified putative miRNA targets that may fine tune KC phenotype. Overall, our work provides insights on the populations targeted by systemic LV biodistribution and identifies active gene networks, which may be of interest for improving in vivo gene engineering approaches, e.g. by selecting promoters or miRNA target sequences to specifically drive gene expression in desired cell populations. Furthermore, we identified an antitumoral function of miR-342-3p in Kupffer cells in the presence of liver metastases.

616 A Scalable, iPS Cell Derived Lymphocyte and Myeloid Multi-Cell-Type Therapeutic Platform for Enhanced Tumor Cell Killing

Abigail J. Blatchford, Mackenzie Parmenter, Ian Hay, Christopher B. Rohde, Matthew Angel

Factor Bioscience Inc., Cambridge, MA

Induced pluripotent stem (iPS) cell therapies have the potential to treat a wide variety of devastating diseases. iPS cell-derived lymphocytes (e.g., T cells and NK cells) engineered to express targeting molecules such as chimeric antigen receptors (CARs) have shown clinical promise to treat hematological malignancies. More recently, iPS cell-derived myeloid cells are being developed to treat both hematological malignancies and solid tumors due to the ability of these cells to infiltrate and modulate the tumor microenvironment. Despite preliminary success, several challenges still remain, including poor infiltration of cytotoxic lymphocytes into solid tumors and insufficient cytotoxicity of myeloid cells. We hypothesized that a multi-cell-type therapy comprising both lymphocyte and myeloid cells may work synergistically, enhancing cytotoxicity and efficacy. We previously demonstrated the directed differentiation of mRNA reprogrammed iPS cells into functional cytotoxic lymphocytes and monocyte-derived M1 and M2 polarized macrophages. Here we describe a scalable bioreactor-based process for parallel differentiation of mRNA reprogrammed iPS cells into both CD14+ (>95% positive) macrophages and $CD56^{bright}/CD16^{dim}$ NK cells. This process yields 1x10^6 myeloid cells/mL and 3x10^5 lymphoid cells/mL, and is amenable to scaling to clinically relevant doses. In vitro, the lymphoid and myeloid cells showed synergistic tumor cell killing of SKOV3 ovarian cancer cells (combined: 15.6%; macrophage alone = 2.2% ($p<0.01$); NK alone = 7.5% ($p<0.05$); E:T = 5:1). The combined cells showed increased expression of TNF-α, and demonstrated enhanced clustering and tumor cell engagement. To further improve the macrophages' ability to target and infiltrate solid tumors, we transfected macrophages with mRNA encoding a humanized ROR1-CAR protein. mRNA transfection increased cytotoxicity towards SKOV3 cells by 6-fold. Here we describe a scalable platform for generating iPS cell-derived multi-cell-type therapies comprising both lymphoid and myeloid cells. We demonstrate that, much like the natural cellular immune response, these cells act synergistically to kill tumor cells in vitro. By more closely mimicking natural cellular immunity, multi-cell-type cell therapies represent a new class of cell therapies that may play an important role in the development of new medicines to treat cancer.



617 RNA-Based Therapy for Solitary Fibrous Tumors

Yi Li[1], John Tran Nguyen[2], Clark Meyer[3], Heather Hayenga[1], Leonidas Bleris[3]

[1]University of Texas at Dallas, Richardson, TX,[2]The University of Texas at Dallas, Plano, TX,[3]UT Dallas, Dallas, TX

Solitary fibrous tumors (SFT) are rare, soft tissue tumors of mesenchymal origin that account for less than 2% of all soft tissue sarcomas. In the latest WHO classification published in April 2020, SFTs are subdivided into three categories: benign (locally aggressive), NOS (rarely metastasizing), and malignant. These tumors traditionally present unique diagnostic challenges because of the common gross and histologic features they express. A breakthrough in their characterization occurred in 2013, when all SFTs were found to exhibit a genetic fusion between NAB2 and STAT6 on chromosome 12. Despite advances in the classification and understanding of the molecular mechanisms of SFTs, no systemic therapeutic options are yet available. CRISPR (Clustered Regularly Interspaced Palindromic Repeats) technology has revolutionized the field of genetic engineering. Various CRISPR-mediated DNA editing technologies, such as the type II CRISPR/spCas9 and type V CRISPR-Cas12 (Cpf1) systems, have been extensively studied and already administered to patients during clinical trials. In parallel, efforts were also made to discover and establish diverse RNA-manipulating Cas effectors. More recently, the Type VI CRISPR/RfxCas13d (CasRx) system, which is derived from *Ruminococcus flavefaciens* XPD3002 and possesses dual RNase activities, was found to efficiently process target RNAs in mammalian cells with fewer non-specific targeting effects than other RNA-editing technologies, such as shRNAs (short hairpin RNA). All NAB2-STAT6 fusion types in SFTs create unique fusion RNA transcripts which are distinct from wild type NAB2 or STAT6 transcripts. In this study, we investigate CasRx-based RNA targeting technologies for the suppression of NAB2-STAT6 fusion transcript expression levels. We hypothesize this will exert anti-tumor benefits for SFTs with fewer off-target effects. Using CRISPR-mediated knock-in technology, we have successfully established stable SFT cell models harboring the NAB2-STAT6 fusion types. In addition, we have established primary cell models from patient tumor samples. We have developed CasRx-based constructs packaged into AAV viral vectors that exhibit dose-dependent suppression of specific NAB2-STAT6 fusion transcripts. Our work provides evidence of the efficiency of RNA-based therapy *in vitro* and aims to accelerate solitary fibrous tumor research.

618 Gene Editing and Immunotherapeutic Targeting of ADGRE2/EMR2 to Enable Combinatorial Targeting in AML

Julia Etchin[1], Yonina Keschner[1], Hannah Mager[1], Mariana Silva[1], Hillary Hoyt[1], Amanda Halfond[1], Julia DiFazio[1], Matthew Ung[1], Guy Mundelboim[1], Jaime Sanchez[1], Julian Scherer[1], John R. Lydeard[2], Tirtha Chakraborty[1]

[1]Discovery and Molecular Engineering, Vor Biopharma, Cambridge, MA,[2]Vor Biopharma, Cambridge, MA

Introduction: Acute myeloid leukemia (AML) is a heterogeneous disease characterized by abnormal clonal expansion. Targeted

immunotherapy of AML has been limited due to lack of true tumor-specific antigens. We developed an approach for increasing the therapeutic index and safety of targeted therapies by genetically ablating biologically dispensable target antigens from hematopoietic stem cell grafts (HCT), thereby restricting these antigens to AML cells, and enabling subsequent immunotherapy without risk of on-target off-tumor toxicities. Simultaneous targeting of multiple AML antigens may be required to help avoid potential antigen escape and address the issue of tumor heterogeneity, while ablation of the targets in the HCT by multiplex genome editing is necessary to protect the transplanted healthy graft. **Methods/Results:** To elucidate surface expression heterogeneity and prioritize antigens for combinatorial targeting, we performed quantitative flow cytometry surface expression profiling on validated AML targets, CD33, CLL1, and CD123, as well as a promising target ADGRE2/EMR2. Cross-sectional and longitudinal assessments of patient bone marrow (BM) was performed in >25 diagnosis (Dx) and >25 relapse samples to define the antigen positivity of blasts and leukemic stem cells (LSCs; CD34+CD38-), as well as antigen density (molecules per cell). The results demonstrate that these antigens are expressed on blasts and LSCs at targetable antigen densities (>1000 molecules per cell), but there is inter- and intra-patient antigen heterogeneity on both blasts and LSCs, suggesting that combinatorial targeting is necessary to fully eradicate leukemic cells in more patients. Healthy BM and peripheral blood flow cytometric analysis shows that these antigens are expressed on hematopoietic stem and progenitor cells (HSPCs) and myeloid lineages, suggesting that ablative editing may be necessary to protect healthy hematopoietic lineages from subsequent immunotherapeutic targeting. Here, we describe the ablative genome editing approach paired with a novel immunotherapeutic targeting for EMR2. Human genetic evidence of *ADGRE2* null individuals with no deleterious phenotype (https://gnomad.broadinstitute.org/) provides compelling evidence of biological dispensability. We utilized CRISPR/Cas9 and base editing technologies to genetically ablate EMR2 in HSPCs, achieving >80% editing with corresponding surface protein loss. Deletion of EMR2 did not impact *in vitro* myeloid differentiation or cytokine production as compared to unedited control cells. To develop EMR2-directed CAR-T cells, we performed a phage display screen to identify novel EMR2-specific human scFv and VH binders. CAR constructs encoding these binders were transduced into primary T cells and tested in cytotoxicity assays against the EMR2$^+$ MOLM13 AML cell line and EMR2-lacking cells. We observed EMR2-specific activation, cytokine secretion and potent killing. **Conclusion**: Our results identify AML antigens for combinatorial targeting and demonstrate feasibility of a novel EMR2-directed AML therapy paired with EMR2 deleted HCT. Moreover, our data provide a rationale for future combination of EMR2 with other AML antigens in a multiplex-editing approach paired with multi-antigen specific immunotherapy to enable next-generation AML treatments.

619 Screening and Identification of Optimal Costimulatory Domains for iPSC Derived CAR-NK Cells Targeting GPC3 Expressing Hepatocellular Carcinoma

Liang Lin

Cytovia Therapeutics, Miami, FL

Introduction: Given the distinct expression profiles of costimulatory receptors in NK and T cells we set out to identify optimal costimulatory domains for the design of our iPSC derived CAR (chimeric antigen receptor) NK cell platform for targeting GPC3 expressing Hepatocellular Carcinoma (HCC). To this end we designed both 2nd and 3rd generation CAR constructs containing costimulatory domains that are specific for NK cells or shared with T cells and evaluated their NK cell cytotoxic function against GPC3 expressing HCC tumors. **Methods:** The following 2nd and 3rd generation CAR constructs containing GPC3 scFV binder (YP7 mAb) and CD28 hinge and transmembrane domains were expressed with the following costimulatory domains: CD28+CD3 zeta (2ndgeneration), 41BB+CD3 zeta (2nd generation), 2B4+CD3 zeta (2nd generation), CD28+41BB+CD3zeta (3rdgeneration). The CAR constructs were expressed in either EF-1a promoter containing vectors for electroporation into NK-92 cells or in gene of interest pAAV6 shuttle vectors for AAV6 production for targeted gene locus knock in (Beta 2 microglobulin locus) with locus specific sgRNA and Cas9 or into retrovirus shuttle vectors for production of retroviral particles containing BaeV envelope proteins for transduction of PBNK cells. Transduced PBNK cells were expanded in K562 feeder cells expressing 41BB ligand and membrane bound IL-21. NK-92 and PBNK cells expressing CARs were phenotyped for CAR expression using soluble GPC3 FITC and tested for cytotoxicity against Hep3B tumors by flow cytometry or in tumor spheroids killing assays using special U-bottom adhesive plates and in serial tumor killing assays using the Incucyte™ Live Cell Analysis System. **Results:** Given the targeted gene loci specific (B2M gene locus) non-disruptive gene knock in approach considered for the iPSC-CAR NK cell platform, we initially focused on AAV6 transduced PBNK cells where the 2nd and 3rdgeneration CARs were knocked in to the B2M locus. Both PBNK donors showed 80-90% of the cells expressing GPC3 CAR and non-disruptive B2M expression suggesting this was a viable approach to drive CAR expression at this locus. In both Hep3B tumor spheroid killing and Hep3B tumor serial killing assays as expected all PBNKs expressing CARs showed significantly higher Hep3B tumor killing compared to control non-transduced PBNKs. Second generation 2B4 CARs showed the highest cytotoxicity compared to all other 2nd generation and 3rd generation CARs with the second generation CD28 CAR showing the least anti-tumor killing activity in both tumor spheroid and serial killing assays. Although CAR expression in retroviral transduced PBNKs was lower (45-50%) in all 2nd and 3rdgeneration CARs, the cytotoxic activity against Hep3B tumors was comparable except for the lower cytotoxicity observed with the CD28 CAR. A similar trend was observed in NK92-CD16 cells expressing 2nd and 3rd generation CARs against Hep3B tumors. These results suggest that NK cell expressed costimulatory domain CAR's show higher cytotoxic activity compared to the T cell specific CD28 costimulatory domain CARs expressed in NK cells. **Conclusion:** The above data enabled the selection of optimal CAR constructs candidates for the derivation of iPSC derived CAR-NK cells against HCC tumors.

620 Development of a Ferret Model of Idiopathic Pulmonary Fibrosis by Bleomycin-Induced Lung Injury

Shuang Wu, Jia Ma, Meihui Luo, Amanita Shonka, Douglas J. Bartels, Xiaoming Liu, John F. Engelhardt

Department of Anatomy and Cell Biology, University of Iowa, Iowa City, IA

Idiopathic Pulmonary fibrosis (IPF) is a progressive and irreversible disease characterized by lung scarring and remodeling with excessive extracellular matrix (ECM) deposition and destruction of lung architecture that ultimately leads to pulmonary function decline and respiratory failure. IPF is the most common and severe form of fibrotic disease in lung with unknown etiology. To date, IPF remains an incurable disease with limited therapeutic options, novel therapeutic targets and strategies are therefore unmet needs for treatment of this lifelong debilitating disease. Gene and cell therapies offer promising avenues to treat a range of fibrotic diseases including IPF. However, the lack of appropriate animal models that are able to recapitulate the human disease feature significantly hinders *the* development of these novel treatments for IPF. While the existing bleomycin (BLM)-induced mouse and rat PF models *has* provided important insights into the pathophysiology of IPF, they fail to reproduce the progressive and irreversible features in IPF patients. Domestic ferrets are recognized as excellent models for medical research of respiratory diseases such as influenza infection, chronic obstructive pulmonary disease (COPD), obliterative bronchiolitis (OB), emphysema caused by alpha-1 antitrypsin deficiency and cystic fibrosis (CF), owing to similarities of airway anatomy, lung cell biology and physiology between ferrets and humans. However, the IPF phenotype in BLM-injured lungs of ferrets has yet been systematically characterized. Here, we evaluated changes in histopathology, pulmonary function, and biomarkers of IPF in ferrets injured by lung challenge with 3 doses of BLM (2.5U. mL-1·Kg-1, 1 week interval). Histopathological analysis showed higher Ashcroft scale scores of pulmonary fibrosis with predominant deposition of collagen and ECM in lungs of ferrets challenged with BLM, compared to healthy ferrets. Pulmonary function test (PFT) demonstrated that the BLM exposures led to the decrease of pulmonary compliance, a typical phenotype of IPF as accessed using the FlexiVent at 4 and 8 weeks post the first BLM challenge. Notably, more severe IPF phenotype was observed in male and older animals compared to female and younger compartments, respectively, as determined by the degree of pathological change and pulmonary function decline. Molecular studies further demonstrated an increase in ECM deposition, epithelial-mesenchymal transition, fibrotic biomarkers of Krebs von den Lungen 6, MUCIN 5B (MUC5B), surfactant protein C (SFTPC) and cytokeratin 8 in lung tissues of BLM-challenged ferrets. In addition, increased abundance of Krebs von den Lungen 6, S100 calcium-binding protein A12, SFTPA, SFTPD, MUC5AC, MUC5B and matrix metalloproteinases were also observed in plasma of IPF ferrets. Together with results of histopathology and PFT, this study provides evidence that the BLM-induced IPF ferrets can reproduce clinical, pathological and molecular features, and disease course observed in IPF patients, indicating that IPF ferrets are a reliable model for understanding mechanisms of IPF pathogenesis and testing therapeutic strategies and agents, including gene and cell therapy for IPF treatments.

621 TNS3 Deficiency Upregulates TGF-β/Smad Signaling and Contributes to Fibrogenic Progression

Wen-Hsin Chang[1], Fujia Guo[1,2], Ssu-Wei Hsu[1], Ji-Min Li[1], Anika Madan[3], Su Hao Lo[4], Ching-Hsien Chen[1]

[1]Division of Pulmonary, Critical Care, and Sleep Medicine, Department of Internal Medicine, University of California Davis, Davis, CA,[2]Department of Microbiology, Immunology & Molecular Genetics, University of California, Los Angeles, Los Angeles, CA,[3]Division of Nephrology, Department of Internal Medicine, University of California Davis, Davis, CA,[4]Department of Biochemistry and Molecular Medicine, University of California Davis, Sacramento, CA

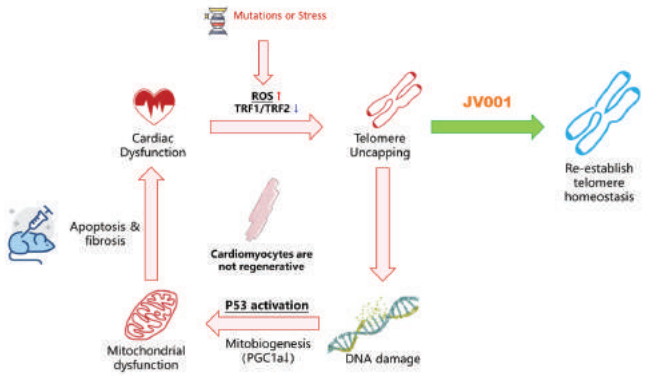
Idiopathic pulmonary fibrosis (IPF) is a progressive and smoking-associated lung disease, with a poor prognosis and limited therapeutic options. Targeting activated fibroblasts, mainly myofibroblast differentiation, has emerged as a therapeutic strategy in IPF management; however, the viable signaling molecules associated with fibroblast activation are yet to be identified. To uncover the regulatory molecules that drive gene expression representative of IPF features in the lung, we analyzed the single-cell RNA sequencing data and noticed dysregulation of integrin-mediated focal adhesions in IPF lung fibroblast populations such as the myofibroblast subpopulation, a key player in fibrogenesis. Of these focal adhesion molecules, a prominent downregulation of Tensin-3 (TNS3), a tensin family member, was noted in IPF lung fibroblasts, whereas no significant change on TNS3 expression was seen in other lung cell types. Analysis of the Comparative Toxicogenomics Database revealed a strong interaction of TNS3 with byproducts of cigarette combustion. Immunoblotting analysis confirmed that normal lung fibroblasts display higher expression of TNS3 compared to that in lung fibroblasts derived from IPF patients. Exposure to either cigarette smoke extracts or a profibrotic factor, TGF-β, downregulates TNS3 expression in lung fibroblasts. This downregulation was also noted in the fibroblastic foci of lung tissue sections from IPF patients by using immunohistochemistry staining. Genetic knockdown of TNS3 studies demonstrated that TNS3 loss activates a critical member of the TGF-β pathway, Smad2, and increases expression of the myofibroblast marker α-SMA. In a bleomycin-induced pulmonary fibrosis model, TNS3-knockout mice manifested severe loss of body weight, a worse survival rate, and extensive lung structural changes and collagen deposition than wild-type mice did. Taken together, our results not only provide a novel understanding of how TNS3 loss mediates fibroblast cell activities but also suggest a potential biomarker for IPF.

622 Mending Broken Ends: AAV Gene Therapy Targeting Telomeric Ends Restores Cardiac Function in Ang2, TAC, and CKD Heart Failure Mouse Models

Yinlong Zhao[1], Danshu Xie[2], Weiyao Xiong[1], Han Gao[3], Zhichu Ren[3], Yangyang Liu[3], Xiaolu Bao[1], Alex Chia Yu Chang[1]

[1]Shanghai Institute of Precision Medicine, Shanghai Ninth People's Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China,[2]Department of Nephrology, Shanghai Ninth People's Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China,[3]Juvensis Therapeutics, Shanghai, China

Cardiovascular disease and heart failure is among the top causes of morbidity and mortality worldwide with a critical need for innovative therapies to reverse the course of ventricular dysfunction. In previous studies, we established that genetic cardiomyopathic cardiomyocytes exhibit accelerate telomere shortening which leads to DNA damage p53 activation and inhibition of mitochondrial biogenesis. Here we present results from three general heart failure mouse models: TAC surgery to model Hypertrophy Cardiomyopathy/HFpEF, Ang2 infusion to mimic Dilated Cardiomyopathy/HFrEF, and 5/6 nephrectomy to mimic chronic kidney disease induced heart failure. Dose response experiments followed by biodistribution and histological examination show good safety profile. Using AAV9 and the cTnT (cardiac troponin T) promoter to express a telomeric capping protein, JV001, heart failure animals (LVEF drops from baseline ~80% to ~50%) were treated with a single *i.v.* dose. An increase of ~20% LVEF were observed in all three heart failure mouse models by 7-10 days post administration and efficacy remained stable at 1-year sacrificial endpoint. Histologically, JV001 treatment prevented further telomere attrition and myocardial loss/cardiac fibrosis. Using live cell labeling and electron microscopy, we confirm that JV001 treatment successfully relieved mitochondrial biogenesis blockage. JV001 treatment also arrested telomere attrition and improved contractile function in Ang2 treated hiPSC-CM model.



623 Concurrent Knockout of RYR2 and Activation of RYR1 or RYR3 in Cardiomyocytes: A Potential Therapy to Rescue Catecholaminergic Polymorphic Ventricular Tachycardia?

Stefan B. Thalhammer[1,2], René Roetzer[1], Juergen Groher[1], Martin Biel[1,2], Elvir Becirovic[3], Stefanie Fenske[1,2]

[1]Department of Pharmacy - Center for Drug Research, Ludwig-Maximilians-University Munich, Munich, Germany,[2]DZHK (German Centre for Cardiovascular Research), partner site Munich, Munich, Germany,[3]Dept. Ophthalmology, University Hospital Zurich, University of Zurich, Zurich, Switzerland

Cardiac excitation-contraction coupling describes the process from the electrical excitation of cardiomyocytes to their contraction. It relies on the concerted action of Cav1.2 channels in the T-tubule system and ryanodine receptors 2 (RYR2), the predominant calcium release channels in the sarcoplasmic reticulum. Disruption or dysfunction of RYR2 results in impairment of cardiomyocyte maturation or occurrence of ventricular arrhythmias, such as Ca^{2+}-release deficiency syndrome and catecholaminergic polymorphic ventricular tachycardia (CPVT1). In mammals, the genome encodes for two additional RYR isoforms which are structurally and functionally highly related but predominantly expressed in the skeletal muscle (RYR1) and the brain (RYR3). Gene supplementation therapy for patients carrying mutations in RYR2 is hardly possible as the coding sequence of this gene (≥16.5 kb) exceeds the packaging capacity of adeno-associated viral (AAV) vectors (4.7 kb). Moreover, CPVT1 is caused by various autosomal dominant gain-of-function mutations in *RYR2*. This suggests that depletion of this gene, along with expression of another gene that can compensate for the lack of RYR2 function (e.g., RYR1 or RYR3), may be suitable to achieve therapeutic benefit. To provide a proof-of-principle for concurrent knockout and activation of different genes in murine cardiomyocytes, we used the Cas9-VPR module in combination with single guide RNAs (sgRNAs) with different spacer lengths, i.e., shortened spacers (< 15 nucleotides) for transcriptional activation and regular spacers (20 nucleotides) for knockout. To deliver Cas9-VPR (5.8 kb) and the sgRNAs driven by a heart-specific cTnT-promoter to the heart, we intraperitoneally injected mice with dual mRNA trans-splicing AAV9 vectors. To distinguish the respective effects of *Ryr2* knockout and *Ryr1* activation on cardiac phenotype, we injected dual AAVs expressing different combinations of sgRNAs in three cohorts: Cohort #1 was expressing one sgRNA for *Ryr2* knockout alone, cohort #2 one sgRNA for *Ryr2* knockout and two sgRNAs for *Ryr1* activation and cohort #3 two sgRNAs for *Ryr1* activation. Analysis of isolated cardiac tissue using qRT-PCR and Western blot experiments confirmed highly efficient *Ryr2* knockout and/or *Ryr1* activation. Isolated hearts of cohort #1 and cohort #2 showed cardiac remodeling with hypotrophic ventricles and significantly enlarged, dilated atria. In the ECG, the lack of RYR2 was manifested in widened P waves and a reduction in the amplitude of QRS complexes compared to control. At the cellular level, morphological changes of cardiomyocytes with disruption of t-tubules were observed. No obvious cardiac abnormalities were detected in cohort #3, suggesting

that RYR1 expression has no adverse effects on cardiac function. Taken together, this study reinforces the critical role of RYR2 in SR homeostasis and in maintaining T-tubule integrity in mature cardiomyocytes. Cardiac defects caused by depletion of RYR2 could not be rescued by transcriptional activation of *Ryr1*. Further experiments are underway to verify whether RYR3 can functionally replace RYR2 in cardiac tissue.

624 Effects of AAV-*TAFAZZIN* in Barth Syndrome Patient-Derived iPSC Cardiomyocytes and Myoblasts

Sree L. Venigalla[1], Russell D'Souza[1], Silveli Suzuki-Hatano[1], Peter B. Kang[1], Barry J. Byrne[2], W. Todd Cade[3], Christina A. Pacak[1]

[1]Neurology, University of Minnesota, Minneapolis, MN,[2]Pediatrics, University of Florida, Gainesville, FL,[3]Physical Therapy Division, Duke University, Durham, NC

Barth syndrome (BTHS) is a rare, X-linked, mitochondrial disease that is caused by mutations in the gene TAFAZZIN. The tafazzin protein is an acyltransferase that remodels the inner mitochondrial membrane protein monolysocardiolipin to mature cardiolipin. BTHS causes severe cardioskeletal myopathy, impaired cardiac and skeletal muscle bioenergetics, and neutropenia. Our prior preclinical studies demonstrated the ability of adeno-associated virus (AAV)-mediated gene therapy to improve heart and skeletal muscle function in a mouse model of BTHS using a wide variety of functional and quantitative proteomic analyses. In addition, we have shown that delivery of AAV-TAFAZZIN to BTHS patient-derived fibroblasts restored mtDNA copy numbers, mitochondrial structure, and function. To further develop our gene therapy approach, we have differentiated healthy and BTHS patient-derived iPSCs into mature cardiomyocytes (iPSC-CMs) and myoblasts (iPSC-Mbs) to test the effects of AAV-mediated gene delivery on disease phenotypes. Our protocol combines both medium-based and substrate stiffness based maturation techniques and yielded more metabolically mature iPSC-CMs based upon electron transport chain complex activities and oxygen consumption assays. Administration of 50,000 vg/cell of AAV-TAFAZZIN for seven days resulted in high level (500-1,500 fold increase) TAFAZZIN expression and significant improvements in spare capacity and other oxygen consumption based assessments in treated BTHS cells as compared to controls. In order to characterize the disease mechanisms of BTHS more fully, a tandem mass tagging (TMT) based proteomics analysis study was performed to compare protein expression profiles between mature human healthy and BTHS-patient derived iPSC-CMs. These data are currently being processed to identify underlying mechanisms of cardiomyocyte dysfunction that represent novel therapeutic targets that are relevant to other cardiomyopathies. A BTHS proteomics study we previously performed to evaluate the effect of AAV-mediated gene therapies on the global proteome of BTHS mouse hearts as compared to healthy controls revealed significantly decreased levels of several proteins that may represent unifying therapeutic targets for heart disease. We have generated an AAV vector to test the effects of overexpression of one of these as compared with two different isoforms of TAFAZZIN in BTHS patient-derived iPSC-CMs and iPSC-Mbs. Ongoing studies include completion of in vitro proteomics assessments, performing a panel of comparative mitochondrial functional assays, and assessing the effects of these treatments on mitochondrial structure and dynamics. Completion of these studies will support further translation of AAV-TAFAZZIN gene therapy towards human clinical trials for individuals with BTHS.

625 Barcoded AAV Libraries Identify Serotypes Capable of Transducing Fibroblasts in Mouse Lungs

Alex Araki, Martin Borch Jensen, Chris Carrico, Linda Chio, Ian Driver, Daniel Fuentes, Akela Kuwahara, Francisco LePort, Hikaru Miyazaki, Wyatt Morgan, Smitha Shambu, Vishwaraj Sontake, Chris Towne

Idiopathic pulmonary fibrosis (IPF) is a complex polygenic disease characterized by the stiffening of the lung and pulmonary fibrosis that is modulated by several cell-types in the lung such as fibroblasts, epithelial alveolar type I (AT1), and type II cells (AT2). While the vast work on the monogenetic disease, cystic fibrosis, has identified AAV serotypes with tropism for epithelial cells, to date there are no examples of AAVs that enable lung fibroblast transduction. In order to enable gene delivery into lung fibroblasts, we have developed a platform that couples single-cell sequencing with barcode expression to both screen AAV serotypes for lung fibroblast transduction and optimize regulatory elements that confer high expression of the transgene payload in this cell type. We performed oropharyngeal injections of a library of 16 barcoded serotypes, at a dose of 1E10 vg/serotype, into several bleomycin-induced IPF model mice as well as non-diseased mice (n = 3 mice for each model). Our resulting screen correctly identified AAV6 as a serotype that effectively transduces AT1 and AT2 cells. Additionally, we identified several serotypes capable of transducing fibroblasts with high efficiency. These serotypes were then individually validated in mice through histology and FACS with a dose of 2E10 vg ($n \geq 2$ for each serotype) giving transduction percentages from 1% to 10% of all fibroblasts transduced. Increasing the dose to 7E11 vg obtained transduction of fibroblasts at 31%. Interestingly, we saw differences in transduction efficiency across subsets of celltypes; the activated myofibroblasts in the IPF mouse model were more likely to be transduced than the lipofibroblasts of the non-diseased mouse model. Thus, by validating serotypes in a single-cell manner in a relevant disease model, our platform can identify differences in AAV tropism to different cell states. The same barcoding and single-cell screening approach was next used to optimize regulatory elements for a gene of interest for the highest relative number of transduced cells and level of expression across different cell-types within the mouse lung. A library consisting of 47 different combinations of promoters, enhances, introns, and polyA signals was delivered via the oropharyngeal route to IPF and healthy mice (n = 10). Fibroblasts were isolated and by sequencing RNA transcripts, we identified a promoter and intron that resulted in transcripts and expression detectable in 2x as many cells as a ubiquitous CMV promoter. Combined, our results have identified a serotype and promoter that enables high expression and targeted gene delivery to mouse lung fibroblasts.

626 Site-Specific Editing Methods to Reverse Severe Combined Immunodeficiency (SCID) in Athabascan-Speaking Native Populations

Severe combined immunodeficiency of Athabascan-speaking Natives (SCID-A) arises from a single C→A nucleotide substitution in exon 8 of the DNA cross-link repair 1C (*DCLRE1C*) gene, resulting in a premature stop codon (pmSTOP) and a non-functional Artemis protein. The absence of Artemis results in an impaired canonical non-homologous end joining NHEJ (c-NHEJ) DNA damage repair and arrested V(D)J recombination, which leads to hypersensitivity to DNA-damaging agents, a $T^-B^-NK^+$ immunophenotype, and susceptibility to severe infections. *Ex vivo* lentiviral therapy of Artemis in SCID-A hematopoietic stem cells (HSCs) has been clinically tested, but shows suboptimal expression and carries the risk of insertional mutagenesis. Here, we demonstrate an alternative, potentially superior approach for site-directed genetic repair of the Artemis-encoding sequence *in situ*, correcting the pmSTOP founder mutation using adenine base editor (ABE). The ABE system can create a site-specific, irreversible DNA edit to convert the pathogenic pmSTOP codon into a conserved tryptophan (TAA→TGG), thereby restoring Artemis activity. We have validated this substitution *in vitro* through assays measuring enzymatic hairpin-opening activity and cell proliferation following ionizing radiation in model K562 lines encoding the SCID-A mutation or the tryptophan conversion **(Fig 1A-C)**. Using the ABE8e-NG variant, we achieved >40% pmSTOP→tryptophan sequence conversion in SCID-A K562s, with the restoration of Artemis validated by Western blot and enzymatic activity assays underway. Furthermore, to facilitate pre-clinical evaluation of *in vivo* correction, we generated a novel murine model of SCID-A by electroporating mouse embryos with Cas9-ribonucleoprotein and transducing them with a recombinant adeno-associated virus (rAAV) donor molecule **(Fig 2A)**. In this model, exon 8 of the murine *Dclre1c* locus was replaced with the human wild-type or mutant *DCLRE1C* human sequence, the latter which recapitulates the SCID-A $T^-B^-NK^+$ phenotype and the absence of Artemis **(Fig 2B-C)**. To test ABE-mediated correction in the mouse model *ex vivo*, we targeted the mutation in lineage-depleted SCID-A hematopoietic stem and progenitor cells (HSPCs) and transplanted them into lethally-irradiated SCID-A recipients. We anticipate that transplanted ABE8e-NG-edited progenitor cells will result in the appearance of significant levels of T or B cells in the peripheral blood, and further analyses will show the restoration of Artemis protein and its endonucleolytic activity within the outgrown cells. Our work demonstrates this site-specific approach's broader potential for treating other primary immunodeficiencies and genetic diseases using gene-corrected autologous transplants and *in vivo* delivery.

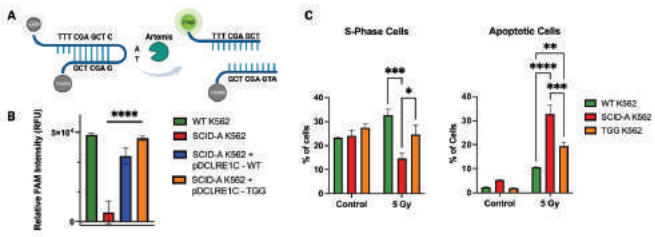

Figure 1. Validation of restoration of Artemis protein activity assays.
A, Artemis enzymatic hairpin-opening activity using a synthetic hairpin with FAM fluorophore at 5' and TAMRA quencher at 3' cleaved by Artemis. **B,** Enzymatic activity of Artemis in WT K562, SCID-A K562, SCID-A K562s encoding WT plasmid and SCID-A K562s encoding conservative tryptophan (TGG) plasmid measured after 6 hours of exposure to synthetic hairpin. **C,** Percentage of S-phase (left) and apoptotic (right) K562 model cells lines after exposure to 5 Gy of radiation.

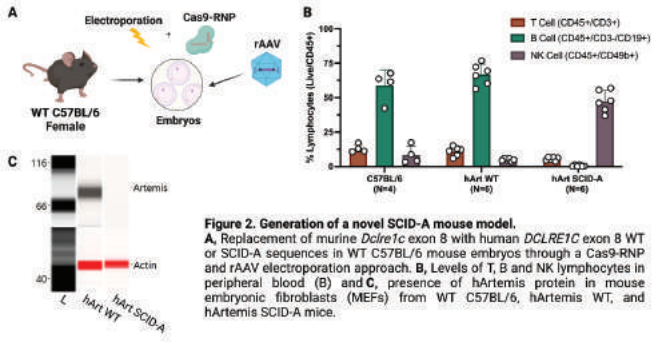

Figure 2. Generation of a novel SCID-A mouse model.
A, Replacement of murine *Dclre1c* exon 8 with human *DCLRE1C* exon 8 WT or SCID-A sequences in WT C57BL/6 mouse embryos through a Cas9-RNP and rAAV electroporation approach. **B,** Levels of T, B and NK lymphocytes in peripheral blood (B) and **C,** presence of hArtemis protein in mouse embryonic fibroblasts (MEFs) from WT C57BL/6, hArtemis WT, and hArtemis SCID-A mice.

627 Long Term Expression of Anti-Sickling Transgenic Beta-Globin after Non-Myeloablative Conditioning Lentiviral Gene Therapy in a Sickle Cell Disease Murine Model

Sickle cell disease (SCD) results from a sequence defect in the adult hemoglobin (HbA) β-globin chain. This disease causes acute and chronic multiorgan failure, and reduced lifespan despite current advances in medical management. To improve these outcomes, gene therapy is being studied in the preclinical and early clinical setting. We have engineered a novel lentiviral vector based on the Lenti/βAS3-FB construct. The βAS3-globin transgene expressed from this vector contains the mutations G16D, E22A and T87Q that increase affinity for healthy β-globin and inhibit axial and lateral contacts with sickle β-globin, thereby conferring anti-sickling properties. We have successfully used our vector in a gene therapy model in the Townes mouse model for SCD. Recipients underwent a non-myeloablative conditioning regimen of 6Gy whole body irradiation and each received 1 million donor cells via retro-orbital injection. We optimized the survival of the mice by implementing a transfusion program following cell injection. Furthermore, we successfully detected lentiviral vector-encoded βAS3-globin in peripheral blood after gene therapy. We followed these mice over 30 weeks post-BMT and report stable peripheral blood vector copy number as well as persistent βAS3-globin measured by mass-spectrometry (see our corresponding poster). We analyzed several parameters in these mice including some for the first time in a Townes mouse gene therapy setting. We assessed

complete blood counts (CBC), *in vitro* sickling of peripheral blood red blood cells, urine osmolality and urine albumin/creatinine ratio. We also completed non-invasive echocardiography, whole body non-invasive plethysmography, von Frey behavioral assay, and a pathologic evaluation by hematoxylin and eosin and Prussian blue staining in transplanted mice. Our findings suggest several readouts that will be useful in evaluating gene therapy approaches in the Townes mouse model of SCD.

628 HDAd6/35++ - A New Helper-Dependent Adenovirus Vector Platform for *In Vivo* Transduction of Hematopoietic Stem Cells

Hongjie Wang[1], Wenli Zhang[2], Jiho Kim[3], Sucheol Gil[1], Anja Ehrhardt[4], Andre Lieber[1]

In previous studies we achieved safe and efficient *in vivo* hematopoietic stem cell transduction in mobilized mice and macaques with intravenously injected helper-dependent adenovirus HDAd5/35++ vectors. These vectors are derivatives of serotype Ad5 containing CD46-affinity enhanced Ad35 fiber knob domains. Considering the impact of anti-Ad5/HDAd5/35++ neutralizing serum antibodies present in the human population, we generated HSC-retargeted HDAd6/35++ vectors derived from serotype 6. We found lower prevalence and titers of serum anti-HDAd6/35++ in human samples compared to HDAd5/35++, potentially allowing for efficient *in vivo* HSC transduction in a greater fraction of human patients. Intravenous injection of an integrating HDAd6/35++-GFP vector into mobilized mice resulted in efficient HSC transduction with subsequent stable, high-level GFP marking in peripheral blood, bone marrow, and spleen cells as well as in tissue macrophages derived from *in vivo* transduced HSCs. In contrast to HDAd5/35++, undesired transduction of hepatocytes was minimal with HDAd6/35++. Furthermore, HDAd6/35++ allowed for efficient *in vivo* HSC transduction in Ad5-pre-immune mice. These features together with the straightforward production of HDAd6/35++ vectors at high purity and yield, make this new HDAd vector platform attractive for clinical translation of the *in vivo* approach.

629 Safety and Efficacy of Liver-Directed AAV Gene Therapy in Privately Owned Dogs with Severe Hemophilia A
